Introduction

Opening a surgical text has a forbidding feel, page after page of closely set print interspersed with pictures which sometimes help to explain the text but more often confuse on account of their lack of clarity. Didactic teaching required dull tomes to buttress the ethos of complexity so often promulgated by the professional. Bailey and Love set out to alter this trend by presenting a text that was colourful, readable and contained the precise information required by the student of surgery. Since the first publication of this book in 1932, surgery has become simpler to study. Greater knowledge simplifies and more exact diagnosis leaves less to supposition and opinion. It is now easy to verify an opinion, and even the most arrogant are worn down by the certainty of the newer imaging techniques in providing an exact diagnosis. The spleen palpated only by the consultant can soon be verified by computerised tomography (CT) (Fig. 1.1).

Surgical diagnosis is based on a sound knowledge of anatomy, physiology and pathology, a specific history and examination with confirmation by imaging and operative surgery. It is unnecessary to learn what can be deduced, and thus studying surgery concerns defining the basic facts on which the consequences of a disease process can be built (Fig. 1.2).

It is often surprising that a book entitled Short Practice of Surgery does not contain more about operative surgery. The actual operation in surgery is but one part of the process of surgical care; diagnosis, preoperative care and postoperative management being of equal importance in differing circumstances. No matter how good the operation, if it is performed for the wrong diagnosis, the benefit to the patient will be limited or void. In other situations, such as the patient who presents as a surgical emergency in association with severe illness, a common occurrence in this era of the elderly patient, skilled preoperative resuscitation and management, often in conjunction with the relevant physician, can turn a high-risk procedure into a routine operation. Similarly, the very ill patient can be salvaged by expert postoperative management. Nevertheless, the trend to denigrate the skills of operative surgery has been exposed as false by audit, which time and time again shows that a surgeon who does a procedure frequently outperforms in every parameter the surgeon who does an operation intermittently. The skills of operative surgery are primarily taught in the operating theatre and by supervised practice aided by specific illustrative texts on operative surgery. The objective of this book is to ensure that the surgeon understands the basis of the craft.
Surgical process

This starts with the patient from whom a careful history is taken. A focused physical examination is performed, and the complete medical status of the patient assessed. The likely diagnosis is considered on the basis of this clinical assessment, and confirmed by the appropriate test. Once confirmed, the specific treatment, be that medical or surgical, is advised. Should the likely diagnosis be wrong, attention is turned to the patient for further details of their ailment, and a more careful differential diagnosis considered as a basis for investigation. Continued observation over a limited period of time remains a powerful tool for achieving a diagnosis.

Despite current concepts, many patients with complaints requiring surgical treatment present with a simple history such as a lump or a pain for which a specific algorithmic approach will provide an answer. Experience will provide an answer for many patients who present with a physical sign, and no amount of history taking or examination will add to that visual assessment. A sebaceous cyst with its punctum standing proud is a simple surgical condition requiring a surgical excision. The patient is operated upon, and the episode complete. Even the woman who presents with an ulcerating lump on her breast can be managed similarly in a diagnostic sense, but the knowledge attained in surgical study warns against a similar simplistic approach, and attention is turned to confirmation of the diagnosis noninvasively, so enabling full assessment of the whole patient on the basis of a confirmed pathology, often in co-operation with colleagues from other disciplines (Fig. 1.3).

Too little attention has been paid by the surgeon to the ancillary process of investigation, more so in some disciplines than others. Just as the stethoscope is helpful in diagnosis, so also ultrasonography, endoscopy and other forms of imaging will lead to a rapid confirmation of the clinical findings: an ultrasound scan is done to confirm gallstones (Fig. 1.4), a sigmoidoscopy to show a rectal carcinoma, a plain radiograph to confirm a fracture (Fig. 1.5), magnetic resonance imaging (MRI) to show a prolapsed disc (Fig. 1.6) and an angiogram to define the cause of anginal pain. Each has a specific place in the surgical process, and each makes the operative approach more specific, but none is the sole reason for operation as the clinical approach dictates that an operation is only performed for a condition causing symptoms in a patient fit to withstand the procedure.

Thus, surgery is about risk assessment. The diagnosis is made, the fitness of the patient assessed, the procedure determined and the outcome known. Will that outcome benefit the patient? A tumour in the head of the pancreas, if left untreated, will kill the patient in 6 months, so treatment appears mandatory, yet the operation has a mortality of 10 per cent, the median survival is only extended by 12 months and the comorbid factors are high, such that many patients will derive little benefit from the extensive surgery (Fig. 1.7). However, a patient with a strangulated femoral hernia, which in the elderly patient carries a mortality risk of 10 per cent, particularly if bowel is resected, faces the same comorbidity risk as the patient who has pancreatic cancer, but is cured by the procedure, and hence there is no doubt that the operation is worthwhile and the procedure is undertaken. At present, such decisions are matters of judgement, but with increasing knowledge of risk assessment, the correct procedure or management can be more easily calculated and fewer errors of judgement made. By and large, it is errors of judgement that cause surgical misadventure. By avoiding these errors through better and more exact diagnosis, preoperative care and postoperative management, the surgical management of patients will improve. The pre-mortem procedure to prove that everything was done for the patient that could be done is no longer acceptable, and a more humane approach to terminal illness is required (Fig. 1.8).
Surgical history

The history of the complaint is the key step in surgical diagnosis. It will vary according to the complaint, and be specific for particular complaints or systems. Such specific histories will be acquired as the particular surgical specialty is studied. There is no such thing as a standard surgical history as there is in medicine; for this reason the student often adapts the medical history to the surgical clerking and misses many of the important points that are required in surgical decision making; thus, as the subject is studied, the form of history is acquired.

There are two types of history in surgical practice. The first is the outpatient or emergency room history in which the specific complaint of the patient is pinpointed; the second is the clerking of a patient admitted for elective surgery. The object of the first history is to obtain a diagnosis on which the treatment is ordered, whereas the second is to assess that the treatment planned is correctly indicated and to ensure that the patient is suitable for that operation.

Invariably the surgical patient presents in the out-patient department or the emergency room with a special problem such as pain or a lump. As opposed to most medical histories, the patient’s story is limited and frequently the surgeon will focus the detail of the history, by a few specific questions. It is important to know when the symptom started, how it has progressed, whether there are associated features and whether the symptom is improving or getting worse. Time can be important, as are relationships to other symptoms. The effect of any treatment on the symptom is of value: Once the symptom complex has been resolved and clarified, the general health of the patient is defined to determine whether the complaint is local or part of a general disease. Questions are asked related to previous illness or concurrent illness, drug therapy, allergies and complications related to anaesthesia, to compose a picture of the patient’s general status and determine suitability for treatment. The surgical history is a dynamic event, in that the pattern of questioning will change according to the answers of the patient, to compose the picture of that patient’s illness.

The clerking history centres on direct questioning of the patient about specific points related to the complaint. For instance, it is important to record the symptoms of prostatism in the patient having prostatic surgery, so that these can easily be compared with the postoperative state to assess the effect of the surgical procedure. Further, in the patient who is referred by a physician for surgery, specific questions related to the indications for surgery are asked, and the surgeon decides whether or not the patient will benefit from the operation; this is particularly important in noncancerous conditions where continued medical management is an option.
Clinical examination

As with the history, so with the examination, there are two aspects of the examination: that concentrating on the specific complaint, the lump or the pain, and that reviewing the whole patient. Examination of the whole patient, particularly before an operation, should be as thorough as that performed in a routine medical examination. In examining a specific surgical feature, it is important to follow an accurate clinical description.

Diagnosis of a lump

First, determine in what anatomical plane the lump is situated: the skin, subcutaneous tissue, muscle, tendon, nerve or bone, or is it attached to some particular organ? Second, determine the physical characteristics of the lump: is it tender or nontender? If not acutely tender, determine: its size — measure in centimetres; shape — round or flattened, regular or irregular; and consistency — very soft (like a jelly), soft (as relaxed muscle), firm (like a contracted muscle), hard (as a contracted biceps) or stony hard.

Having completed the examination, it is a useful discipline to consider whether the lump is congenital, traumatic, inflammatory (acute or chronic), neoplastic (benign or malignant) and, if malignant, a primary or secondary neoplasm. If it is none of these, a degenerative, metabolic or hormonal disorder may provide the key.

Important specific signs

- **Thrust:** three fingers are placed on a swelling, the middle one being pressed firmly and the lateral ones lightly. The middle finger is percussed firmly, and after each stroke, the percussing finger is allowed to rest momentarily. The thrill felt by the adjacent fingers confirms the presence of fluid under pressure.

- **Sign of compression:** when the swelling is compressed it diminishes in size considerably or disappears. When the pressure is released it refills slowly.
  Characteristically the sign is related to vascular swellings.

- **Sign of indentation:** certain cysts containing putty-like material can be moulded — thus the swelling is indented by the finger. Faeces can be indented.

- **Sign of an aneurysm:** difficulty can be encountered in deciding whether the pulsation of a swelling is transmitted or whether the swelling itself is pulsating. If the swelling is expansile and pushes the fingers apart, then it is an aneurysmal swelling, while if the swelling is deflected by the pulsation it is transmitted.

Ulcers

An ulcer is a loss of epithelial lining; when examining an ulcer.

Attention should be paid to the following points.

- **Shape:** is it round, oval, irregular or serpiginous?

- **Edge:** this may slope downwards towards the crater, be undermined, punched out or everted.

- **Floor:** the most typical is a slough in the base of an ulcer.

- **Base:** whether indurated or attached to deeper structures.

- **Surrounding tissues:** examine for signs of inflammation, pigmentation or the presence of varicosities.

  After an ulcer has been examined it is essential to consider the lymphatic drainage, and in particular the regional nodes.

Ulcers are of five main varieties:

- the septic ulcer with sloping edges;
- the tuberculous ulcer with undermined edges;
- the carcinomatous ulcer with everted hard edges;
- the rodent ulcer with barely visible pearly edges;
- the syphilitic punctated ulcer.

Terminology

In describing an examination, terms should be used specifically and correctly.

- **A fistula** implies a tunnel connecting two epithelial surfaces. A sinus is a blind track opening on to the skin or a mucous surface.

  Fluid may discharge from a sinus or fistula; the discharge should be examined and noted: is it blood, blood-stained, clear, bile like, serous, faecal or purulent? The type of fluid may give a clue to the possible diagnosis.

- **Lymphangitis** is inflammation within a lymphatic vessel and appears as a red line often leading to an inflamed regional lymph node.

- **Phlebitis** is a thrombosed and inflamed vein — it is more usual in superficial veins often associated with varicose veins, which are tender and hard.

- **Cellulitis** is inflammation of tissues, usually superficial or subcutaneous tissue. The part affected is swollen, tense and tender. Later it becomes red, shiny and boggy. It may progress to an abscess, which is the presence of pus in the tissue concerned.

  Inflammation, which is the earlier stage of cellulitis, is the presence of redness, swelling, heat and tenderness, often associated with the loss of function.

- **Crepitus** is a term used in a variety of conditions but in each having a fundamental diagnostic importance. Bone crepitus is noted as coarse grating on movement of a bone — it is very painful to the patient, and an unmistakable diagnosis of a fracture of a bone. Joint crepitus is elucidated by placing one hand on a joint and passively moving the joint with the other hand: fine, evenly spaced crepitations are present in many subacute and chronic joint conditions. Coarse, irregular crepitations signify osteoarthritis.

  The crepitus of tenosynovitis is found over an inflamed tendon sheath when effusion has occurred into the sheath.

  The crepitus of subcutaneous emphysema is due to gas in the tissues: a peculiar crackling sensation is imparted to the examining fingers. It may be due to trauma when gas is released into the tissues after a rib fracture or damage to the oesophagus, or due to gas-forming organisms as in gas gangrene.

  **Translucency:** there are occasions when swellings containing clear fluid lie adjacent to the skin. When a torch is shone through the swelling it lightens the area, confirming the diagnosis.
**Ballotement** is when a swelling can be tapped away from the examining finger, often due to fluid adjacent to the swelling. The term also describes the ability to palpate bimanually a renal swelling and to tap the kidney forward from the loin to the examining fingers of the other hand on the abdomen. A swelling may be balloted from the pelvis, by a finger in the vagina, to the examining abdominal hand.

**Fluctuation** is a specific term to elucidate the presence of fluid. Two watching fingers are placed on either side of a swelling and a central displacing finger presses momentarily. An impulse is felt by the watching finger confirming the presence of fluid, provided the sign is elicited in more than one plane.
The reason for great emphasis on physical signs in the past was the absence of confirmatory imaging techniques. Because of the facility with which these facilities confirm or refute a physical sign, care in their interpretation is rarely taken. Yet, it is physical signs which may lead to a diagnosis, and the constant observation of the patient can delineate changes that are helpful to management.

Most physical signs can be confirmed by ultrasonography, plain radiography, CT or MRI. It is important to be aware of the appropriate test. If a swelling has been defined an ultrasound scan will usually confirm or refute the claim. It will define whether the swelling is solid or cystic, and whether it is aneurysmal, particularly with the aid of Doppler imaging. Biopsy using ultrasonography or CT guidance will give histological confirmation of the nature of the swelling (Fig. 1.9). Plain radiographs will define bony changes and fractures (Fig. 1.10), and gas shadows, such as in abdominal distension. MRI will define abnormalities in joints (Fig. 1.11) and within the skull, whereas CT, particularly with contrast enhancement, will outline solid organs (Fig. 1.12).

Imaging, to reach its full diagnostic potential, must be used correctly, and thus requires study within each surgical discipline.
Diagnostic process

The initial surgical process is complete when a diagnosis has been obtained by history, examination and imaging, supported by pathology. Experience enables correct weighting to be placed on each aspect of this process to define the correct treatment. All pieces of the jigsaw must fit together, and when they do not, great care must be exercised. Surgical conditions tend to follow a logic based on anatomy, physiology and pathology (Fig. 1.13); if that logic is transgressed, mistakes are made, and the patient may be wrongly treated.

Before submitting a patient to surgery, the diagnosis should be exact, the patient’s condition carefully assessed and physiological variables corrected as far as possible. Any additional risks should be taken into account and allowance made for them in the surgical process.
Introduction

Accurate diagnosis is the key to good surgical practice. Over the last two decades the introduction and increased availability of new imaging modalities have made the diagnostic process easier. Imaging helps to resolve the uncertainties of diagnosis based on physical signs and clinical judgement. To achieve the optimum diagnostic potential it is necessary to understand the complexities of modern imaging and to recognise the most appropriate test to fit the clinical context. Communication between the clinician and radiologist is vital for each to understand the clinical problem, and the strengths and weaknesses of the imaging test selected. An ability to interpret images gives a new depth of understanding of the disease process and of the nature and timing of surgical intervention.

There is no standard approach to imaging although some basic principles apply. It is generally good practice to perform the simplest and least expensive test first if this will provide the answer. For example, the plain abdominal film remains the diagnostic cornerstone in assessing the acute abdomen; in a patient with a clear history of biliary colic, a simple ultrasound examination may be sufficient to determine management. However, in a patient with a more complex clinical presentation, it may be more cost-effective to perform a more expensive test [e.g. computerised tomography (CT) scan] early in the diagnostic work-up as this may lead to a more confident diagnosis and management, and potentially shorten the hospital stay. Cost-effectiveness requires that more complex tests are not merely layered on top of existing more standard procedures. Through consultation, the best test must be determined. The selection of the best investigation for a particular clinical context has been made more complex by the rapid changes in existing technology. The development of spiral (helical) CT, for example, has created new diagnostic possibilities based on the patterns of arterial and venous blood flow providing information not previously available on older equipment. Decision making therefore must be tailored to both the available technology and local expertise. It is also essential to view the imaging results in conjunction with the clinical condition of the patient and to treat the patient rather than the X-rays. In a patient with inflammatory bowel disease, for example, the extent and severity of the abnormality demonstrated on a small bowel barium examination may have little correlation with the patient’s clinical presentation (Fig. 2.1). In contrast, a patient with fulminant colitis may be clinically toxic but with only minimal signs on the plain film before the reflex dilatation signaling toxic megacolon develops.

There is a general increase in public awareness of the adverse effect of radiation in the induction of cancer and genetic defects. Most of the received ionising radiation comes from the sun and earth’s core. However, medical radiation accounts for approximately 12 per cent of the total received by humans.

As more nonradiation dependent imaging techniques become more widely available [e.g. ultrasound, magnetic resonance imaging (MRI)], radiation hazard is an increasingly important factor influencing the selection of investigation, particularly in children and young people. The effective dose imparted by a CT scan, for example, is equivalent to 400 chest X-rays (CXRs). However, this theoretical risk must be balanced against the likely diagnostic yield of the examination in terms of benefit to the patient. The aim must be to reduce unnecessary investigations, which not only add needlessly to patient irradiation but also waste limited resources and increase waiting times. The Royal College of Radiologists has published a very useful booklet, Making the Best Use of a Department of Clinical Radiology (see Further reading section). This gives guidelines for investigations most likely to contribute to the clinical diagnosis and management in particular clinical situations. It highlights the chief causes of wasteful use of radiology (Tab. 2.1). Other factors must also be taken into consideration when deciding on the appropriate investigation, including the age and condition of the patient and their ability to undergo the chosen investigation (Tab. 2.2).
Diagnostic imaging Imaging techniques

Conventional radiology

Conventional radiographs depend on the differential absorption by soft tissue, bone, gas and fat of X-rays passing through the body. The unabsorbed rays blacken a photographic film, contained within light-sensitive screens, which is then processed to produce the hard copy. Modern radiology involves the use of many technical modifications to reduce the dose of X-rays to the patient. Plain X-rays remain the primary diagnostic tool in the chest and abdomen, and in trauma and orthopaedics. With careful interpretation, accurate diagnosis can be achieved and it is vital that the plain film is not jettisoned in favour of more complex and expensive imaging techniques.

When X-rays strike a fluorescent screen, light is emitted which, by means of an imaging intensifier, can be projected on a television screen. This is the basis of fluoroscopy (screening) which allows continuous monitoring of a moving process. It also provides guidance for many interventional and angiographic procedures and for barium investigations of the gastrointestinal tract. Barium studies remain a standard technique for evaluating disorders of swallowing and oesophageal function and for the small bowel. The role of the barium meal and enema is challenged by the expansion of endoscopy. However, there is little evidence to indicate that in the diagnosis of significant disease, e.g. ulcer/cancer, endoscopy is superior (Fig. 2.4). Choice of examination depends on local expertise and availability. Endoscopy is preferable where there is gastrointestinal bleeding (upper or lower) or inflammatory bowel disease.

Intravenous contrast contains iodine which absorbs X-rays by virtue of its high atomic number. It provides arterial or venous opacification depending on the route and timing of injection. Contrast injected intravenously is excreted rapidly by the kidneys which forms the basis of the intravenous urogram/IVU where the nephrographic (renal parenchymal) and pelvicalyceal (collecting system) phases, ureters and bladder are successively demonstrated and recorded over approximately 30 minutes following contrast injection. The IVU remains the best method for investigating renal stones and haematuria. No other technique can equally visualise the pelvicalyceal systems and ureters (Figs. 2.5).

Ultrasound

Ultrasound is inexpensive, quick, reliable and noninvasive and is an excellent initial investigation for a wide range of clinical problems. It is technically demanding and requires an experienced operator to maximise the potential of the examination. Despite the advances in technology, there are still problems with gas (which reflects sound completely) and obese patients, who are often unsuitable for ultrasound. As ultrasound is so accessible there is a tendency to overload departments with requests which may be on the margins of appropriateness. As with all investigations, clinicians should consider whether the request for ultrasound is justified as to its likely yield and its subsequent effect on patient management.

Ultrasound depends on the generation of high-frequency sound waves, usually of between 3 and 7 MHz, by a transducer placed on the skin. Sound is reflected by tissue interfaces in the body and the echoes generated are picked up by the same transducer and converted into an image which is then displayed in real time on a monitor. The scope of ultrasound has increased vastly over the last decade with higher frequency probes of diminishing size producing high-resolution images. The current range of ultrasound includes probes measuring only millimetres and operating at 20 MHz, which can be introduced via a catheter into a blood vessel to image the vessel wall; probes combined with fibre-optic endoscopes to visualise the out wall at echo endoscopy (EUS) (7.5—20MHz) (Fig. 2.6); endoluminal probes for transvaginal and trans-rectal scanning (7.5 MHz); dedicated very-high-frequency probes of up to 15 MHz for scanning the breast, other superficial structures and musculoskeletal work; and an increasing array of specialised probes for abdominal scanning. Ultrasound is the first-line investigation in hepatobiliary disease, suspected pancreatic, aortic and many other intra-abdominal disorders (Fig. 2.7).

There is an increasing recognition of the value of intra-operative ultrasound scanning, acknowledging the fact that visualisation at surgery is frequently incomplete, the surgeon seeing only the exposed surfaces. These limitations are accentuated by the restrictions imposed by minimally invasive and laparoscopic surgery.

Doppler ultrasound measures the shift in frequency between transmitted and received sound and can therefore measure blood flow. The spectral Doppler wave form and ultrasound image are combined in duplex scanning. Colour Doppler imaging displays flowing blood as red or blue, depending on its direction, towards or away from the transducer (Fig. 2.8). Power Doppler is not dependent on frequency or direction of flow but is exquisitely sensitive to low flow and has the poten-tial to demonstrate tissue perfusion (Fig. 2.9). Contrast agents have been developed based on micro-bubbles to enhance the Doppler effect. These techniques have revolutionised the diagnosis of both arterial and venous vascular disease.

Computerised tomography

To create a CT scan, a thinly collimated beam of X-rays passes through an axial ‘slice’ of tissue and strikes an array of very sensitive detectors which can distinguish very subtle differences in tissue density. By analysis of the collected data, the digital information is translated to a greyscale image where the attenuation value of tissues is related to water, which is given a CT number of zero Hounsfield units (HU). Tissue densities range from + 1000 (bone) down to —1000 (air). An observer working at a viewing console can, by varying the range and centering of densities represented (window width/level), display an image appropriate to the tissue being examined (Fig. 2.10).

In conventional CT, a series of individual scans is acquired during suspended respiration. Helical or spiral CT involves continuous rotation of the X-ray tube with the beam tracing a spiral path around the patient such that a volume of tissue is scanned. In this way, during a single breath-hold of up to 30 seconds, 30 cm or more of tissue can be covered in one acquisition. Further developments have allowed thinner collimation and stretching of the spiral to cover greater distances. The volumetric data can then be processed to produce conventional transaxial images or multiplanar (sagittal and coronal) and three-dimensional images (Figs. 2.11). The development of spiral scanning has greatly enhanced the diagnostic potential of CT (Fig. 2.12). It is now possible to exploit the enhancement characteristics of tissues in both the arterial and venous phases of imaging and this modification has opened up the fields of CT angiography, three dimensional imaging and ‘virtual endoscopy’ of the bronchial tree and colon (Fig. 2.13).

CT scanning is usually performed after simpler investigations such as plain films or ultrasound. In many centres, however, CT is often used as a first line examination
In most published studies, cross-sectional imaging techniques (CT, ultrasound, MRI) are more accurate in staging advanced (T3, T4) than early (T1, T2) diseases and systems are based on the TNM classification (tumour/node/metastasis). Imaging techniques have considerably improved the ability to define the extent of tumour, although the pathological specimen remains the gold standard. Many staging accurately by imaging before surgical and pathological staging. Once a diagnosis of tumour has been established, often by percutaneous or endoscopic biopsy, new development of stage-dependent treatment protocols involving neoadjuvant chemotherapy and preoperative radiotherapy relies on the ability to define tumour stage.

Modern surgical treatment of tumour requires an understanding of tumour staging systems, as in many instances this will define appropriate management. The primary diagnosis (Fig. 2.24) centres — particularly in the USA — the use of spiral CT as a first-line investigation is being promoted as a cost-effective alternative to increase the specificity of CT may contribute valuable information in inflammatory disease within the abdomen — notably in diverticulitis, appendicitis and in inflammatory bowel disease. In some imaging in oncology has a major role in cancer staging and an increasing role in ‘problem solving’ in the chest and abdomen. Some centres advocate early CT in assessment of the acute abdomen (vide infra). The development of the technique of CT spiral pneumocolon is challenging the barium enema and colonoscopy in the investigation of large bowel disorders (Fig. 2.14).

Magnetic resonance imaging

The basic principle of magnetic resonance imaging (MRI) centres on the concept that the nuclei of hydrogen, most prevalent in water molecules, behave like small spinning bar magnets and align with a strong external magnetic field. When knocked out of alignment by a radio frequency pulse, a proportion of these protons rotates in phase with each other and gradually returns to their original position, releasing small amounts of energy which can be detected by sensitive coils placed around the patient. The strength of the signal depends not only on the proton density but on the relaxation times, T1 and T2. T1 reflects the time taken to return to the axis of the original field and T2 on the time the protons take to dephase. T1 images usually demonstrate exquisite anatomical detail because of the high soft tissue discrimination. Most pathological processes increase T2 relaxation times, producing a higher signal than the surrounding normal tissue on T2-weighted scans.

The complexity of the imaging process is compounded by the variety of pulse sequences available. In general, image acquisition time is longer than CT. Respiratory and cardiac motion degrade the image but this can be largely overcome with cardiac and respiratory gating. Technological developments are fast and scanning times are shortening. Intravenous gadolinium acts as a contrast agent by reducing T1 relaxation and enhancing lesions which then appear as areas of high signal intensity (Fig. 2.16). Specific sequences have been developed to demonstrate flowing blood and produce images resembling conventional angiography. This technique of magnetic resonance angiography (MRA) can be achieved without the risks of intravascular injection of contrast and may ultimately replace conventional studies (Fig. 2.16). Heavily T2-weighted sequences which demonstrate fluid-filled structures as areas of very high signal intensity have been developed to show the biliary and pancreatic ducts in magnetic resonance cholangiopancreatography (MRCP). It seems likely that this technique will take over from diagnostic endoscopic retrograde cholangiopancreatography (ERCP) (Fig. 2.17).

The major strength of MRI is in intracranial, spinal and musculoskeletal imaging, where it is superior to any other imaging technique because of its high contrast resolution and multiplanar imaging capability. Cardiac MRI is firmly established and the value of breast MRI, particularly in multifocal and recurrent cancer, is increasingly recognised. It is currently the best investigation for staging cervical cancer and for anorectal sepsis (Fig. 2.18).

Open access magnets have been developed which allow interventional procedures to be performed with MRI guidance and there is no doubt that this will revolutionise the operating room of the future (Fig. 2.19). There is a vast potential for MRI in the assessment of disease in the abdomen and pelvis and undoubtedly the role of MRI will continue to expand. However, because of the expense of the equipment and its installation, the provision of scanners cannot keep up with the demands for scanning time and most hospitals have to impose strict guidelines for access.

Radionuclide imaging

Radionuclides can be tagged to substances which concentrate selectively in certain tissues of the body. These radio-pharmaceuticals are injected intravenously and, in general, emit gamma radiation detected by a gamma camera. The emitted radiation strikes a sodium iodide crystal which generates a small flash of light which is then enhanced by photomultiplier tubes to produce the image. Many studies employ technetium-99m (99mTc) which has a short half-life and imparts a radiation dose to the patient which is lower than many other imaging investigations.

In general, spatial resolution is poor as the technique demonstrates physiological and functional changes rather than anatomy (Fig. 2.20). A standard gamma camera provides only a two-dimensional display of activity. Single photon emission tomography (SPECT) creates a three-dimensional image by means of an array of photomultiplier tubes that surround the patient in the same way as with CT and MRI. This technique uses conventional radionuclides. Positron emission tomography (PET) scanning is more sensitive, depending on the coincidence detection of annihilation protons resulting from radionuclides that decay by positron emission.

However, these studies require specially designed, dedicated and currently expensive cameras and an in-hospital cyclotron to generate the radionuclide. These scans are therefore not widely available.

Cross-sectional imaging techniques have replaced many radionuclide studies (liver colloid scans, brain scans). Bone scanning remains a sensitive tool for detection of bone metastases and occult fractures. Ventilation—perfusion scans are widely used to detect pulmonary embolic disease, although contrast-enhanced spiral CT of the pulmonary vessels is challenging this role. New exciting techniques of radiopharmaceutical labelling of monoclonal antibodies are opening up possibilities of targeted cancer therapy and early detection of micrometastases.

Imaging in the acute abdomen

The term ‘acute abdomen’ encompasses many diverse entities. Imaging tests are selected based on the likely diagnosis (Fig. 2.21). The erect CXR and supine abdomen remain the investigation of choice where perforation or intestinal obstruction is suspected (Fig. 2.22 and Fig. 2.23). In many patients this will provide sufficient information to determine further management. When the diagnosis is less clear, new imaging techniques are challenging the traditional approach. Both ultrasound and CT may contribute valuable information in inflammatory disease within the abdomen — notably in diverticulitis, appendicitis and in inflammatory bowel disease. In some centres — particularly in the USA — the use of spiral CT as a first-line investigation is being promoted as a cost-effective alternative to increase the specificity of primary diagnosis (Fig. 2.24).

Imaging in oncology

Modern surgical treatment of tumour requires an understanding of tumour staging systems, as in many instances this will define appropriate management. The development of stage-dependent treatment protocols involving neoadjuvant chemotherapy and preoperative radiotherapy relies on the ability to define tumour stage accurately by imaging before surgical and pathological staging. Once a diagnosis of tumour has been established, often by percutaneous or endoscopic biopsy, new imaging techniques have considerably improved the ability to define the extent of tumour, although the pathological specimen remains the gold standard. Many staging systems are based on the TNM classification (tumour/node/metastasis).

Tumour

In most published studies, cross-sectional imaging techniques (CT, ultrasound, MRI) are more accurate in staging advanced (T3, T4) than early (T1, T2) diseases and
the staging of early disease remains a challenge. In gut tumours, endoscopic ultrasound is more accurate than CT or MRI in staging early disease (T1 and T2) by virtue of its ability to demonstrate the layered structure of the bowel wall and the depth of tumour penetration (Fig. 2.25). Developments in MRI may also improve staging accuracy of early disease.

**Nodes**

Accurate assessment of nodal involvement remains a challenge for imaging. Most imaging techniques rely purely on size criteria to demonstrate lymph node involvement with no possibility of identifying micrometastases in normal sized nodes. A size criterion of 8—10 mm is taken but it is not usually possible to distinguish benign reactive nodes from infiltrated nodes. This is a particular problem with intrathoracic neoplasms where enlarged benign reactive mediastinal nodes are common. The echo characteristics of nodes at endoscopic ultrasound have been used in many centres to increase the accuracy of nodal staging and nodal sampling, via either mediastinoscopy or transmural biopsy under EUS control. New radiolabelled monoclonal antibodies against tumour antigens which may increase detection of nodal involvement by demonstrating micrometastases in nonenlarged nodes.

**Metastases**

The demonstration of metastatic disease will usually significantly affect surgical management. Modern cross-sectional imaging has greatly improved the detection of metastases but occult lesions will be missed in between 10 and 30 per cent of patients. CT is the most sensitive technique for detection of lung deposits, although the decision to perform CT will depend on the site of the primary tumour, its likelihood of intrapulmonary spread and the effect on staging and subsequent therapy of the demonstration of intrapulmonary deposits.

Ultrasound and CT are most frequently used to detect liver metastases. Contrast-enhanced CT can detect most lesions of greater than 1 cm, although accuracy rates of CT vary with the technique used and range from 70 to 90 per cent. Recent studies suggest that MRI may be more accurate than CT in demonstrating metastatic disease. While enhanced CT is used in most centres for screening for liver deposits, CT AP (CT with arterial portography), which requires contrast injection via the superior mesenteric artery, is used in many centres as the most accurate technique for staging liver metastases if surgical resection is being considered. Preoperative identification of the segment of the liver involved can be determined by translation of the segmental surgical anatomy as defined by Couinaud to the cross-sectional CT images (Fig. 2.26).

Intraoperative ultrasound is an alternative method of staging that provides superb high-resolution imaging of sub-centimetre liver nodules that may not be palpable at surgery.

**Imaging in trauma**

The response of the skeleton to trauma changes both with the nature and force of the injury and with the maturity and strength of the skeleton. In children the ‘physis’ or growth plate provides the weakest link and therefore epiphyseal injuries or apophyseal displacements are common. The skeleton is less brittle, resulting in buckling of the cortex or incomplete ‘green-stick’ fractures. In the mature adult skeleton the soft tissues — ligaments and muscular insertions are the weakest link, and sprains and strains occur more commonly than fractures. The elderly osteopenic skeleton is brittle and susceptible to fracture often with minimal force.

Fracture radiographs should be performed in two planes and where possible should include the adjacent joint. Most fractures are easily diagnosed but some may be subtle and occult. Where a fracture is strongly suspected but not demonstrated, a repeat X-ray 5—10 days after the injury may identify the fracture line when bone absorption has begun. Stress fractures, either ‘fatigue fractures’ (normal bone) or ‘insufficiency fractures’ (abnormal bone), can be difficult to diagnose. Radionuclide bone scanning and more recently MRI are useful additional investigations if stress fractures are strongly suspected. The ability of CT to scan in the axial plane, together with excellent resolution of bony detail and the ability for multiplanar reconstruction, makes CT valuable in assessment of fractures of the spine, foot and pelvis (Fig. 2.22).

**Severe trauma**

In patients who survive the immediate injury, imaging is considered after clinical evaluation and acute resuscitation. Acute spinal trauma is initially assessed by plain films. In approximately 10 per cent of patients there are multiple levels of injury. If spinal instability or spinal canal disruption is suspected, thin-section CT scanning with reconstruction of the images is required. Suspected cord damage may require an urgent MRI scan (Fig. 2.26). Evaluation of severe head, chest and abdominal trauma usually necessitates CT scanning after initial plain films (Fig. 2.29).
Interventional radiology

Over the last 20—30 years, interventional radiology has made an essential contribution to patient management. The specialty has developed from angiographic techniques, with guidewires and catheters as key ingredients. The parallel developments in cross-sectional imaging have provided enhanced guidance for interventional procedures and radiology has evolved from providing purely diagnostic information to therapy, offering effective alternatives in the treatment of abdominal and thoracic disorders. In some instances, interventional radiology techniques have replaced the conventional surgical approach, removing the need for a general anaesthetic with consequent decreased morbidity and length of hospital stay, with similar patient outcome. The increasing complexity and sophistication of both surgery and available interventional techniques requires close liaison in decision making between the surgeon and radiologist to choose the optimum method of treatment.

Percutaneous biopsy

Percutaneous biopsy is possible for most radiologically detected abnormalities. Small lesions immediately adjacent to major vessels or a biopsy path that traverses the colon may be regarded as relative contraindications but the decision often depends on local expertise. In general, the shortest route from skin to lesion is chosen if no vital structure intervenes. Fluoroscopy usually provides suitable guidance for biopsy of large parenchymal or peril hilar masses in the chest. CT guidance may be necessary for small lesions. Ultrasound or CT guidance is most commonly employed in the abdomen. Ultrasound is quick and flexible and allows the needle path to be followed in real time without additional radiation burden to the patient. Small lesions and lesions which cannot be adequately imaged with ultrasound, particularly those biopsied under CT control (Fig. 2.30).

A platelet count of less than 80 000 or an international normalised ratio (INR) of greater than 1.3 should be corrected where possible, by the administration of fresh frozen plasma and/or vitamin K, where appropriate, prior to biopsy. Gross ascites should be drained prior to liver biopsy unless biopsy via a transjugular approach is available. The choice of needles is wide. In general, an 18G automatic spring-loaded cutting needle provides an excellent core biopsy. Larger 14G needles may be useful where architectural assessment is required in patchy disease, e.g. cirrhosis. Cytological analysis via 22G needle is often adequate for the diagnosis of malignancy. Accuracy rates exceed 80 per cent. Negative biopsies may be due to faulty needle placement. Complications are unusual, occurring in less than 2 per cent of patients and include haemorrhage, pancreatitis, pneumothorax and occasional seeding of the needle track by tumour.

Drainage of abscesses and fluid collections

Almost any fluid collection in the chest, abdomen or pelvis may be considered for percutaneous catheter drainage, which has largely replaced surgery as the treatment of choice. Initially percutaneous drainage was confined to large superficial postoperative collections, but use has broadened to include complex multilocular collections, multiple abscesses and collections in difficult locations (e.g. presacral space, psoas muscle).

CT or ultrasound is used to define a safe access route avoiding the penetration of major vessels or bowel. Ultrasound is adequate for superficial collections and may be preferable where an angled approach is required, e.g. sub-pleural collections (Fig. 2.31). Superficial collections, where there is little risk of misdirection, may be safely drained via a simple one-step trochar catheter system. More complex or deep collections often require the more precise guidance of CT, using the needle guidewire and catheter exchange system originally devised by Seldinger for arterial puncture (Fig. 2.32). Diagnostic fine needle aspiration should be performed before drainage to determine the nature and viscosity of the collection. Nonviscous fluid — ascites, cysts, seromas, biliomas. urinomas — can be satisfactorily drained via an 8—10 French catheter. Thick, inspissated, infected material often requires a larger bore catheter (10—14 French) with multiple side holes and, ideally, a double lumen for cavity irrigation. At catheter insertion, the cavity should be evacuated as completely as possible. Saline irrigation may help to decrease the viscosity of the contents and encourage drainage. Patients should be given broad-spectrum antibiotic cover before and after the procedure. Following catheter placement, regular saline irrigation (10—20 ml tds) is important to maintain catheter patency. The catheter should be left in situ for several days until drainage ceases. Continued drainage of 50 ml or more suggests possible fistulous communication which may be confirmed by a contrast study via the catheter. Prolonged catheter drainage over several weeks may be necessary in such cases to allow fistulae to close. Successful catheter drainage of simple postoperative collections or localised abscesses can be achieved in over 90 per cent of cases. The cure rate for more complex collections such as pancreatic abscesses, abscesses caused by leak from enteric, biliary or urinary anastomosis and thoracic empyema is lower, between 70 and 85 per cent. The multicellular nature of many of these collections makes complete evacuation difficult. However, in many patients percutaneous drainage achieves palliation and allows the patient to undergo delayed, elective, single-stage surgery in a more stable condition with a relatively clean operative bed.

Percutaneous biliary procedures

Drainage of an obstructed biliary system is usually achieved by ERCP. Endoscopic cannulation of the ampulla allows the passage of guidewires and catheters, and the majority of strictures can be bypassed and stented by this approach. In gallstone obstruction of the common bile duct, endoscopic stone removal can be achieved following sphincterotomy by basket retrieval, mechanical lithotripsy or balloon sweepage of the duct. A proportion of patients with obstructive jaundice is not suitable for this endoscopic approach, because of previous gastric surgery, difficulties with cannulation of the ampulla or a tight stricture which cannot be negotiated from below. In these patients, a percutaneous tranhepatic approach is required. Percutaneous transcatheter cholangiography involves puncture of an intrahepatic bile duct with a fine needle from a right intercostal approach. Successful visualisation of the ducts is achieved in almost all patients with dilated ducts and over 85 per cent of patients with nondilated ducts (Fig. 2.33). Dilated systems require drainage to reduce the risk of sepsis and relive jaundice. A peripheral duct with a direct line of approach to the common hepatic duct is chosen for cannulation. Teflon-coated hydrophilic guidewires are particularly useful in traversing even the tightest strictures. Subsequent management depends on the nature of the obstruction demonstrated:

Options include the following:

- balloon dilatation;
- simple external drainage;
- external/internal drainage;
- endoprosthesis — plastic or expanding metal.

Balloon dilatation

Over 90 per cent of benign biliary structures are post-operative, the remainder resulting from sclerosing cholangitis or pancreatitis. If there is biliary sepsis, balloon dilatation should not be attempted until this has been treated with antibiotics and a period of external biliary drainage. A 7—9 French balloon-tipped catheter is placed in the stricture segment with fluoroscopic guidance and the balloon inflated until the ‘waist’ of the balloon within the stricture segment is obliterated. Results suggest that 75—80 per cent of strictures will remain patent for at least 3 years.

External/internal drainage

The majority of biliary strictures is malignant and is due to carcinoma of the pancreas, primary bile duct tumours, nodal enlargement at the porta hepatis or encroachment on the major bile ducts by hepatic metastases. Treatment is aimed at palliation. If there is hilar obstruction, it is usually sufficient to drain only one side of the system in order to allow the other duct to function. If a stricture cannot be bypassed, a catheter may be left in situ with external biliary drainage. This will decompress the system, control the risk of sepsis and will result in resolution of oedema such that a second delayed attempt to traverse the stricture is often successful. A percutaneous catheter is manipulated through the obstruction, into the normal distal common duct or duodenum. Side holes in the catheter that are located above and below the obstruction permit the re-establishment of enterohepatic circulation of bile such that the catheter may be clamped (Fig. 2.34).

Endoprosthesis

An endoprosthesis may be placed into the bile duct to remove the inconvenience of a catheter protruding from the skin and reduce the risks of infection. Percutaneous
placement of plastic endoprostheses requires a transhepatic track of 12 French or greater, which carries an increased morbidity (Fig. 2.35).

The recent introduction of self-expanding metallic prostheses means that a smaller percutaneous track is sufficient and the stent can often be inserted immediately without a period of external drainage. Often a percutaneous approach with guidewire manipulation through a stricture is combined with an endoscopic approach. The guidewire is ‘grabbed’ in the duodenum and a stent placed endoscopically. Stent occlusion, by either bile encrustation or tumour ingrowth or overgrowth, remains a problem, although the expanding metal stents have a longer life span than plastic endoprostheses (Fig. 2.36).

Major complications in these patients who generally have severe underlying disease have been observed in 2—5 per cent of patients (death, sepsis, haemorrhage).

Minor complications (pain, fever, catheter blockage or leakage) occur in 20—40 per cent of patients.

**Gall bladder drainage**

Percutaneous gall bladder puncture and drainage may be beneficial in acute calculous or acalculous cholecystitis, or gall bladder empyema in patients who are high risk for surgery or whose medical condition is unstable. The procedure is usually performed under ultrasound guidance. A transhepatic route is advocated to reduce the risk of biliary peritonitis, although a transperitoneal approach is acceptable as the complication rate does not appear to be significantly increased. In severely ill patients the procedure can be performed at the bedside. Ideally, a self-retaining catheter with a locking loop should be left within the gall bladder. In septic patients, recovery is usually rapid and can be followed 2—3 weeks later by elective cholecystectomy. Complications are uncommon although vagal effects (bradycardia and hypotension) do occur and may be treated with atropine and intravenous fluid. Percutaneous gall bladder puncture and aspiration has been advocated in intensive therapy unit (ITU) patients who are pyrexial, without a demonstrable cause, in whom the gall bladder is distended and contains sludge, raising the possibility of acalculous cholecystitis. Approximately 50 per cent of such patients may improve following gall bladder drainage.

**Percutaneous renal intervention**

Percutaneous drainage of obstructed kidneys, percutaneous nephrostomy, is performed in patients who are septic or in renal failure due to ureteric obstruction by neoplasm, calculi or stricture. Other percutaneous techniques have evolved from this, including antegrade ureteric stent placement, balloon dilatation of ureteric strictures and the creation of a track for percutaneous stone removal (nephrolithotomy) in patients not suitable for lithotripsy.

In a patient presenting with renal failure, it is vital not to miss the presence of bilateral obstruction or an obstructed solitary kidney, and an ultrasound examination is mandatory. The decision to drain the kidney is usually straightforward, particularly in the presence of sepsis. In bilateral obstruction, the better functioning kidney (larger, thicker parenchyma) should be drained first to enable the uraemia and hyper-kalaemia to be corrected. If known malignant pelvic disease is resulting in bilateral obstruction, then discussion and consideration of the likely prognosis of the underlying disease process is advisable before proceeding. The indications for percutaneous nephrostomy are shown in (Fig. 2.37).

Nephrostomy tube placement may be performed under fluoroscopic or ultrasound guidance. The aim is usually to puncture a lower pole calyx rather than a direct central puncture which is more likely to cause vascular damage. A middle calyx approach may be preferred if antegrade stent placement is contemplated. Using a flexible sheathed needle and guidewire with dilatation of the track, final placement of a small pigtail catheter is achieved with minimal trauma to the kidney and discomfort to the patient (Fig. 2.38). The use of self-locking catheters reduces the risk of subsequent catheter dislodgement. Haemorrhage is usually venous and mild, lasting for up to 24 hours. Significant haemorrhage occurs in 1—2 per cent of patients and may occasionally require arteriography to identify a bleeding point or false aneurysm, which may then be treated with selective embolisation. Septic complications occur in 1—2 per cent. They can be minimised by appropriate prophylactic and antibiotic cover and minimising catheter/guidewire manipulation.

Ureteric J-J pigtail stent insertion is usually approached-retrogradely by cystoscopy. It is of value where long-term drainage is required. Indications include calculous obstruction, often in relation to extracorporeal shock wave lithotripsy (ESWL) which produces many small fragments which may block the ureter, benign or malignant ureteric strictures and to allow ureteric perforations to heal. If a retrograde approach fails then an antegrade approach is possible. Most strictures can be traversed with modern flexible hydrophilic guidewires.
Gastrointestinal Intervention

Enteric strictures

Dilatation of benign or malignant oesophageal strictures can be performed with either endoscopic or fluoroscopic guidance. The choice depends on local expertise but screening during dilatation is advisable to reduce the risk of oesophageal perforation. Balloon dilatation is achieved by the introduction of a balloon over a guidewire under fluoroscopic guidance. Balloon dilatation has the advantage of providing a controlled radial dilating force without the longitudinal shearing forces associated with conventional oesophageal bougie dilatation, which is thought to predispose to oesophageal rupture. Obliteration of the waist of the balloon with inflation can be observed in real time and provides an indication of the likely success of the procedure.

In patients with malignant oesophageal disease, considered incurable by surgical intervention, oesophageal stent placement provides good palliation. The use of rigid plastic stents (Celestin or Atkinson tubes) has been gradually superseded by self-expanding metal stents (Fig. 2.35). Some of these are covered with plastic, minimising tumour ingrowth and sealing any associated perforation or fistula. Placement rapidly relieves symptoms, allowing the patient to return home to a relatively normal diet. These techniques are being expanded to strictures elsewhere in the gastrointestinal tract. Duodenal and colonic strictures have been satisfactorily stented although experience is currently limited and the long-term prospects for such procedures are currently unknown.

Percutaneous gastrostomy

Percutaneous gastrostomy placement provides a more comfortable alternative to long-term nasogastric feeding in patients who are unable to maintain nutrition with oral intake. This is usually as a result of upper aerodigestive tract malignancy or an inability to swallow as a result of a previous cerebrovascular accident. Percutaneous placement of gastrostomy feeding tubes can be achieved using either endoscopy or fluoroscopy. The choice again largely depends on local expertise and both methods are technically satisfactory. Fluoroscopic placement is essential in patients in whom nasopharyngeal or oesophageal narrowing is such that even the smallest endoscope cannot bypass the obstruction. The fluoroscopic technique requires insufflation of the stomach with air or CO₂ via a fine nasogastric tube. This renders it fluoroscopically visible and distends the stomach against the anterior abdominal wall. A puncture site is selected over the lower body of the stomach. Following guidewire placement, the track is dilated co-axially and a 12-French loop catheter finally positioned with a retention loop in the stomach. Minor complications include wound infection and tube dislodgment. Peritonitis does occasionally occur which may be minimised by gastropexy, i.e. fixation of the stomach to the anterior abdominal wall by removable sutures (Fig. 2.40).
Interventional vascular techniques

A wide range of interventional vascular techniques has developed from basic angiographic principles and has had a profound impact on many aspects of medicine and surgery.

Vascular therapy

By selective arterial cannulation it is possible to deliver a high local dose of a chemotherapeutic agent to the feeding vessels of a tumour. This technique has been used with success for liver tumours, particular hepatocellular carcinoma, metastatic colorectal cancer and ocular melanoma.

There has been a resurgence of interest in the potential of low dose intra-arterial infusion of thrombolytic agents in peripheral arterial thromboembolic occlusion. The choice of therapy between surgical embolectomy and thrombolysis is controversial.

In patients with recurrent or threatened pulmonary embolism from lower extremity or pelvic thrombus, inferior vena caval filters may be inserted percutaneously, from either a femoral or jugular approach to prevent the passage of a major embolus. A femoral approach is appropriate if the thrombus does not extend proximally into the inferior vena cava and if the contralateral femoral and pelvic veins are patent. Otherwise, a jugular approach is indicated, assuming the superior vena cava is patent.

Management of vascular obstruction

Percutaneous transluminal angioplasty

This technique of balloon dilatation of a vascular stenosis, with the aim of increasing blood flow and improving perfusion, has had a profound impact on the treatment of vascular disease. Initially described by Dotter and Judkins in 1964, the technique has undergone many modifications and now provides a lower risk alternative treatment to surgical bypass graft.

Indications include:

- peripheral vascular disease with relatively short occlusions (10—15 cm in length);
- ischaemic heart disease with coronary artery stenosis;
- hypertension or chronic renal failure with renal transplant artery stenosis;
- mesenteric/coeliac artery stenosis.

The technical success rate for femoral and popliteal angioplasty is between 85 and 95 per cent for stenoses with a 20—70 per cent patency rate at 5 years (Fig. 2.41). Complications include local haemorrhage and haematoma, false aneurysm formation at the puncture site, subintimal dissection and arterial perforation. The incidence of peripheral embolisation of atheromatous deposits is low, reported as between 3 and 5 per cent of cases and rarely resulting in clinically apparent ischaemia.

Vascular stenting

In 1988, Palmaz reported the use of intravascular stents in atherosclerotic arterial stenosis. The therapeutic potential of expanding metal stents in vascular disease is great and stents are being successfully used in renal ostial stenosis, abdominal aortic aneurysm repair, coronary artery disease and other major peripheral vessels. A major problem of intravascular stents is their thrombogenic potential as fibrin and platelets are deposited within the mesh of the stent. This can be inhibited by anticoagulation and over a period of weeks endothelialisation of the stent occurs. It is likely that with further technical developments, stents will be developed that will be antithrombotic, encourage endothelialisation and inhibit neo-intimal hyperplasia.

Transjugular intrahepatic porto-systemic shunt

(TIPSS)

A particular use of expanding metal stents has been in the development of TIPSS, which involves the percutaneous creation of a communication between the portal and hepatic venous systems for the relief of portal hypertension (Fig. 2.42). This procedure was first performed by Richter in 1988 and is now firmly established as an alternative to surgery in patients with recurrent variceal bleeding who are resistant to sclerotherapy or endoscopic banding. The technical success rate is over 90 per cent. The major complication is hepatic encephalopathy which can develop following the procedure. Shunt occlusion may develop, usually as a result of intimal hyperplasia. This may require re-intervention with balloon dilatation or a second stent insertion.

Therapeutic embolisation

Deliberate vascular embolisation with the aim of occluding a vessel can be achieved using a variety of different materials including gelatin, sponge fragments, polyvinyl alcohol foam particles (PVA) and spiral metal coils.

Arterial embolisation may be used in the treatment of:

- acute haemorrhage;
- tumour therapy;
- arterio-venous malformations;
- hypersplenism;
- priapism.

Venous embolisation is used for treatment of:

- gastro-oesophageal varices;
- testicular varicocele.

The technique can be performed under local anaesthetic and requires a highly skilled radiologist to position selectively the catheter. The technique is not without risk as accidental embolisation of adjacent normal structures may occur. Tissue necrosis following the procedure may cause pain and fever due to tissue infarction and occasionally results in abscess formation.

Wounds

Wounds and their management are fundamental to the practice of surgery. Any elective surgical intervention will result in a wound in order to gain access to and deal with the underlying pathology. In the surgery of trauma the wound is the primary pathology. In both situations the surgeon’s task is to minimise the adverse effects of the wound, remove or repair damaged structures and harness the processes of wound healing to restore function.
Wound Healing

In human regeneration is limited to epithelium and the liver; most tissues heal by repair resulting in scarring. Wound healing is the summation of a number of processes which follow injury including coagulation, inflammation, matrix synthesis and deposition, angiogenesis, fibroplasia, epithelialisation, contraction, remodelling and scar maturation (Fig. 3.1). Where wound edges are apposed healing proceeds rapidly to closure; this is known as healing by first intention or primary healing (Figs 3.2 and Fig 3.3). Where the wound edges are apart, such as when there has been tissue loss, the same biological processes occur, but rapid closure is not possible. Angiogenesis and fibroblast proliferation result in the formation of granulation tissue. This contracts to reduce wound area and allows epithelialisation across its surface to achieve wound closure. This is known as healing by second intention (Fig 3.4). This process is slower, the contraction involved may cause contracture and functional restriction (Fig. 3.9) and the resultant healed surface is a thin layer of epithelium on scar tissue that may not prove durable in the long term. In general, healing by second intention will give a worse aesthetic outcome. It is because of the poor functional and aesthetic results of healing by second intention that surgical endeavour is usually directed towards achieving primary wound healing.
A wound can be caused by almost any injurious agent and can involve almost any tissue or structure. The most useful classification of wounds from a practical point of view is that of Rank and Wakefield into tidy and untidy wounds.

**Tidy wounds**

Tidy wounds are inflicted by sharp instruments and contain no devitalised tissue (Fig. 3.6); such wounds can be closed primarily with the expectation of quiet primary healing. Examples are surgical incisions, cuts from glass and knife wounds. Skin wounds will usually be single and clean cut. Tendons, arteries and nerves will commonly be injured in tidy wounds, but repair of these structures is usually possible (Fig. 3.7). Fractures are uncommon in tidy wounds.

**Untidy wounds**

Untidy wounds result from crushing, tearing, avulsion, vascular injury or burns, and contain devitalised tissue (Fig. 3.8). Skin wounds will often be multiple and irregular. Tendons, arteries and nerves may be exposed, and might be injured in continuity, but will usually not be divided. Fractures are common and may be multifragmentary. Such wounds must not be closed primarily; if they are closed wound healing is unlikely to occur without complications. At best there may be wound dehiscence, infection and delayed healing, at worst gas gangrene and death may result. The correct management of untidy wounds is wound excision, by this is meant excision of all devitalised tissue to create a tidy wound. Once the untidy wound has been converted to a tidy wound by the process of wound excision it can be safely closed (Fig. 3.9) (or allowed to heal by second intention).
Wound excision

The most important step in the management of any untidy wound is wound excision. This process is sometimes called 'wound toilet' or 'debridement'. The former implies washing and the latter laying open or fasciotomy, all of which may be important in wound management but do not describe excision of devitalised tissue which is the most important process. For this reason the term 'wound excision' is preferred. In order to excise a wound adequate anaesthesia — local, regional or general — must be provided. Where possible a bloodless field also aids identification of structures. For superficial wounds the use of local anaesthetic with 1 in 200,000 adrenaline gives good haemostasis of skin edges. In the limbs a pneumatic tourniquet is used. It is helpful to use a skin marking pen to plan the skin excision and any wound extensions. Excision should proceed in a systematic fashion dealing with each tissue layer in turn, usually starting superficial and moving deep. Longitudinal structures such as blood vessels, nerves and tendons are identified and exposed, but left incontinuity. With experience the surgeon learns to recognise dead tissues. Devitalised dermis is pink rather than white; devitalised fat is pink rather than yellow; devitalised muscle is a dark colour, has lost its usual sheen and turgor, and does not twitch when picked up with forceps. Bone fragments with no soft-tissue attachment or nonvital soft tissue attachments are also discarded. This approach to radical wound excision is sometimes called a 'pseudotumour' approach, because the entire wound is excised with an appropriate margin back to healthy tissue (Fig 3.8 and Fig 3.9). At the end of wound excision the wound should resemble an anatomical dissection. Normal bleeding should be observed from each layer. Occasionally in very extensive wounds this radical approach must be modified. Where radical wound excision would threaten the viability or function of the limb it is reasonable to excise what is definitely nonviable, carry out fasciotomy as appropriate and dress the wound, with a view to returning 48 hours later for a second look, and thereafter further serial wound excisions until a tidy wound is achieved.
Wound closure

Wound closure can be achieved by number of differing techniques. Most tidy wounds that do not involve loss of tissue can be closed directly. Where there is tissue loss a technique to import appropriate tissue is needed. Reconstructive plastic surgical techniques can range from simple skin grafts to complex composite free tissue transfers (Table 3.1). This list used to be described as a ‘reconstructive ladder’: unfortunately this implies that the correct approach is to use the simplest technique and only when it fails move to a more complex technique. This approach is not appropriate in modern surgical practice. The available techniques should be regarded as a ‘toolbox’ from which to select the technique that provides most rapid healing, earliest return to function and superior aesthetic outcome.
Types of wound

Bruise, contusion and haematoma

A closed blunt injury may result in a bruise or contusion. There is bleeding into the tissues and visible discolouration. Where the amount of bleeding is sufficient to create a localised collection in the tissues, this is described as a haematoma. Initially this will be fluid, but it will clot within one or two hours. Later, after a few days, the haematoma will again liquefy. There is a danger of secondary infection. Bruises require no specific management, and no treatment is of proven value. The patient should be advised that the time required for bruising to clear is extremely variable and in some individuals, in some sites, discoloration may persist for months. A haematoma should be evacuated by open surgery if large or causing pressure effects (such as intracranially), or aspirated by a large-bore needle if smaller or in a cosmetically sensitive site. It may be necessary to await liquefaction (which may take several days) and to perform repeated aspirations, with appropriate antiseptic precautions. A haematoma will generally reabsorb without scarring, but on occasions there may be persistent tethering of the skin. Blunt injuries carry a high risk of fat injury with fat necrosis that can manifest as a localised area of hyperaemia and tenderness. The danger of degloving or avulsion injuries is that there is devascularisation of tissue and skin necrosis may become apparent in the following few days. Even tissue that initially demonstrates venous bleeding may subsequently undergo necrosis if the

Puncture wounds and bites

A puncture wound is an open injury in which foreign material and organisms are likely to be carried deeply into the underlying tissues. Common causes are standing on a nail or other sharp object. There may be little to see on the surface. Radiological examination may detect metal fragments or glass. Treatment is essentially by wound irrigation, antibiotic treatment and tetanus prophylaxis. Large foreign bodies should be removed, but small particles may be surprisingly difficult to find without a destructive dissection and are better left undisturbed. When a foreign body is visualised on radiograph a surface marker should be taped to the skin to aid localisation. A metal detector may be helpful during exploration. The danger of puncture injuries is that they may give rise to an abscess deep within the tissues and on such occasions drainage may be required. It is likely that it will take 24–48 hours for an abscess to declare itself and arrangement should be made for review. Needle-stick injuries are a particular cause for concern. Although these are a particular hazard for hospital staff, discarded needles from drug abuse are surprisingly a common hazard to the public. Medical, nursing and ancillary staff should have hepatitis B immunisation. The chance of HIV infection from a needle-stick injury seems to be low but all such injuries should be recorded and, if dealing with a high-risk patient, HIV tests should be performed at 3 and 6 months after the episode. Bites are a particular type of puncture wound associated with a high incidence of infection, presumably from mouth organisms. Animal bites may result in small, sharp, incised wounds or in severe tissue crushing as in horse bites. Dog bites may also be associated with a degree of tissue avulsion (Fig. 3.10), and often there are puncture wounds from upper and lower teeth and contusion of the intervening tissue. Human bites may be associated with avulsion of pieces of the nose or ear. An accidental type of ‘bite’ injury may result from an attacker striking the victim’s incisor teeth with the knuckles. This is a frequent injury that presents with a puncture wound over the metacarpophalangeal (MP) joints. It is important to recognise the nature of the injury as the history is often less than truthful. Radiological examination may demonstrate parts of a tooth within the MP joints. As all of the layers over the joints glide over one another on making a fist, the through-and-through nature of the puncture wound is often not appreciated with the hand extended. If there has been sufficient force to penetrate the skin, it must be assumed that the MP joint has been penetrated. Such wounds are best treated by open surgical exploration excision of skin margins, irrigation of the joint and antibiotic therapy.

Abrasions and friction burns

An abrasion is a shearing injury of skin in which the surface is rubbed off. Most are superficial and will heal by epithelialisation, but some may result in full-thickness skin loss. Abrasions may be dirt ingrained and if this dirt is not removed at the time of primary treatment permanent tattooing of the skin will result. Treatment is by cleaning with a scrubbing brush, gently brushing along the grain of the scratch lines. A friction burn is similar, but there will be an element of thermal damage as well as abrasion. Treatment is as for other types of burn.

Laceration

A laceration or cut is the result of contact with a sharp object (the surgical equivalent is an incised wound). Once the cutting implement has gone deep to the dermis, there is less resistance in the subcutaneous tissues and the cut may therefore penetrate to a considerable depth. It is important to ascertain from the history the amount of force involved. The clinical examination must therefore assess the integrity of all structures in the area: arteries, nerves, muscles, tendons and ligaments (Fig. 3.6). The ideal form of management of an incised wound is surgical inspection, cleaning and closure. The wound must be thoroughly inspected to ensure that there is no damage to deep structures or, where encountered, these must be repaired (Fig. 3.7). As a general rule, the damage to nerves and tendons is generally greater than suspected preoperatively. Once all of the damaged layers have been identified, each structure must be repaired individually by the appropriate technique. Haemostasis must be ensured throughout the exploration. There are precise suture placement techniques for nerves, tendons and blood vessels. Muscles can be apposed in layers by mattress sutures and fascia, and subcutaneous fat should be opposed by interrupted absorbable sutures to allow a firm platform for skin closure in such a way that the skin margins do not invert. It is an important principle to prevent collections of blood or other fluids in a wound as they separate tissues and act as a nidus for infection. A corrugated or suction drain may be required. In a simple incised laceration, a method of wound closure should be selected which is appropriate for the needs of function and appearance. On the face, fine (5/0 or 6/0) nylon sutures should be placed near to the wound margins, to be removed on the fifth day. Alternatively, subcuticular (intradermal) sutures avoid suture marks and can be left in place longer (2 weeks or more). An alternative to suturing is the application of adhesive tape strips. It is necessary to apply these with the same care as sutures ensuring that all bleeding has stopped and that the skin is dry. For limb and trunk wounds, a heavier suture is required but it is rarely necessary to use more than 4/0 or 3/0 sutures for skin closure. Monofilament sutures, such as nylon, are said to leave less obvious suture marks than braided material such as silk, but other factors contribute to stitch marks, such as inflammation (from infection or reaction to organic material such as silk), wound tension and late removal. All patients sustaining open wounds should have prophylaxis against tetanus, and antibiotics should be administered where there is significant contamination, commencing generally with a broad-spectrum antibiotic active against Gram positive organisms.

Traction and avulsion

Avulsion injuries are open injuries where there has been a severe degree of tissue damage. Such injuries occur when hands or limbs are trapped in moving machinery, such as in rollers, producing a degloving injury. Degloving is caused by shearing forces that separate tissue planes, rupturing their vascular interconnections and causing tissue ischaemia. This most frequently occurs between the subcutaneous fat and deep fascia. Degloving injuries can be open or closed. Degloving can be localised or circumferential. It can occur only in the single, subcutaneous plane, but where present in multiple planes, such as between muscles and fascia and between muscles and bone, is an indication of a severe high-energy injury with a limited potential for primary healing. Similar injuries occur as a result of runover road traffic accident injuries where friction from rubber tyres will avulse skin and subcutaneous tissue from the underlying deep fascia (Fig. 3.11). The history should raise the examiner’s suspicion and it is often possible to pinch the skin and lift it upwards revealing its detachment from the normal anchorage. The danger of degloving or avulsion injuries is that there is devascularisation of tissue and skin necrosis may become slowly apparent in the following few days. Even tissue that initially demonstrates venous bleeding may subsequently undergo necrosis if the
circulation is insufficient. Treatment of such injuries is to identify the area of devitalised skin and to remove the skin, defat it and reapply it as a full-thickness skin graft. Avulsion injuries of hands or feet may require immediate flap cover using a one-stage microvascular tissue transfer of skin and/or muscle.

Crush

Crush injuries are a further variant of blunt injury and are often accompanied by degloving and compartment syndrome. Injury to tissues within a closed fascial compartment leads to bleeding, exudate and swelling of these tissues, and increased interstitial pressure. As the interstitial pressure rises above capillary perfusion pressure the blood supply to the viable tissues is reduced, resulting in further ischaemic tissue injury and swelling (Fig. 3.12). This cycle causes a worsening compartment syndrome with muscle ischaemia and nerve ischaemia progressing to muscle necrosis, skin necrosis and limb loss. Muscle necrosis may result in renal failure. This process can be arrested by early recognition and decompression of the affected compartment(s) by fasciotomy. The most reliable clinical sign of compartment syndrome is pain worsened by passive stretching of affected muscles. Where any doubt exists compartment pressure measurements can be carried out. Loss of peripheral pulses is not a sign of compartment syndrome, but indicates major vessel damage. Where compartment syndrome is suspected or confirmed fasciotomy is advised. Longitudinal incisions are made in the deep fascia and it may also be necessary to make extensive longitudinal releases in the skin. It is important to release the fascia over each individual compartment in a limb.
Injury to internal organs.

Wounds such as stab wounds may be associated with damage to internal organs. Treatment of penetrating abdominal or thoracic wounds has been discussed elsewhere. The possibility of blunt or sharp abdominal trauma must not be overlooked when treating extensive injuries elsewhere, particularly in an unconscious patient.

War wounds and gunshot injuries

Gunshot injuries are associated with different severity of tissue damage depending upon whether the injury is of low or high velocity. Low-velocity injuries, such as from a hand gun, result in an entry and exit wound, the latter being the larger, and damage along the tract of the missile. Such injuries are often associated with severe tissue contamination from clothing, dirt or other foreign materials. High-velocity injuries (from modern assault rifles) cause explosive pressure and decompression effect, such that there is widespread tissue damage, with injury to major limb vessels and nerves situated some distance from the tract of the missile. Where a high-velocity missile strikes bone, the high-energy exchange results in fragmentation of the bone. Gunshot wounds and war wounds require careful surgical excision and such wounds should be left open. Following high-velocity injuries, fasciotomy of all of the fascial compartments of the limb should be undertaken. The damage from a shotgun wound depends on the scatter of the shot and therefore on the range. A large track of damage may result in severe bleeding or a pneumothorax, which requires immediate appropriate emergency management.

Injuries to bone and joints

Fractures may be closed where the skin is intact or open where there is a wound. Open fractures may have a skin wound due to penetration from the outside or, more frequently, due to bursting of the skin from within by bone fragments. The bone displacement is worst at the very moment of injury and bone fragments partially reduce spontaneously thereafter. It is important to appreciate that a puncture wound of the skin overlying a fracture is almost certainly evidence that the skin was penetrated by bone. The usual principles of wound management apply in that an adequate excision of the wound is necessary followed by antibiotic treatment and appropriate treatment of the fracture. Severe open lower limb injuries often have extensive damage to the skin and muscle in addition to fractures. It is best to treat the fracture and soft-tissue injuries simultaneously. Extensive removal of damaged soft tissue may be required and skin cover achieved by a one-stage microvascular tissue transfer.

Injury to nerves

Glass does not bruise nerves. Where there is an open wound, nerve division must always be suspected. Clinical examination should be undertaken to assess the motor and sensory function of every nerve in the region of the open wound, and it must be assumed that an underlying nerve has been divided until its function can be demonstrated to be intact. A sharp, wounding implement can travel a considerable distance in the soft tissues, and with limb injuries it is necessary to assess all the major nerve trunks at that level in the limb. Where there is doubt the nerve should be explored and visualised. Divided nerves should be repaired. Magnification and fine suture materials have improved results.

Injuries to arteries and veins

Where a wound is associated with much bleeding there is the possibility that a significantly large vessel has been divided. As a first aid measure, bleeding will almost always be controlled by direct pressure, and elevation of the part where practicable. Limb tourniquets should not be applied as a first aid measure. In the emergency department it is never desirable to plunge vascular clamps or artery forceps into a wound without a proper view of the bleeding point, as grasping nerves can inflict great harm. Where a major limb vessel has been damaged it may be necessary to apply direct manual pressure while the patient is taken into an operating room. Under anaesthesia, the appropriate way to deal with bleeding in the limb is to explore the wound under pneumatic tourniquet control.
Chronic wounds

Several conditions are classified as varieties of chronic wounds, although they may not clearly follow mechanical trauma.

Ulcers

An ulcer is any breach in an epithelial surface. Chronic ulcers are wounds that fail to heal. In generally, they have a fibrotic margin and a bed of granulation tissue which may include areas of slough (necrotic tissue). Ulcers are particularly common in the lower third of the lower limb and foot. They have a number of different aetiologies, often being associated with arterial or venous insufficiency or a lack of normal skin innervation. The wound healing process is delayed by a variety of mechanisms including infection, mechanical irritation, ischaemia or other metabolic factors. Ulcers are common in diabetes and rheumatoid arthritis. Treatment consists of specific management of the underlying cause. The ulcer is managed either by dressings to allow healing by second intention or by surgical excision of granulation tissue and split-skin grafting. Recurrence is inevitable if the underlying cause is not corrected.

Pressure sores

These are chronic wounds following tissue necrosis from pressure. They occur over bony prominences. Their pathogenesis is identical to compartment syndrome in that they arise where there is unrelieved pressure in the soft tissues overlying bone such that the external pressure exceeds capillary perfusion pressure and ischaemic necrosis occurs. They occur in paraplegic individuals who lack the usual sensory input that tissue ischaemia is beginning and may lack the ability to move themselves and relieve this pressure. They also occur in situations where perfusion pressure is low, such as hypotension and peripheral vascular disease. Sacral and trochanteric sores occur in bed-bound patients, both paraplegic and nonparaplegic. Ischial pressure sores occur in chair-bound paraplegics. Patients with peripheral vascular disease are prone to heel pressure sores. On occasions almost any bony prominence may be involved. Prevention is better than cure. This depends on an awareness of pressure sore risk in all patients and the implementation of appropriate measures that may include turning or lifting the patient, pressure-relieving mattresses and beds, special seating and cushions, and educating the patient and their carers in taking responsibility for pressure relief. When a sore occurs it is essential to identify and correct the underlying cause. If this can be done most sores will heal by second intention. Incontinence should be managed appropriately and nutritional support provided if needed. Surgical treatment can accelerate healing. The sore is excised and closed using a flap. Pressure sore closure is indicated for nonparaplegics where the sore is delaying or complicating their recovery from an illness, and in paraplegics who have identified and corrected the precipitating cause and who are motivated to maintain adequate pressure relief. Surgery is usually inappropriate in those in the later stages of progressive neurological illnesses.
Scars

The most superficial wounds such as superficial burns and abrasions will heal by epithelialisation alone without scar formation. In these circumstances adnexal structures are preserved and the epithelium regenerates from these structures. This may leave alterations in keratinisation, texture or pigmentation of the healed area, but not scarring as such. A scar is the inevitable consequence of wound repair. The final phase of wound repair is the process of remodelling and scar maturation (Fig. 3.1). The fibroblasts, capillaries, glycosaminoglycans, and immature collagen of granulation tissue and the newly healed wound are replaced by relatively acellular, avascular scar tissue composed of mature collagen with scattered fibroblasts. This biological process is manifest by a change in appearance of the scar from a red, raised, firm, contracting, perhaps itchy nodule to a pale, flat, softer, static, symptomless plaque of mature scar. The rate at which any given scar passes through this process can vary widely depending on the age of the individual, the site of the wound, the time the wound took to heal, the direction of the scar and the tension across it (Fig. 3.13). In general, scars in younger patients with wounds on the trunk that heal slowly, perhaps with infection or dehiscence, and scars that have a lot of tension across them will take much longer to mature than scars in older people, in thin-skinned areas, that heal rapidly by first intention and that have minimal tension across them (Table 3.2). It is important to be aware of this variation in the natural history of scar maturation in order to counsel patients regarding the likely progress and outcome of their scar, advise those having elective surgery what the consequences in terms of scarring will be, and to recognise the various types of adverse scarring which can occur. One of the most frequent types of adverse scar, a hypertrophic scar, is one that remains red, raised, itchy and tender for longer than might generally be expected.
Adverse scar

There are many types of adverse scar (Table 3.3), many of which can be avoided or prevented by correct incision planning and adequate wound management. Some types, however, cannot be prevented and are unpredictable in their occurrence. The appearance of some scars can be improved by surgical or other means, but scars can never be removed totally. The types of adverse scar will be discussed and suggestions for avoidance or management made.

Wrong direction

Incisions that pass along ideal lines are more likely to leave acceptable scars. There are many types of ‘lines of election’ for incisions, most of which pass along skin wrinkles or along relaxed skin tension lines (that is a line along which maximal skin tension passes when the part is in a relaxed position). These lines have minimal tension across the wound edges. A scar which crosses these lines will have a greater tendency to stretch or become hypertrophic, and even if not hypertrophic will usually appear more conspicuous than one which follows a relaxed skin tension line. Other ideal positions for scars are at junctions between anatomical areas such as the nose and the cheek, the cheek and the ear or the junction between a hairy and hairless area.

Poor alignment of features

Where a scar crosses the junction between distinct anatomical features, such as the vermilion of the lip, it is essential that these features are accurately realigned. Such misalignments result in conspicuous adverse scars.

Stretched scar

Scars from excisional wounds on the trunk and limbs often stretch. It has been shown that the width of a scar depends on the tension across the wound at the time of wound closure. In general, steps to avoid excessive tension across the wound will be rewarded with narrower scars. Where tension cannot be avoided there is evidence that prolonged wound support with buried nonabsorbable or long-term absorbable sutures can minimise scar stretching.

Contracted scar

The process of wound contraction continues in the remodeling phase of scar maturation such that a scar will always be shorter than the incision from which it results. Where a linear scar crosses a flexor surface this shortening may result in a scar contracture which may prevent full extension of that part. This will occur on the flexor surface of a finger if a straight-line incision is used. Curved or zigzag incisions will avoid this problem. Where scar is extensive such as burn scars then scar contractures may be inevitable. Linear scar contractures can be corrected by realignment of the scar; there are various techniques to do this including Z-plasty and multiple Y—V-plasty. More extensive contractures will require release and introduction of additional skin by means of grafts or flaps.

Pigment alteration

The new epidermis of a scar will often not have the same degree of pigmentation as surrounding unscarred areas. Most scars are hypopigmented, but hyperpigmentation can also occur. The only ways to deal with this problem are cosmetic camouflage or tattooing.

Contour deformity

Where wound edges are not anatomically aligned in the vertical plane or where a bevelled cut is not repaired accurately there is a risk of contour irregularity in the healed scar. This can usually be avoided by accurate wound repair, if necessary excising bevelled edges to restore even vertical edges for repair. A variation of this problem occurs when a curved laceration heals, in that the scar shortens and that portion of skin within the concavity of the curved scar tends to become raised. This problem is known as trapdoorning or mushrooming. It will often improve with time, but scar revision is sometimes indicated to correct it.

Tattooing

In traumatic wounds it is possible for particles of grit, dirt or soot to become implanted in the wound as it heals. This results in tattooed scars where the particles of foreign material show through as blue or black discoloration of the scar. Adequate primary wound management can avoid this. Abrasions with ingrained dirt should be scrubbed with a stiff brush; more deeply tattooed wounds should be excised. Late correction of tattooed scars can be very difficult.

Stitch marks

If skin sutures are left in place for more than 7 days then scars from the stitch marks will usually result. This problem can be avoided by using subcuticular sutures wherever possible, removing skin sutures before 7 days and, where prolonged wound support is needed, supplementing skin sutures with subcuticular sutures allowing early removal of the skin sutures. Adverse scars due to prominent stitch marks can rarely be improved by scar revision.

Hypertrophic scars

In some circumstances scars remain in the remodelling phase for longer than is usual. These hypertrophic scars are more cellular and more vascular than mature scars, there is increased collagen production and collagen breakdown, but the balance is such that excess collagen is produced. Clinically these scars are red, raised, itchy and tender (Fig. 3.14). Such scars will eventually mature to become pale and flat, and it is this spon-taneous resolution which distinguishes hypertrophic scars from keloid scars. Hypertrophic scars typically occur in wounds where healing was delayed, perhaps where complications such as infection or dehiscence occurred. They are more common in children and where skin tension is high such as the tip of the shoulder or any scar that runs across relaxed skin tension lines.

The risk of developing a hypertrophic scar can be minimised by ensuring quiet primary healing. Where hypertrophy does occur patience is usually rewarded by improvement with time. Massage of the scar with moisturising cream or the application of pressure to the remodelling scar can accelerate the natural process of maturation. Patients with hypertrophic burn scars are supplied with custom made Lycra pressure garments that promote acceleration of scar maturation. Revision of hypertrophic scars is appropriate where they cross skin tension lines or where a specific wound healing complication occurred. In the absence of these factors scar revision should be avoided as it will usually be met with recurrence.

Keloid scars
In some situations there is an extreme overgrowth of scar tissue that grows beyond the limits of the original wound and shows no tendency to resolve. Keloid scars are biologically identical to hypertrophic scars that in turn are an extension of normal scar behaviour. Whilst it is usually possible to make the distinction between these scar types, they are best regarded as a spectrum of scar behaviour (Table 3.4). Keloid scars are more frequent in Afro-Caribbean and oriental racial groups (Fig. 3.10). They often occur in wounds that healed perfectly without complications. They are more common in certain sites such as the central chest, the back and shoulders and the ear-lobes. Many keloid scars are untreatable and surgical treatment as a single modality will usually be met with recurrence. Some keloid scars will improve with the application of pressure. Intralesional injections of steroids such as triamcinolone can be helpful. The best cure rates are achieved with a combination of surgery and postoperative interstitial radiotherapy.

Fluid intake

Fluids (Tab 4.1)

Fluid intake is derived from two sources: (1) exogenous; and (2) endogenous.

**Exogenous** water is either drunk or ingested in solid food. The quantities vary within wide limits, but average 2—3 litres per 24 hours, of which nearly half is contained in solid food.

Taking into consideration their body weight, the water requirements of infants and children are relatively greater than those of adults because of: (1) the larger surface area per unit of body weight; (2) the greater metabolic activity due to growth; and (3) the comparatively poor concentrating ability of the immature kidney.

**Endogenous** water is released during the oxidation of ingested food; the amount is normally less than 500 ml/24 hours. However, during starvation, this amount is supplemented by water released from the breakdown of body tissues.

Fluid output

Water is lost from the body by four routes.

- **By the lungs.** About 400 ml of water is lost in expired air each 24 hours. In a dry atmosphere, and when the respiratory rate is increased, the loss is correspondingly greater (this also applies to the patient who has their trachea intubated).

- **By the skin.** When the body becomes overheated, there is visible perspiration, but throughout life invisible perspiration is always occurring. The cutaneous fluid loss varies within wide limits in accordance with the atmospheric temperature and humidity, muscular activity and body temperature. In a temperate climate the average loss is between 600 and 1000 ml/24 hours.

- **Faeces.** Between 60 and 150 ml of water are lost by this route daily. In diarrhoea this amount is greatly multiplied.

- **Urine.** The output of urine is under the control of multiple influences, such as blood volume, hormonal and nervous influences, among which the antidiuretic hormone plays a major role controlling tonicity of the body fluids, a function that it performs by stimulating the reabsorption of water from the renal tubules, thus varying the amount excreted after the requirements of the first three routes have been met. The normal urinary output is approximately 1500 ml/24 hours, and provided that the kidneys are healthy, the specific gravity of the urine bears a direct relationship to the volume. A minimum urinary output of approximately 400 ml/24 hours is required to excrete the end products of protein metabolism.

**Water depletion**

Pure water depletion is usually due to diminished intake. This may be due to lack of availability, difficulty or inability to swallow because of painful conditions of the mouth and pharynx, or obstruction in the oesophagus. Exhaustion and paresis of the pharyngeal muscles will produce a similar picture. Pure water depletion may also follow the increased loss from the lungs after tracheostomy. This loss may be as much as 500 ml in excess of the normal insensible loss. After tracheostomy, humidification of the inspired air is an important preventive measure.

**Clinical features**

The main symptoms are weakness and intense thirst. The urinary output is diminished and its specific gravity increased. The increased serum osmotic pressure causes water to leave the cells (intracellular dehydration), and thus delays the onset of overt compensated hypovolaemia (see below).

**Water intoxication**

This can occur when excessive amounts of water, low sodium or hypotonic solutions are taken or given by any route. The commonest cause on surgical wards is the overprescribing of intravenous 5 per cent glucose solutions to postoperative patients. Colorectal washouts with plain water, instead of saline, have caused water intoxication during total bowel wash-through prior to colonic surgery. A major component of the TURP (transurethral resection of the prostate) syndrome is the water intoxication caused by excessive uptake of water (and glycine) from irrigation fluid.

Similarly, water intoxication can occur if the body retains water in excess to plasma solutes. This can be seen in the syndrome of inappropriate antidiuretic hormone (SIADH) secretion which is most commonly associated with lung conditions such as lobar pneumonia, empyema and oat-cell carcinoma of bronchus, as well as head injury.

**Clinical features**

These include drowsiness, weakness, sometimes convulsions and coma. Nausea and vomiting of clear fluid are common, and, with the notable exception of the SIADH, usually the patient passes a considerable amount of dilute urine. Laboratory investigations may show a falling haematocrit, serum sodium and other electrolyte concentrations.

**Treatment**

The intake of water having been stopped, the best course is water restriction. If the patient fails to improve, transfer to an intensive care or high dependency unit will be necessary for more invasive monitoring and controlled manipulation of fluids and electrolytes. The administration of diuretics or hypertonic saline should not be undertaken lightly as rapid changes in serum sodium concentration may result in neuronal demyelination and a fatal outcome.
Sodium balance

Sodium is the principal cation content of the extracellular fluid. The total body sodium amounts to approximately 5000 mmol, of which 44 per cent is in the extracellular fluid, 9 per cent in the intracellular fluid and the remaining 47 per cent in bone. The sodium housed in bone merits special notice: a little more than half of it is osmotically inactive and requires acid for its solution; the remainder is water soluble and exchangeable. Thus, there is a large storehouse of sodium ready to compensate abnormal loss from the body. The daily intake of sodium is inconstant. On average it is 1 mmol/kg sodium chloride or 500 ml of isotonic 0.9 per cent saline solution. An equivalent amount is excreted daily, mainly in the urine and some in the faeces. The loss in perspiration normally is negligible; however, in people not acclimatized to tropical heat, prolonged profuse sweating results in a considerable loss of sodium — as much as 85 mmol/hour. If water alone is given to counter-balance the fluid loss, serious sodium depletion can occur from excessive sweating. (See also mucoviscidosis, in Chapter 54 of this book on ‘The gallbladder and bile ducts’.)

Control by adrenal corticoids

The output of sodium, governed by the variation in the avidity with which the renal tubules reabsorb sodium from the glomerular filtrate and the amount of sodium excreted by the sweat glands, is under the control of the adrenal corticoids, the most powerful conservator of sodium being aldosterone. When the adrenal glands have been destroyed by disease or extirpated, there is an unbridled loss of sodium in the urine.

The sodium excretion shut down of trauma

Following trauma/surgery there is a variable period of reduced excretion of sodium. For this reason it may be inadvisable to administer large quantities of isotonic (0.9 per cent) saline solution after an operation. The period of sodium excretion shut down can last for up to 48 hours and is due to increased adrenocortical activity.

Sodium depletion (syn. hyponatraemia)

The most frequent cause of sodium depletion seen in surgical practice is obstruction of the small intestine, with its rapid loss of gastric, biliary, pancreatic and intestinal secretions by antiperistalsis and ejection, whether by vomiting or aspiration. Duodenal, total biliary, pancreatic and high intestinal external fistulae also are all notorious for bringing about early and profound hyponatraemia. Severe diarrhoea due to dysentery, cholera, ulcerative colitis or pseudomembranous colitis will cause hyponatraemia with acidosis. The finding of hyponatraemia with elevated potassium would suggest adrenocortical insufficiency. Hyponatraemia is also seen in SIADH.

There is one other less obvious, and surreptitious, means whereby the patient is robbed of sodium and that is by gastric aspiration combined with allowing the patient to drink as he or she pleases and promptly aspirating the fluid swallowed. The act of drinking excites the flow of gastric juice, and this is also aspirated. During this form of therapy, should the patient be receiving intravenous dextrose solution to maintain fluid balance, he or she will soon become a victim of hyponatraemia.

Clinical features. Clinical features of hyponatraemia with salt and water depletion are due to extracellular dehydration. In established cases the eyes are sunken and the face is drawn. In infants the anterior fontanelle is depressed. The tongue is coated and dry; in advanced cases it is brown in colour. Unlike the dehydration produced by loss of water only, in water and salt depletion thirst is not particularly in evidence. The skin is dry and often wrinkled, making the patient look older than his or her years. The subcutaneous tissue feels lax. Peripheral veins are contracted and contain dark blood. The arterial blood pressure is likely to be below normal. The urine is scanty, dark in colour, of a high specific gravity and, except in cases of salt-losing nephritis, contains little or no chloride.

Presuming that the haemoglobin level before the dehydration commenced was normal, the haematocrit reading (PCV) provides an index of the degree of haemoconcentration. However, haemoconcentrations can be masked by pre-existing anaemia. Laboratory investigations would show normal or slightly reduced serum sodium with low urinary output and low urinary potassium.

Postoperative hyponatraemia

Hyponatraemia with a normal or increased extracellular fluid volume arises as a result of too prolonged administration of a sodium-free solution (cf. Water intoxication, above).

Sodium excess (syn. hypernatraemia)

This is likely to arise if a patient is given an excessive amount of 0.9 per cent saline solution intravenously during the early postoperative period when, as has been described, some degree of sodium retention is to be expected. The result is an overloading of the circulation with salt and...
its accompanying water.

Clinical features. Slight puffiness of the face is the only early sign. The patient makes no complaint. Pitting oedema should be sought, especially in the sacral region, but for pitting oedema to be present at least 4.5 litres of excess fluid must have accumulated in the tissue spaces. The patient’s weight increases pari passu with the water-logging. Signs of overhydration in infancy (infants are very susceptible) are increased tension in the anterior fontanelle, increased weight, an increase in the number of urinations and oedema.

Potassium balance

Potassium is almost entirely intracellular. No less than 98 per cent is intracellular, and only 2 per cent is present in the extracellular fluid. Three quarters of the total body potassium (approximately 3500 mmol) is found in skeletal muscles. When the body needs endogenous protein as a source of energy, potassium, as well as nitrogen, is mobilised. The mobilised potassium passes to the extracellular fluid, but the surplus over and above the normal content is so rapidly excreted by healthy kidneys that the concentration of potassium in the serum remains unaltered. Each day a normal adult ingests approximately 1.0 mmol/kg of potassium in food; fruit, milk and honey are rich in this cation. Except for a very small quantity in formed faeces, and a still smaller quantity in sweat, an amount corresponding to the intake is excreted in the urine.

Potassium depletion

The augmented potassium excretion of trauma. Following trauma, including operation trauma, there is a spell, varying directly with the degree of tissue damage, of increased excretion of potassium by the kidneys. This loss is greatest during the first 24 hours and lasts, for example in the case of partial gastrectomy, for about 3 or 4 days. So great are the body’s reserves of potassium that, unless the patient was severely depleted at the time of the operation, hypokalaemia may not reveal itself for 48 hours. However, potassium is such a key intracellular cation that carefully monitored replacement should start early in the postoperative period in all patients, with the exception of those that have evidence of renal dysfunction.

Hypokalaemia. Hypokalaemia can occur suddenly or gradually.

Sudden hypokalaemia is unlikely to be encountered in surgical practice. It occurs most frequently in diabetic coma treated by insulin and prolonged infusion of saline solution.

Gradual hypokalaemia is the type encountered in surgical practice. It is most commonly seen in patients who present for surgery with chronic hypokalaemia as a result of potas-sium-losing medications such as diuretics. The diarrhoea from ulcerative colitis, villous tumours of the rectum (see Chapter 59 of this book on ‘The vermiform appendix’) and the loss from external fistulae of the alimentary tract are also common causes (e.g. duodenal fistula, ileostomy); the potassium content of the discharge from some of these fistulae is twice that of the plasma potassium concentration. Another frequent cause of hypokalaemia is prolonged gastro-duodenal aspiration with fluid replacement by intravenous isotonic saline solution. It is also prone to occur in the postoperative period following extensive resections for carcinoma of the alimentary tract, because often the operation has to be undertaken after months of weight loss and potassium depletion.

Clinical features

Most patients are asymptomatic, but at risk of the sequelae of hypokalaemia such as cardiac arrhythmias. Such consequences are more likely during surgery and anaesthesia, especially in the presence of pre-existing myocardial disease. Symptoms of severe hypokalaemia include listlessness and slurred speech; muscular hypotonia, depressed reflexes and abdominal distension as a result of a paralytic ileus. Weakness of the respiratory muscles may result in rapid, shallow, gasping respirations; these are conducive to postoperative pulmonary complications. The diagnosis is supported by electrocardiography (ECG), which may show a prolonged QT interval, depression of the ST segment and flattening of the T-wave.

Treatment

Oral potassium. Potassium can be given in the form of milk, meat extracts, fruit juices and honey. However, in hospital practice, effervescent or inversion of the T-wave.

Estimation of electrolyte balance

Sodium

Sodium, with its equivalent anions, accounts for about 90 per cent of the osmotic pressure of the plasma. Changes in the sodium content coincide with changes in the osmolality of all the body fluids. The serum sodium value is normally between 137 and 147 mmol/litre. Whenever possible, the serum chlo-ride and bicarbonates should be estimated simultaneously because variations in the one may be accompanied by oppo-site changes in the other. The normal level of chloride is 95—105 mmol/litre, and of bicarbonate 25—30 mmol/litre; the sum of the two remains roughly constant at 120—135 mmol/litre.

Potassium

Potassium deficiency is present if the serum potassium value is less than 3.5 mmol/litre. The normal range is 3.5—5.0 mmol/litre. It must be remembered that intracellular potassium deficiency may be present although the plasma concentration is normal, and that deficiency is to be expected if oral feeding has been withheld for more than 4 days. Estimation of potassium in the urine or aspirated gastrointestinal contents serves as a guide to the rate of depletion and the replacement necessary.

Calcium

Calcium is an extracellular cation with a plasma concentration of 2.2—2.5 mmol/litre. It exists in three forms: bound to protein, free nonionised and free ionised — the last form being the component necessary for blood coagulation and affecting neuromuscular excitability. The ionised proportion falls with increasing pH; thus in respiratory alkalosis due to hyperventilation there may be tetany — with an apparently normal total
serum calcium level. In the urine, the ionisation and the solubility of calcium are similarly depressed if the pH is elevated, thus promoting stone formation. The serum level of calcium is likely to be modified by any factor promoting or inhibiting its absorption from the bowel, its storage in bone or its elimination by the kidneys: such factors include vitamin D and phytic acid, parathormone and calcitonin (see Chapter 44), and the state of renal and small-bowel function.

The management of abnormal calcium blood levels depends, where possible, on removal of the cause, for example removal of a parathyroid tumour (see Chapter 44), or in the coagulation disorder due to massive transfusion of blood containing acid citrate dextrose (ACD, see below), 10 ml of 10 per cent calcium gluconate may be injected slowly intra-venously. If oral administration is possible, calcium aspirin is useful (see Chapter 44). On a long-term basis, the diet should be adjusted to provide a high calcium and a low phosphate intake.

Magnesium

Magnesium is an intracellular cation which shares some of the properties of potassium and some of calcium. The normal magnesium concentration is 0.7—0.9 mmol /litre. The average daily intake is approximately 10 mmol. Magnesium deficiency may occur when there is prolonged loss of gastrointestinal secretions due to fistulae or ulcerative colitis, very prolonged administration of intravenous fluids without magnesium supplements, following massive small bowel resections, and in some cases of cirrhosis of the liver or disease of the parathyroids. The clinical picture of magnesium deficiency is marked by central nervous system irritability, ECG changes, lowered blood pressure and lowered protein synthesis. Postoperative cardiac arrhythmias (e.g. de novo atrial fibrillation) are commonly associated with both hypokalaemia and hypomagnesaemia.

Treatment. For the treatment of mild hypomagnesaemia 20 mmol as magnesium sulphate can be added to 5 percent-dextrose or normal saline over a 24-hour period. Magnesium supplements are essential in hyperalimentation.
Acid-base balance

In health, blood hydrogen ion concentration lies within the range pH 7.36—7.44. The terms acidosis and alkalosis in clinical practice indicate a change or a tendency to a change in the pH of the blood in a particular direction. In acidosis, there is an accumulation of acid or a loss of a base causing a fall or a tendency to a fall in the pH. The converse occurs in alkalosis. The pH of the blood is regulated and controlled by various buffering systems essentially consisting of weak acids and bases, of which the most important is the bicarbonate:carbonic acid ratio $\text{HCO}_3^-:\text{H}_2\text{CO}_3$. It is also regulated by the removal of carbon dioxide by the lungs and by the excretion of both acids and bases by the kidneys.

The ratio of bicarbonate to carbonic acid is normally 20:1. Alteration in this ratio alters the pH regardless of the absolute values of the bicarbonate and carbonic acid. A decrease in the ratio leads to increased acidity and vice versa.

The bicarbonate level can be altered by metabolic factors, while the carbonic acid level is subject to alteration by respiratory factors. Alteration of one is followed automatically by a compensatory alteration in the other, so that the ratio ($\text{HCO}_3^-:\text{H}_2\text{CO}_3$) and therefore the pH of the blood remains constant.

Measurement of acid—base disturbances

These measurements are normally made on arterial or materialized capillary blood. $\text{PCO}_2$ is a measurement of the tension or partial pressure of carbon dioxide in the blood. The normal arterial $\text{PCO}_2$ is 4.1—5.6 kPa (31—42 mmHg). $\text{PO}_2$ is a measurement of the tension or partial pressure of oxygen in the blood. The normal arterial $\text{PO}_2$ is 10.5—14.5 kPa (80—110 mmHg).

**Standard bicarbonate** the concentration of the serum bicarbonate after fully oxygenated blood has been equilibrated with carbon dioxide at 40 mmHg (5.3 kPa) at 38°C. This eliminates respiratory causes and respiratory compensation for altered bicarbonate levels. Normal levels are 22—25 mmol/litre.

**Base excess or deficit** expresses, in mmol, the total buffer anions present in the blood in excess of deficit of normal. (Normal base excess or deficit ±2.5.) Base excess or deficit multiplied by 0.3 times the body weight in kg gives the total extracellular excess or deficit of base in mmol. Metabolic causes of acid—base disturbances are indicated by changes in the standard bicarbonate level and base excess or deficit. Respiratory causes of acid—base disturbances are indicated by changes in the PCO$_2$ and PO$_2$.

Alkalosis

**Metabolic alkalosis**

Metabolic alkalosis, a condition of base excess or a deficit of any acid other than $\text{H}_2\text{CO}_3$, can be caused by:

- excessive ingestion of absorbable alkali. This is not uncommon in patients who take proprietary indigestion remedies without medical supervision;
- loss of acid from the stomach by repeated vomiting or aspiration;
- cortisone excess, usually the result of over-administration of adrenal corticoids, but occasionally due to Cushing’s syndrome (see Chapter 44).

Compensation is effected by: (a) retention of carbon dioxide by the lungs; and (b) excretion of bicarbonate base by the kidneys (alkaline urine).

**Clinical features.**

Alkalosis due to loss of acid from the sto-mach is the most common and most important. In its most typical form, it is seen in patients with pyloric stenosis in whom the loss of acid by repeated vomiting is often accentuated by the taking of medicines containing sodium bicarbonate. The most striking feature of severe alkalosis is Cheyne—Stokes respiration with periods of apnoea lasting from 5s to 30 seconds. Tetany sometimes occurs. Latent tetany is more common, and can be unveiled by Trouseau’s sign (see Chapter 44). Regarding other signs, the dual phenomenon of severe alkalosis and hypokalaemia is so interwoven that their clinical separation is well-nigh impossible. Subclinical degrees of alkalosis are recognisable only by a raised standard bicarbonate concentration and a positive base excess. Severe alkalosis may result in renal epithelial damage and consequent renal insufficiency.

**Treatment.**

Metabolic alkalosis without hypokalaemia seldom requires direct treatment. The cause of the alkalosis should be removed where possible and a high urinary output encouraged.

**Hypokalaemic alkalosis**

Hypokalaemic alkalosis is seen in patients who have lost potassium and acid owing to repeated vomiting from pyloric stenosis. The low serum potassium causes potassium to leave the cell and be replaced by Na$^+$ and H$^+$ ions. The shift of H$^+$ ion into the cell causes intracellular acidosis and increases the cellular acidosis of the kidney cells.

**Treatment.** When hypokalaemia is sufficient to cause a metabolic alkalosis, the losses can be massive (> 1000 mmol). Replacement is a serious undertaking (see above). It can be achieved gradually and relatively safely by supplementing intravenous fluids with 40 mmol/litre of KCl if the urine output is adequate. More rapid replacement (up to 60 mmol/hour) will require intensive monitoring and supervision with continuous ECG monitoring in a high dependency or intensive care environment.

**Respiratory alkalosis**

Respiratory alkalosis, a condition where the arterialPCO$_2$ is below the normal range of 31—42 mmHg (4.1—5.6 kPa), is caused most commonly in surgical practice by excessive pulmonary ventilation carried out upon an anaesthetised patient. Other causes are hyperventilation occasioned by high altitudes, hyperpyrexia, a lesion of the hypothalamus and hysteria. Compensation, which depends on increased renal excretion of bicarbonate, usually is inadequate. During anaesthesia alkalosis is accompanied by pallor and a fall in blood pressure. In severe cases respiratory arrest follows.
Treatment.

Respiratory suppression due to alkalosis is rectified by insufflation of carbon dioxide.

**Acidosis**

**Metabolic acidosis**

Metabolic acidosis, a condition where there is a deficit of base or an excess of any acid other than H$_2$CO$_3$, occurs as a result of:

- **increase in fixed acids** due to the formation of ketone bodies as in diabetes or starvation, the retention of metabolites in renal insufficiency, and the rapid increase of lactic and pyruvic acids by anaerobic tissue metabolism, following cardiac arrest, or the release of the clamped aorta in the surgery of abdominal aneurysm. Acute acidosis with pH levels of 7.1 is frequently encountered in such cases;

- **loss of bases** such as occurs in sustained diarrhoea, ulcerative colitis, gastrocolic fistula, a high intestinal fistula or prolonged intestinal aspiration.

Clinical features.

In severe acidosis, the leading sign is rapid, deep, noisy breathing. The hyperpnoea is due to over stimulation of the respiratory centre by the reduction in pH of the blood, and the physiological purpose of overbreathing is to eliminate as much as possible of the acid substance H$_2$CO$_3$. Except in renal acidosis, the urine is strongly acidic. The standard bicarbonate level is lowered and there is a base deficit.

**Treatment.**

The commonest cause of an acute peroperative metabolic acidosis is tissue hypoxia and the correct treatment is restoration of adequate tissue perfusion. Treatment with bicarbonate solutions will correct the measured metabolic acidosis but not treat the problem. Indeed, as bicarbonate is rapidly converted into carbon dioxide intracellular acidosis may, in fact, get worse. The administration of bicarbonate solutions should be reserved solely for situations where bases have been lost or where the degree of acidosis is so severe that myocardial function is compromised (this is rare).

The acute acidosis seen in prolonged cardiac arrest may require the infusion of 50 mmol of 8.4 per cent sodium bicarbonate solution.

**Acidosis due to transplantation of the ureters into the colon**

Acidosis due to transplantation of the ureters into the colon is discussed in Chapter 63 of this book.

**Respiratory acidosis**

Respiratory acidosis, a condition where the PCO$_2$ is above the normal range, is caused by impaired alveolar ventilation.

In practice this problem most commonly occurs when there is inadequate ventilation of the anaesthetised patient, or when the effects of muscle relaxants have not worn off or been fully reversed at the end of the anaesthetic. There is also a risk of respiratory acidosis when the patient undergoing surgery already has pre-existing pulmonary disease (e.g. chronic bronchitis or emphysema), and this is accentuated by thoracic and upper abdominal incisions.

**The anion gap**

This is a calculated estimation of the undetermined or un-measured anions in the blood. It is sometimes used to establish the cause of a metabolic acidosis. Anion gap = (Na + K) — (HCO$_3$ + Cl). The normal anion gap is 10—16 mmol/litre. An increased anion gap is seen in metabolic acidosis due to ketoacidosis, lactic acidosis, poisoning (salicylates) and renal failure. A normal anion gap is seen in metabolic acidosis due to renal tubular acidosis and loss of alkali due to diarrhoea, intestinal obstruction or intestinal fistula, and in the hyperchloraemia of ureterocolic anastomosis.
Haemorrhage

Recognition of types of haemorrhage

Arterial haemorrhage

Arterial haemorrhage is recognised as bright red blood, spurting as a jet which rises and falls in time with the pulse. In protracted bleeding, and when quantities of intravenous fluids other than blood are given, it can become watery in appearance.

Venous haemorrhage

Venous haemorrhage is a darker red, a steady and copious flow. The colour darkens still further from excessive oxygen desaturation when blood loss is severe, or in respiratory depression or obstruction. Blood loss is particularly rapid when large veins are opened, e.g. common femoral or jugular.

Venous bleeding can be under increased pressure as in asphyxia, or from ruptured varicose veins. Portal vein pressures (see Chapter 47) are high enough to cause rapid blood loss, especially in portal hypertension with oesophageal varices. Pulmonary artery haemorrhage is dark red (venous blood) at around 30 mmHg (4 kPa), whereas bleeding from the pulmonary veins is bright red (oxygenated).

Capillary haemorrhage

Capillary haemorrhage is a bright red, often rapid, ooze. If continuing for many hours, blood loss can become serious, as in haemophilia.

Primary haemorrhage

Primary haemorrhage occurs at the time of injury or operation.

Reactionary haemorrhage

Reactionary haemorrhage may follow primary haemorrhage within 24 hours (usually 4—6 hours) and is mainly due to rolling (‘slipping’) of a ligature, dislodgement of a clot or cessation of reflex vasospasm. The precipitating circumstances are: (1) the rise in blood pressure and the refilling of the venous system on recovery from shock; and (2) restlessness, coughing and vomiting which raise the venous pressure (e.g. reactionary venous haemorrhage within a few hours of thyroidectomy).

Venous haemorrhage, whether primary or reactionary, can tax the skill of even an experienced surgeon, for it may be exceedingly difficult to bring under control. Penetrating wounds involving main veins in the thigh or groin are potentially fatal, as exsanguination may follow the removal of a first aid dressing which has apparently controlled the bleeding (butcher’s thigh). Such a wound should never be treated in a perfunctory manner; it requires careful examination and closure in an operating theatre.

Secondary haemorrhage

Secondary haemorrhage occurs after 7—14 days, and is due to infection and sloughing of part of the wall of an artery. Predisposing factors are pressure of a drainage tube, a fragment of bone, a ligature in an infected area or cancer. It is also a complication of arterial surgery and amputations. It is heralded by ‘warning’ haemorrhages, which are bright red stains on the dressing, followed by a sudden severe haemorrhage which may be fatal. A warning haematemesis may occur in the case of a peptic ulcer, and is a danger signal which it is imprudent to ignore. In advanced cancer, the erosion of a main vessel (e.g. carotid or uterine) by a locally ulcerating growth becomes the way of a swift and merciful termination to the patient’s suffering. Secondary haemorrhage is prone to occur with anorectal wounds, for example after haemorrhoidectomy.

External haemorrhage

External haemorrhage is visible, revealed haemorrhage.

Internal haemorrhage

Internal haemorrhage is invisible, concealed haemorrhage. Internal bleeding may be concealed as in ruptured spleen or liver, fractured femur, ruptured ectopic gestation or in cerebral haemorrhage. Concealed haemorrhage may become revealed as in haematemesis or melaena from a bleeding peptic ulcer, as in haematuria from a ruptured kidney, or via the vagina in accidental uterine haemorrhage of pregnancy.

Measurement of acute blood loss

Assessment and management of blood loss must be related to the pre-existing circulating blood volume, which can be derived from the patient’s weight:

- infant 80—85 ml/kg;
- adult 65—75 ml/kg.

Measuring blood loss

- **Blood clot** the size of a clenched fist is roughly equal to 500 ml.
- **Swelling in closed fractures**. Moderate swelling in closed fracture of the tibia equals 500—1500 ml blood loss. Moderate swelling in a fractured shaft of femur equals 500—2000 ml blood loss.
- **Swab weighing**. In the operating theatre, blood loss can be measured by weighing the swabs after use and subtracting the dry weight. The resulting total obtained (1 g = 1 ml) is added to the volume of blood collected in the suction or drainage bottles. In extensive wounds and operations, the blood loss is grossly underestimated, due to evaporation of water from the swabs before weighing each batch. Prompt transfer of discarded swabs into polythene bags reduces this source of error. Blood, plasma and water are also lost from the vascular system
because of evaporation from open wounds, into the tissues, sweating and expired water via the lungs. Indeed, for operations such as radical mastectomy or partial gastrectomy it may be necessary to multiply the swab weighing total by a factor of 1.5. For prolonged surgery via larger wounds, as in abdomino-thoracic or abdominoperineal operations, the total measured may need to be multiplied by 2.

**Haemoglobin level**

This is estimated in g/100 ml (g/dl), normal values being 12—16 g/100 ml (12—16 g/dl). There is no immediate change in haemorrhage, but after some hours the level falls by influx of interstitial fluid into the vascular compartment in order to restore the blood volume.

**Measurement of central venous pressure**

For measurement of central venous pressure (CVP) see later.

**The treatment of haemorrhage**

Minimise further blood loss by pressure and packing, position and rest, operative procedures (ligation, repair and excision) and then fluid resuscitation as described below.

Restore blood volume by blood transfusion, albumin 4.6 percent, SAG-mannitol (SAG-M) blood, saline, gelatin, dextran and plasma infusions.

**Pressure and packing**

The first-aid treatment of haemorrhage from a wound is a pressure dressing made from anything handy which is soft and clean. The dressing or pack should be bound on tightly.

Other examples of pressure used to control haemorrhage include digital pressure, for example the use of forefinger and thumb or a clothespeg for epistaxis. The use of a double balloon in the oesophagus and the stomach to control the bleeding from oesophageal varices is another example of pressure being applied.

Packing by means of rolls of wide gauze is an important standby in operative surgery. If several rolls are used, the ends must be tied together to ensure complete removal later.

N.B. If on removal of pressure or packing, bleeding appears to have ceased completely, one should not assume that all is well, especially when dealing with deep wounds involving large veins. Continued close observation is required and rapid operative action may be called for.

**Position and rest**

**Elevation of limbs** (e.g. in ruptured varicose veins) employs gravity to reduce bleeding. Elevation also causes helpful vasoconstriction (Lister). A bed elevator is often used to raise the foot of the bed, and thus increasing venous return to the heart also augmenting cardiac output. Gravity is also used in certain operations, as in thyroidectomy when the patient is tilted feet downwards (reverse Trendelenburg position) or as in stripping of varicose veins when a head-down tilt is used (Trendelenburg).

**Examples of operative techniques in haemorrhage**

Artery forceps (haemostats) and clips are mechanical means of controlling bleeding by pressure. The clamped vessel can be ligated or it can be cauterized with diathermy. When an incision is made through the scalp for craniotomy, the profuse bleeding is not easily arrested by direct pressure, so the cranial aponeurosis is picked up by a series of forceps which are everted together, thus exerting pressure. Silver clips (Cushing) may be applied to cerebral vessels.

Suturing may be employed. The vessel can be underrun or transfixed by needle and suture, and then ligated, while if the continuity of a main vessel is to be restored 4/0 silk or poly-propylene is used on a 20-mm atraumatic needle.

Pressure by packing, using rolls of wide gauze, has been previously mentioned, but temporary light pressure with a 'peanut' of gauze held by forceps aids the sealing of an arterial suture line after reconstruction following trauma, embolectomy or in artery grafting. About 5 minutes is required for the platelets to seal the join.

Patches of vein or Dacron mesh may be used to repair a vascular defect. A patch of muscle, lightly hammered, provides thrombokinase to stop a troublesome ooze.

Other topical applications for oozing include gauze or sponge, which is absorbed by the body. 'Oxycel' or gelatin sponge provides a network upon which fibrin and platelets can be deposited. This is the modern counterpart of the use of cobwebs by our forefathers, or sphagnum moss by our neolithic ancestors. Gauze soaked in adrenaline (1:1000) can be applied. Bone wax (Horsley) is used for oozing bone.

The whole or part of a bleeding viscus may have to be excised (e.g. splenectomy or partial hepatectomy). A ruptured kidney is treated conservatively if possible (see Chapter 63).

**Natural blood volume and red cell recovery**

The recovery of blood volume begins immediately by the withdrawal of fluid from the tissues into the circulation. There is haemodilution. Plasma proteins are replaced by the liver. Red cell recovery takes some 5—6 weeks. The iron content will be less than normal if stores are depleted or absorption is impaired, for example after gastrectomy.
Transfusion of blood and blood products

The indications for transfusion in surgical practice are as follows.

• Following traumatic incidents where there has been severe blood loss, or haemorrhage from pathological lesions, for example from the gastrointestinal tract.

• During major operative procedures where a certain amount of blood loss is inevitable, for example abdominoperineal or cardiovascular surgery.

• Following severe burns where, despite initial fluid and protein replacement, there may be associated haemolysis.

• Postoperatively in a patient who has become severely anaemic.

• Preoperatively, usually in the form of packed cells given slowly (see Blood fractions and Complications, later) in cases of chronic anaemia where surgery is indicated urgently, i.e. where there is inadequate time for effective iron or other replacement therapy, or where the anaemia is unresponsive to therapy, for example aplastic anaemia.

• To arrest haemorrhage or as a prophylactic measure prior to surgery, in a patient with a haemorrhagic state such as thrombocytopenia, haemophilia or liver disease (see Blood fractions, later).

Preparation of blood products for transfusion

It is important that blood donors should be fit and with no evidence of infection, in particular hepatitis and human immunodeficiency virus (HIV) infection acquired immunodeficiency syndrome (AIDS), which are transmitted in donor blood.

Blood is collected into a sterile commercially prepared plastic bag with needle and plastic tube attached in a complete, closed sterile unit.

With the donor lying on a couch, a sphygmomanometer cuff is applied to the upper arm and inflated to a pressure of 70 mmHg (9.3 kPa) or 80 mmHg (10.6 kPa). After introducing 0.5 ml of local anaesthetic, a 15G needle is introduced into the median cubital vein and 410 ml of blood allowed to run into the bag containing 75 ml of anticoagulant solution (CPD — citrate potassium dextrose).

During collection, the blood is constantly mixed with the anticoagulant to prevent clotting, and at the end of the procedure the tube is clamped and the needle removed. Specimens for use in blood grouping and cross-matching procedures may be obtained by clamping off small sections of the plastic tubing containing the donor blood.

Blood storage

All blood for transfusion must be stored in special blood bank refrigerators controlled at 4°C ±2°C. Blood allowed to stand at higher temperatures for more than 2 hours is in danger of transmitting infection.

CPD blood has a shelf-life of 3 weeks (CPDA 1—5 weeks). The red blood cells, or erythrocytes, suffer a temporary reduction (24—72 hours) in their ability to release oxygen to the tissues of the recipient, so if a patient requires an urgent and massive transfusion it is wise to give 1 or 2 units of blood which are less than 7 days old.

White blood cells

White blood cells are rapidly destroyed in stored blood.

Platelets

At 4°C the survival of platelets is considerably reduced, and few are functionally useful after 24 hours. Platelets which are separated (see Blood fractions below) show good survival even after 72 hours.

Clotting factors

Like platelets, clotting factors VIII and V are labile and their levels fall quickly.

Blood fractions

Whole blood may be divided into various fractions. This is not only more economical of blood donors, but certain fractions are more appropriate than whole blood transfusion for certain clinical conditions. Fractionation procedures are relatively safe and simple, using sealed sterile plastic bag units.

Packed red cells

Packed red cells are especially advisable in patients with chronic anaemia, in the elderly, in small children and in patients in whom introduction of large volumes of fluid may cause cardiac failure. Packed red cells are suitable for most forms of transfusion therapy, including major surgery, especially in association with clear fluids. Good packing can be obtained by letting the blood sediment and removing the plasma, or by centrifugation of whole blood at 2000—2300g for 15—20 minutes.

Platelet-rich plasma

Platelet-rich plasma is suitable for transfusions to patients with thrombocytopenia who are either bleeding or require surgery. It is prepared by centrifugation of freshly donated blood at 15 0—200 g for 15—20 minutes.

Platelet concentrate

Platelet concentrate for transfusion to patients with thrombocytopenia is prepared by centrifugation of platelet rich plasma at 1200—15 00 g for 15—20 minutes.
Blood transfusion is commenced by:

- Giving blood should be given and this should always be available in acute emergency situations. Alternatively, donor blood, group 0-negative, which is compatible with the majority of individuals, may be advisable to restore the patient's blood volume by saline, gelatin (e.g. Haemaccel), dextran or human albumin 4.5 per cent until blood has been made available. In such emergencies, it may be necessary to reduce the patient's blood volume by saline, gelatin (e.g. Haemaccel), dextran or human albumin 4.5 per cent until blood has been made available. If this is not available, more SAG-M blood may be given, supplemented by 1 unit (400 ml) of 4.5 per cent human albumin solution BP for every 2 units of SAG-M blood. After 8 units of SAG-M red cells have been transfused, the need for fresh frozen plasma and platelets should be considered, after first checking the coagulation status and platelet count.

- Blood grouping and cross-matching require full laboratory procedures and take 1 hour. In emergencies it may be necessary to reduce this time, but the risk of doing this must be weighed against the danger to the patient by the delay in transfusion entailed by the full procedures. In such emergencies, it may be advisable to restore the patient's blood volume by saline, gelatin (e.g. Haemaccel), dextran or human albumin 4.5 per cent until blood has been made available. Alternatively, donor blood, group 0-negative, which is compatible with the majority of individuals, should be given and this should always be available in acute emergency situations.

### Antigens of the ABO blood groups

These are strongly antigenic and are associated with naturally occurring antibodies in the serum. Individuals show four different ABO cell groups, as shown in Table 4.2.

### Antigens of the rhesus (Rh) blood groups

The antigen of major importance in this group is Rh(D), which is strongly antigenic and is present in approximately 85 per cent of the population in the UK. Antibodies to the D antigen are not naturally present in the serum of the remaining 15 per cent of individuals, but their formation may be stimulated by the transfusion of Rh-positive red cells. Such acquired antibodies are capable, during pregnancy, of crossing the placenta and, if present in a Rh-negative mother, may cause severe haemolytic anaemia and even death (hydrops fetalis) in a Rh-positive fetus in utero. The other minor blood group antigens may be associated with naturally occurring antibodies, or may stimulate the formation of antibodies on relatively rare occasions.

### Incompatibility

If antibodies present in the recipient's serum are incompatible with the donor's cells, a transfusion reaction will result. This is the result of agglutination and haemolysis of the donated cells leading in severe cases to acute renal tubular necrosis and renal failure. For this reason, therefore, it is essential that all transfusion should be preceded by:

- ABO and rhesus grouping of the recipient's and donor's cells so that only ABO and Rh(D) compatible blood is given;
- direct matching of the recipient's serum with the donor's cells to confirm ABO compatibility and to test for rhesus and any other blood group antibody present in the serum of the recipient.

Blood grouping and cross-matching require full laboratory procedures and take 1 hour. In emergencies it may be necessary to reduce this time, but the risk of doing this must be weighed against the danger to the patient by the delay in transfusion entailed by the full procedures. In such emergencies, it may be advisable to restore the patient's blood volume by saline, gelatin (e.g. Haemaccel), dextran or human albumin 4.5 per cent until blood has been made available. Alternatively, donor blood, group 0-negative, which is compatible with the majority of individuals, should be given and this should always be available in acute emergency situations.

### Giving blood

Blood transfusion is commenced by:
• selection and preparation of the site;

• careful checking of the donor blood: this should bear a compatibility label stating the patient’s name, hospital reference number, ward and blood group;

• insertion of the needle or cannula — the latter may be valuable if intravenous therapy is required for any length of time;

• giving detailed written instructions as to the rate of flow, for example 40 drops/min allows one 540 ml unit of blood to be transfused in 4 hours.

In acute emergencies, it may be necessary to increase the rate of flow and it is possible to give 1—2 units in 30 minutes using a pressure cuff around a plastic bag of blood.

Warming blood. During cardiopulmonary operations, the blood must be warmed before reaching the patient by passing it through a carefully temperature-regulated blood warming unit, thus reducing the risk of cardiac arrest from large volumes of cold blood direct from the refrigerator.

Filtering blood. A filter (Pall) with an absolute filtration rating of 40 micron will filter off platelet aggregates and leucocytes membranes in stored blood.

**Autotransfusion**

This is an old, well-tried method of immediately restoring a patient’s blood volume, by transfusion with his or her own blood. In an emergency, for example, in a case of ruptured ectopic gestation, the blood is collected from the peritoneal cavity and put into a sterile container suitable for connecting to transfusion tubing. The classical method of filtration of this blood to prevent the transfusion of any small clots is to place a piece of sterile gauze within the container. Nowadays, special autotransfusion apparatus is being marketed. For major elective procedures, the patient may ‘donate’ his or her own blood, withdrawal and storage taking place up to 3 weeks before it is required. Natural blood volume and most of the red cell recovery will have taken place in that time.

**Complications of blood transfusion**

**Congestive cardiac failure**

This is especially liable to occur in the elderly or where there is cardiovascular insufficiency, and may result from too rapid infusion of large volumes of blood. It is advisable in the individual with chronic anaemia to give packed red cells and, at the same time, give diuretic drugs. In an individual with congestive cardiac failure it is advisable to give only one unit of blood over 4—6 hours and, if necessary, on two separate occasions.

**Transfusion reactions**

These may be the result of the following problems:

• **Incompatibility.** This should be avoided if the correct procedures of grouping and cross-matching have been adopted but, in fact, it is nearly always due to human error in the collection, labelling or checking of the specimens and donor bags. The patient develops a rigor, temperature and pain in the loins, and may become extremely alarmed. The transfusion should be stopped immediately, and a fresh specimen of venous blood and urine from the patient sent together with the residue of the used units of donor blood to the laboratory for checking.

A close watch should be kept on the patient’s pulse, blood pressure and urinary output. Frusemide 80—120 mg i.v. should be given to provoke a diuresis, and repeated if the urine output falls below 30 ml/hour. Dialysis may be necessary.

• **Simple pyrexial reactions** in which the patient develops pyrexia, rigor and some increase in pulse rate. These are the result of ‘pyrogens’ in the donor apparatus and are largely avoided by the use of plastic disposable giving sets.

• **Allergic reactions** in which the patient develops mild tachycardia and an urticarial rash; rarely an acute anaphylactic reaction may occur. This is the result of allergic reaction toplasma products in the donor blood. The reaction is treated by stopping the transfusion and giving an antihista-mine drug (chlorpheniramine 10 mg or diphenhydrazine 25 mg).

• **Sensitisation to leucocytes and platelets.** This is not uncommon in those patients who have received many transfusions in the past, for example for thalassaemia, refractory anaemia or aplastic anaemia. The individual develops antibodies to donated white cells or platelets, which cause reactions with each transfusion. They may be minimised by giving packed red cells from which plasma and ‘huffy coat layers’ have been removed or by ‘washing’ of donor cells. Aspirin, antihistamines or steroids may also be given to the recipient if necessary.

• **Immunological sensitisation.** Only the ABO, Kell and Rh(D) groups are considered for blood transfusion. Immune antibodies may be stimulated by transfusion, and may give rise to difficulties with compatibility tests or to haemolytic transfusion reactions.

**Infections**

There are four main reasons for blood transfusion causing infection in the recipient.

• **Serum hepatitis virus** may be transmitted from the donor and is usually a severe hepatitis arising approximately 3 months after the transfusion. It should be avoided by adequate verbal screening of the blood donor and by testing for the presence of the hepatitis associated antigen in the blood prior to transfusion.

• **HIV infection** can be transmitted by blood and blood products. All donors must be screened (see AIDS in Chapter 7). Haemophiliacs are at special risk because of their more frequent requirements for blood products.

• **Bacterial infection** may result faulty storage. This arises most commonly from the donor blood being left in a warm room for some hours before the transfusion is commenced. This allows proliferation of any bacteria, and transfusion of such infected blood may result in severe septicaemia in the recipient and rapid death.

• **Malaria** can be transmitted by blood transfusion in areas where the disease is endemic. Whenever possible, donors should be screened and the disease eradicated (by treatment of the donors who are positive) before blood is obtained or given. If the need for transfused blood is so urgent that precautions are impossible before transfusion, then the patient should be given prophylactic antimalarial drugs.
Thrombo phlebitis

For more on thrombophlebitis see Chapter 16 of this book.

Air embolism

For more on air embolism see Chapter 15 of this book.

Coagulation failure

Coagulation failure is due to:

- **dilution of clotting factors/platelets** due to large volumes of stored blood being used to replace losses as stored blood is low in platelets, Factor VIII and Factor V;

- **disseminated intravascular coagulation (DIC)** following an incompatible blood transfusion, particularly ABO incompatibility. The further haemorrhage may be treated by replacement of the deficient factors (usually fibrinogen, Factors VIII, V and II, and platelets), with fresh frozen plasma, cryoprecipitate and platelet concentrates. Paradoxically, heparin may be used sometimes for the treatment of DIC.

Haemophilia and the congenital haemorrhagic diseases

**Haemophilia**

Haemophilia (haemophilia A) is a haemorrhagic diathesis caused by the congenital deficiency in the blood of Factor VIII [antihaemophilic globulin (AHG)]. It is a sex-linked characteristic, transmitted by the asymptomatic female carriers, and manifest only in males.

The levels of Factor VIII in the blood of severe haemophiliacs may be less than 1 percent of the average normal level. In the case of spontaneous haemorrhage (e.g. into joints) treatment should aim at raising the level to at least 20 per cent. Should surgery be anticipated in the haemophiliac, the level should be raised to 50—100 per cent.

Factor VIII concentrates are superseding cryoprecipitates. The amount of either preparation depends on the problem and the level required for haemostasis, i.e. more for surgery than for a haemarthrosis. Frequent monitoring of the Factor VIII level will be necessary in cases involving surgery.

Additional forms of therapy may include fresh blood, if necessary for blood loss, fresh frozen plasma or, more rarely, dried concentrates of animal AHG (see also AIDS).

**Christmas disease**

Christmas disease (haemophilia B) is a congenital disease resulting from the deficiency of Factor IX (Christmas factor). Clinically, the manifestations of the disease are similar to haemophilia. Factor IX is replaced by the transfusion of fresh frozen plasma, or by reconstituted dried concentrates of human Factor IX.

**Haemophilic joints**

In both haemophilia and Christmas disease, haemorrhage into joints is very common, and persistent and recurrent haemarthrosis may result in permanent damage to the articular surfaces and disorganisation of the joint. The most important feature of treatment is that it should be prompt. Replacement of the clotting factor should be instituted immediately and before severe tension is allowed to build up in the joint.

**Von Willebrand’s disease**

Von Willebrand’s disease, with episodic bleeding manifestations, is a type of haemorrhagic disease, with low plasma levels of both Factor VIII complement and Factor VIII related antigen, and platelet abnormalities.

**Sickle-cell disorders**

Sickle-cell disorders can be a serious problem in surgery, especially with children. All patients of the negroid ethnic type should be screened for the presence of sickle haemoglobin. In sickle-cell trait (HbA + S) care to avoid hypoxia during anaesthesia is important. In sickle-cell anaemia, a preoperative partial exchange transfusion of packed cells to reduce the haemoglobin S level to less than 30 percent may be required, depending on the procedure and the length of the operation. Oxygen is given for the prevention of hypoxia; hypothermia and dehydration must be strenuously avoided. Spinal anaesthesia and tourniquets are contraindicated. Pigments gallstone formation is common.

**Blood substitutes — albumin, dextran, gelatin**

One of the most urgent requirements in a patient suffering from acute blood loss is the re-establishment of a normal blood volume. This may be achieved satisfactorily with a number of plasma substitutes.

**Human albumin 4.5 per cent** has superseded the use of dried plasma and can be used whilst cross-matching is being performed. Two to three units (1.2 litres) are given intravenously over 30 minutes. It is valuable in patients with burns where there has been severe loss of protein. There is no risk of transmitting hepatitis.

**Dextran** are polysaccharide polymers of varying molecular weight producing an osmotic pressure similar to that of plasma. They have the disadvantage of inducing rouleaux of the red cells and this interferes with blood-grouping and cross-matching procedures, hence the need for a blood sample beforehand. Dextran interfere with platelet function and may be associated with abnormal bleeding, and for this reason it is recommended that the total volume of dextran should not exceed 1000 ml.

**Low-molecular-weight dextan (40 000)** (dextran 40, Rheomacrodex) has an immediate effect in a restoring plasma volume, but it is transitory because the small molecules are readily excreted by the kidney. It may be useful in preventing sludging of red cells in small blood vessels, for example of the kidney, and thus preventing the renal shut-down associated with severe hypotension. It is less likely to induce rouleaux formation than the high-molecular-weight compounds.
The **high-molecular-weight dextrans** (110 000 and 70 000) (dextran 110 and dextran 70) are less effective in the early phase of hypovolaemia but are longer acting as they are retained for some time within the circulation.

**Gelatin** in a degraded form (molecular weight around 30 000) is used increasingly as a plasma expander. Up to 1000 ml of a 3.4—4 per cent solution (containing anions and cations) is given intravenously (e.g. Haemaccel, Gelafusine).
Blood transfusion

After initial use of plasma expanders, major acute blood loss requires rapid blood transfusion. While it is vital to restore blood volume and oxygen-carrying capacity, rapid transfusion may produce problems over and above those which can occur with any administration of blood products (such as group incompatibility and risk of infection).

Urgent provision by the transfusion laboratory and quick checking of multiple units of blood in an emergency inevitably enhances the chances of omission or error. However urgent the situation, unless one has resorted to giving uncross-matched or universal donor blood, safety standards must be maintained, if necessary by one member of staff dedicated to the checking and recording of blood units.

Other unwanted side effects result from the differences between fresh and stored blood. Some occur as a result of changes with time, and some relate to additives or extraction of plasma components. Blood is stored at 4°C and rapid transfusion has caused arrhythmias and worsened intraoperative hypothermia. Newer warming devices are able to raise the temperature satisfactorily even at very fast transfusion rates, but may require considerable pressure to force the blood through tortuous or narrow tubes. Cellular metabolism, membrane ion pump failure and haemolysis during storage lead to hypokalaemia and acidaemia with rapid transfusion, compounding the effects of reperfusing ischaemic areas and again may impair cardiac performance.

Anticoagulant (usually citrate to chelate calcium) and early loss of clotting factors and active platelets result in dilutional coagulopathy during massive transfusion. Ideally clotting should be monitored (such as by thromboelastography in theatre, or in the laboratory), and specific defects identified and treated. However, the situation is often too fraught and rapidly changing, and it may be necessary to administer fresh frozen plasma and/or platelets on an empirical basis (per 6—10 units of blood transfused). Calcium is usually maintained by mobilisation from bone, except in severe circulatory failure; however, it too should be measured or empirical administration considered if clotting appears clinically inadequate.

Parenteral fluid therapy

The solutions mainly in use are given below and summarised in Table 4.3.

• Plasma, albumin 4.5 per cent;

• dextrose 5 per cent is an isotonic solution that supplies calories without electrolytes. It is useful in the postoperative period when sodium excretion is reduced. It is also valuable when the salt requirements of a patient needing much fluid have been satisfied on a particular day. Pro-longed administration of 5 per cent dextrose solution alone is liable to result in hyponatraemia, and may cause thrombosis of the vein used;

• isotonic (0.9 per cent) saline solution is required to replace the normal sodium requirement (500 ml isotonic saline/day) and additional volume is required when a large amount of sodium has been lost by vomiting, or by gastric, duodenal or intestinal aspiration, or through an alimentary fistula. Possibly, on occasions, excessive sweating may justify its use;

• dextrose 4.3 per cent with saline 0.18 per cent (one-fifth isotonic saline) — this solution is isotonic. Usually it is referred to as dextrose—saline. It must not be confused with 5 per cent dextrose in saline, which is hypertonic;

• Ringer’s lactate solution contains sodium, potassium and chloride in almost the same concentrations as they are in the plasma. It also contains some calcium and some lactate. This solution can be used in hypovolaemic shock while awaiting blood. It is also suitable for replacing lost intestinal secretions.
Shock

Shock is a life-threatening situation. In most cases, it is due to poor tissue perfusion with impaired cellular metabolism, manifested in turn by serious pathophysiological abnormalities.

Types of shock

While there is some practical wisdom in the saying ‘shock means haemorrhage, and haemorrhage means shock’, there are other causes of shock with different features.

Vasovagal shock

Vasovagal shock is brought about by pooling of blood in larger vascular reservoirs (limb muscles), and by dilatation of the splanchnic arteriolar bed, causing reduced venous return to the heart, low cardiac output and reflex bradycardia. Consequently, the reduced cerebral perfusion causes cerebral hypoxia and unconsciousness, but prostration and reflex vasoconstriction so increases the venous return and cardiac output as to restore cerebral perfusion and consciousness. It must be remembered that if the patient is maintained in an upright or a sitting position (e.g. in a dental chair) permanent cerebral damage will occur.

Psychogenic shock

Psychogenic shock immediately follows a sudden fright (e.g. bad news) or accompanies severe pain (e.g. a blow to the testes). The expression ‘I nearly died of fright’ reflects the danger of the uncorrected faint.

Neurogenic shock

Neurogenic shock is caused by traumatic or pharmacological blockade of the sympathetic nervous system, producing dilatation of resistance arterioles and capacitance veins (see below) leading to relative hypovolaemia and hypotension. There is a low blood pressure, a normal or decreased cardiac output, a normal pulse rate and a warm dry skin. Trauma to the spinal cord and spinal anaesthesia lead to a systolic pressure of around 70 mmHg, which may be corrected by putting the patient in the Trendelenburg position, the rapid administration of fluids and or a vasopressor drug.

Hypovolaemic shock

Hypovolaemic shock is due to loss of intravascular volume by haemorrhage, dehydration, vomiting and diarrhoea (e.g. cholera, acute enterocolitis). Until 10—15 per cent blood volume is lost, the blood pressure is maintained by tachycardia and vasoconstriction. Fluid moves into the intra-vascular space from the interstitial space a ‘transcapillary refill’ which may exceed 1 litre in 1 hour in injured but otherwise fit patients. In addition, the venous capacitance vessels constrict, pushing blood into the arterial system and therefore compensating for the volume deficit.

Traumatic shock

Traumatic shock is due primarily to hypovolaemia from bleeding externally (open wounds), from bleeding internally (torn vessels in the mediastinal or peritoneal cavities, ruptured organs such as liver and spleen or fractured bones) or by fluid loss into contused tissue or into distended bowel. Traumatic contusion to the heart itself may cause pump failure and shock, while damage to the nervous system or to the respiratory system results in hypoxia.

Burns shock

Burns shock occurs as a result of rapid plasma loss from the damaged tissues, causing hypovolaemia. When 25 per cent or more of the body surface area is burnt, a generalised capillary leakage may result in gross hypovolaemia in the first 24 hours. Endotoxaemia due to infection makes matters worse and large volumes of colloidal and crystalloid fluids are required for resuscitation.

Cardiogenic shock

Cardiogenic shock occurs when more than 50 per cent of the wall of the left ventricle is damaged by infarction. Fluid over-load, particularly when using colloids, can lead to over-distension of the left ventricle, with pump failure. The resultant high filling pressures exerted by the right ventricle make fluid leak out of the pulmonary capillaries, thereby causing pulmonary oedema and hypoxia. If an arrhythmia occurs this will reduce the pumping efficiency of the heart, while hypovolaemia from excess sweating, vomiting and diarrhoea will further diminish cardiac output.

Acute massive pulmonary embolism from a thrombus originating in a deep vein or an air embolus (more than 50 ml), if obstructing more than 50 per cent of the pulmonary vasculature, will cause acute right ventricular failure. This greatly reduces venous return to the left ventricle, and cardiac output falls catastrophically causing sudden death or severe shock.

Septic (endotoxic) shock

Hyperdynamic (warm) septic shock. This occurs in serious Gram-negative infections (see Chapter 5), for example from strangulated intestine, peritonitis, leaking oesophageal or intestinal anastomoses, or suppurrative biliary conditions. At first, the patient has abnormal or increased cardiac output with tachycardia and a warm, dry skin, but the blood is shunted past the tissue cells, which become damaged by anaerobic metabolism (lactic acidosis). The capillary membranes start to leak and endotoxin is absorbed into the blood-stream, leading to a generalised systemic inflammatory state. The immediate and ready treatment of the cause, including the drainage of pus, is vital to the recovery of the patient at this stage (in strangulated hernia ‘the danger is in the delay, not in the operation’).

Hypovolaemic hypodynamic (cold) septic shock. This follows if severe sepsis or endotoxaemia is allowed to persist. Generalised capillary leakage and other fluid losses lead to severe hypovolaemia with reduced cardiac output, tachycardia and vasoconstriction. The systemic infection induces cardiac depression, pulmonary hypertension, pulmonary oedema and hypoxia which, in turn, reduce cardiac output still further. The patient becomes cold, clammy, drowsy and tachypnoeic, but still can be converted to hyperdynamic (warm) shock by the administration of several litres of plasma or other colloidal solution. The similar use of crys-talloid solutions may give rise to systemic and pulmonary oedema because of the larger volumes necessary.
**Anaphylactic shock**

Penicillin administration is amongst the common causes of anaphylaxis. Other causes include anaesthetics, dextran, serum injections, stings and the consumption of shellfish. The antigen combines with immunoglobulin E (IgE) on the mast cells and basophils, releasing large amounts of histamine and SRS-A (slow-release substance-anaphylaxis). These compounds cause bronchospasm, laryngeal oedema and respiratory distress with hypoxia, massive vasodilatation, hypotension and shock. The mortality is around 10 per cent.

**Notes on terms used**

Resistance arterioles are the small-calibre vessels, 0.02—0.05 mm in diameter, containing abundant smooth muscle in their walls, the tone of which is controlled by local hormonal factors and the sympathetic nerve fibres. The calibre of these small vessels gives rise to the peripheral vascular resistance, controlling blood pressure and blood flow through the capillary beds. The larger arteries merely serve to supply the arterioles with blood.

Capacitance veins comprise the entire venous network from the postcapillary venules to the large-calibre veins in limbs, abdomen and thorax and which normally contain 70 per cent of the circulating blood volume. Although thin walled with relatively little smooth muscle, sympathetic nerve stimulation contracts them, reducing their diameter and emptying the blood into the arterial side of the circulation.

A colloid solution is one in which the majority of solute particles has a molecular weight greater than 30,000. The term includes all plasma solutions, including human plasma protein fraction (HPPF), dextran, gelatin (e.g. Haemaccel) and hydroxyethyl starch. Blood is not usually included in this term.

Minute volume ventilation is the volume of air (or oxygen) which enters the patient’s lungs in 1 (each) minute, and is the product of respiratory rate and tidal volume.

Hyperventilation occurs when the patient is ‘overbreathing’ due to pain, anxiety or shock, such that the arterial carbon dioxide tension (PaCO₂) is lowered from the normal 40 mmHg (5.5 kPa).

Aspects of the pathophysiology of haemorrhage and shock

Low cardiac output is an early feature in shock, except for warm septic shock and neurogenic shock. Vasconstriction occurs in an attempt to maintain perfusion pressures to the vital organs, such as the brain, liver and kidneys, as well as the heart muscle itself. Vasoconstriction pushes more blood into the dynamic circulation whilst tachycardia helps to maintain a failing cardiac output. The minute ventilation rises 1.5—2 times and the respiratory rate 2—3 times maintaining oxygena-tion (except in cardiogenic shock with pulmonary oedema). The renal blood flow is reduced with consequent reduction in glomerular filtration and urine output. The renin—angiotensin mechanism is activated with further vasoconstriction and aldosterone release, causing salt and water retention. Release of antidiuretic hormone (ADH) decreases the volume and increases the concentration of urine. However, in early sepsis the patient, although hypovolaemic, may produce inappropriately large amounts of dilute urine (see below).

As cardiac output falls, the hypotension and tachycardia cause poor perfusion of the coronary arteries, and this, in conjunction with hypoxia, metabolic acidosis and the release of specific cardiac depressants (endotoxaemia or pancreatitis), causes yet further cardiac depression and pump failure.

The cells become starved of oxygen, and anaerobic metabolism leads to lactic acidosis. Eventually, the cell membranes cannot pump sodium out of the cells; sodium enters the cells and potassium leaks out. Thus, the serum potassium is elevated. Calcium, however, leaks into the cells lowering the serum calcium. Furthermore, the intracellular lysosomes break down and release powerful enzymes causing further damage—‘the sick cell syndrome’.

The platelets are activated in shock owing to the stagnation of blood in the capillaries. Blood sludging with red cell aggregation may progress to the formation of small clots and, indeed, to DIC. Several coagulation factors are consumed (platelets, fibrinogen, Factor V, Factor VIII, prothrombin), and troublesome bleeding may occur from needle puncture sites, wound edges and mucosal surfaces.

**Diagnosis**

The prognosis of a shocked patient is related to the duration and degree of the shocked state, therefore prompt diagnosis of the type of shock is essential. It should be remembered that a thready and irregular pulse can make the measurement of blood pressure inaccurate and misleading. Intra-arterial pressure monitoring should be used. The ECG should be monitored to detect any arrhythmias that may occur. A chest X-ray may reveal mediastinal trauma or cardiac tamponade.

**Central venous pressure**

The measurement of central venous pressure (CVP) and its response to a small fluid challenge (200 ml of crystalloid or colloid) may assist in distinguishing between cardiogenic shock and hypovolaemic shock, but it must be emphasised that, in the seriously ill patient, the CVP is not a reliable indicator of left ventricular function because of the wide disparity that can exist between the left and the right ventricular functions.

**Pulmonary capillary wedge pressure**

The pulmonary capillary wedge pressure (PCWP) is a better indicator of both circulating blood volume and left ventricular function. PCWP is obtained by a pulmonary artery flotation balloon catheter (Swan—Ganz). This can be used to differentiate between left and right ventricular failure, pulmonary embolus, septic shock and ruptured mitral valve, and can also be an accurate guide to therapy with fluids, inotropic agents and vasodilators. It may also be used to measure cardiac output by a thermodilution technique simply at the bedside.

**Measurement of pulmonary capillary wedge pressure**

This specialised procedure requires supervised training, practice, patience and experience in interpreting the values measured and waveforms indicated. Complications include arrhythmias, pulmonary infarction, pulmonary artery rupture, balloon rupture and catheter knotting, in addition to the complication from central venous cannulation. The catheter should not be left in situ for more than 72 hours; if further haemodynamic monitoring is required, a new catheter should be inserted.
Method. Strict aseptic central venous cannulation should be performed (e.g. via right internal jugular vein) and using the appropriate introducers, cannula and guidewire, the catheter, flushed and wiped with heparin saline, introduced into the right atrium. The balloon, inflated with 1.5 ml of air, should be advanced slowly via the right ventricle into the pulmonary artery, checked by x-ray and monitored by pressure tracing, which becomes characteristically flat when the balloon wedges in a small branch to give the capillary pressure (indicating left atrial pressure). When the balloon is deflated, the pulmonary artery pressure is obtained. The balloon must never be reinflated in the absence of a normal pulmonary artery waveform as this means that the tip alone is wedged and reinflation might therefore rupture the pulmonary artery. Withdrawal of 2—3 cm is mandatory until the waveform reappears and reinflation can be permitted.

The transducer should be placed at the midaxillary point (zero reference point); the normal PCWP is between 8 and 12 mmHg (10.5 and 15.5 cmH$_2$O), and normal pulmonary artery pressure is 25 mmHg systolic and 10 mmHg diastolic.

Clinical monitoring
In summary, patient monitoring in shock should include:

- pulse;
- blood pressure (recording systolic and diastolic pressure, the pulse pressure, using an intra-arterial line if necessary);
- heart rate and rhythm (cardioscope);
- respiratory rate and depth;
- CVP;
- PCWP in severe shock when the diagnosis is in doubt;
- urine output;
- serial blood gases and serum electrolyte measurements.

Method of central venous catheter insertion (the Seldinger technique)

A commercially available intravenous catheter, made to proper standards and of requisite length (20 cm), is passed into the right, or left, internal jugular vein. A line is drawn between the mastoid process and the sternoclavicular joint.

The carotid artery is palpated on this line and the internal jugular vein lies immediately lateral to it at the midpoint of this line. The head-down position is used to prevent air being sucked in (air embolus) and to distend the vein.

Using full aseptic technique, a 7cm needle, mounted on a syringe, is inserted caudally at 45 degree to the vertical into the internal jugular vein, the syringe removed and the soft end of the Seldinger wire passed through the needle into the vein. The needle is removed over the wire, and the catheter, placed over the wire, is passed into the vein. The wire is removed, and the catheter sutured into position and covered with a sterile, transparent, self-adherent dressing (e.g. Opsite 2000).

The catheter tip should be positioned in the superior vena cava or right atrium (confirmed radiologically at the first opportunity). Preceding every measurement, the patency of the catheter is confirmed by checking for a swinging movement of the saline column level in time with the patient’s respiration. The patency of the catheter may be confirmed by lowering the saline reservoir briefly to check the free reflux of blood in the connecting tubing. It must be emphasised that the use of this method requires supervised training, skill, practice and patience, also referring to the special manuals, because the complications can be serious, for example pneumothorax, haemothorax, brachial plexus and phrenic nerve damage, and carotid artery perforation. The catheter must be removed when not required for CVP measurement, and should not be kept in position as a matter of convenience for electrolyte or parenteral infusions (the latter entering the pleural cavity or the mediastinum can be lethal).

The alternative, subclavian (infraclavicular) approach can be used, but has a higher incidence of complications (e.g. pneumothorax or haemothorax). The catheter may be tunnelled subcutaneously to improve fixation for a long duration and to reduce the incidence of septic complications.

A third approach is the insertion of a longer (60 cm) catheter into the median basilic vein in the antecubital fossa; the tip often does not reach the superior vena cava or right atrium, and therefore may not give an accurate CVP measurement; however, it is useful for a central infusion of fluids or drugs.

Central venous pressure measurement

A saline manometer for measuring central venous pressure should be used. This has a sterile glass or plastic tube manometer against a centimeter scale; a spirit level is used to set zero (0) to the midaxillary point or the manubriosternal angle. A three-way stopcock allows isotonic saline: (1) to run into the vein from the reservoir; (2) to fill the manometer; and (3) to exclude the reservoir and to allow the fluid in the manometer to fall to the level of the CVP.

The catheter is connected to the saline manometer, and readings are taken of the saline level with the zero reference point at the midaxillary level. The normal is 5—8 cm; if the CVP is low, the venous return should be supplemented by intravenous infusion, but not if the pressure is high. Readings with the zero reference point at the midaxillary level should never exceed 10; if the readings are taken at the manubriosternal angle (angle of Louis), as they may have to be in a surgically draped patient, the range is 3—4 cm lower than midaxillary readings.

Treatment of shock

The management of all types of shock should be vigorous and dedicated. The objectives are to increase the cardiac output and to improve tissue perfusion, especially in the coronary, cerebral, renal and mesenteric vascular beds. The plan of action should be based on: (1) the primary problem — arrest of haemorrhage, draining pus, etc.; (2) improving ventricular filling by giving adequate fluid replacement, for example human albumin solution or fresh frozen plasma, in sepsis and burns; (3) improving myocardial contractility with inotropic agents — dopamine, dobutamine, adrenaline infusions; and (4) correcting acid-base disturbances, using molar sodium bicarbonate when the pH of arterial blood is
less than 7.2, and electrolyte abnormalities, especially potassium and calcium levels.

_in endotoxic shock_, once the haemodynamic status has been improved, full doses of the appropriate antibiotics are given to treat the causal infection. The circulation may be deluged with bacterial membrane debris which may intensify the endotoxic insult to the patient. This may be ameliorated by giving specific gammaglobulins to bind the endotoxin; the antibiotic polymixin E may also adsorb some of the endotoxins. This will reduce systemic inflammatory effects, diminish capillary leakage and improve organ perfusion.

**Diabetic patients** in endotoxic shock are in a precarious position. Careful monitoring and control of their nutrition and insulin requirements are necessary under the instruction of a clinician with a special interest in diabetes.

**Vasodilators** (hydralazine, phentolamine, glyceryl trinitrate infusions and chlorpromazine boluses) may be given provided the blood volume has been corrected and cardiac depression treated such that the systolic blood pressure is 90 mmHg or more. The indication is persistent vasoconstriction with oliguria, high CVP or PCWP and pulmonary oedema. Such therapy will improve cardiac output and tissue perfusion, and reduce the work done by the heart. _It must be emphasised that vasodilators can only be used with extreme caution and full haemodynamic monitoring_, because the sudden production of vasodilation in a hypovolaemic or dehydrated patient can be followed by a catastrophic fall in arterial blood pressure. These drugs should be given only in small intravenous doses or infusions and only until the extremities become warm and pink, and the veins are dilated and well filled.
Parenteral fluid therapy

The rational administration of parenteral fluids is one of the most significant advances in the care of acutely ill patients in the twentieth century. However, despite advances in the monitoring of cardiovascular variables, the questions of what? when? and how much? remain areas of enormous controversy.

In the 1930s Blalock suggested that it was the loss of blood rather than the release of evil humors that led to death after major trauma and recommended treatment by the administration of intravenous fluids. It was not until the 1940s and World War II that blood and plasma were widely used for the treatment of blood loss. Ironically, the same period highlighted the problems of inducing anaesthesia in vasoconstricted hypovolaemic casualties. When thiopentone was used as a sole intravenous anaesthetic agent at Pearl Harbour on 9 December 1941 there were numerous deaths as a result of vasodilatation and cardiovascular collapse. In the 1940s and 1950s descriptions of postoperative retention of salt and water as part of the metabolic response to surgery led to a widespread reluctance amongst surgeons and anaesthetists to administer crystalloids to their patients. The 1960s brought a swing back the other way when Shires and others demonstrated an increased survival in experimental animals that were bled and then reinfused blood plus additional crystalloid. The ensuing enthusiasm for the infusion of crystalloids led to the publication of Moore and Shires’ now famous article calling for ‘moderation’.

Colloids or crystalloids?

The colloid—crystalloid argument rages to this day: if one was clearly better than the other there would not be a controversy. The common link in the majority of articles on this subject is the final conclusion that it is dose not choice of fluid that is the real issue — and ‘the proper dose of any drug is enough’ (Dr J.H. Drysedale). Certainly if the aim is to restore the circulating blood volume this will be achieved with a smaller volume and thus more rapidly by using a colloid.

Diagnosing hypovolaemia

Hypovolaemia can occur as a consequence of a wide variety of pathological processes. The nature of the fluid lost should dictate the choice of replacement fluid. Clinical history, whether first or second hand, in combination with appropriate laboratory investigations, should be the most useful guides to a rational fluid regimen. However, hypovolaemia from whatever cause is an acute medical emergency. Any degree of hypovolaemia jeopardises oxygen transport and increases the risk of tissue hypoxia and the development of organ failure. The greater the degree and duration of hypovolaemia the greater the risk. Therefore, the initial treatment is to restore the circulating volume as quickly and effectively as possible.

Hypovolaemia may be divided into three categories: covert compensated hypovolaemia, overt compensated hypovolaemia and decompensated hypovolaemia.

Covert compensated hypovolaemia

This is the commonest yet least often diagnosed form of hypovolaemia. It refers to the presence of a reduced circulating blood volume without very obvious associated physical signs. Price found that healthy volunteers could have 10—15 per cent of their blood volume removed with no significant change in heart rate, blood pressure, cardiac output or blood flow to the splanchnic bed (gut, etc.). However, splanchnic blood volume was reduced by 40 per cent. The subjects in his study had essentially autotransfused and were maintaining the systemic circulating volume at the expense of the splanchnic circulating volume. This same process happens when we donate a unit of blood with no obvious adverse effects. Over the course of the next few hours we feel thirsty and therefore drink more, we also ingest salt and at the same time reduce urine output of salt and water. We make new proteins and blood cells, and very soon everything has returned to normal with no sequelae. In sick patients, however, many of the natural compensating mechanisms malfunction and this, coupled with the fact that fluid intake is being determined by a second party, namely the physician, makes hypovolaemia common.

Covert compensated hypovolaemia is extremely difficult to diagnose. In the conscious patient central nervous system (CNS) symptoms are the best guide. In the experiments performed above, all of the subjects developed CNS symptoms ranging from drowsiness and nausea to hiccoughs. Any thirsty patient should be assumed to be hypovolaemic until proven otherwise. Urinalysis showing an increased urinary osmolality and decreased sodium concentration is the most useful laboratory investigation.

Although covert compensated hypovolaemia is common and probably contributes significantly to morbidity, the majority of patients withstands the insult. If the hypovolaemia persists consequent end organ hypoperfusion may be present for many days before it manifests itself as organ dysfunction. By this time the patient is usually in a state of overt compensated hypovolaemia.

Overt compensated hypovolaemia

Here there is hypovolaemia to an extent that the reflex mechanisms required to maintain perfusion to vital organs are obvious on clinical examination but the blood pressure is maintained. As before, clinical history is essential. On examination the patient will demonstrate the manifestations of an increased sympathetic drive with tachycardia, a wide arterial pulse pressure, and typically increased systolic blood pressure and cool clammy skin, particularly at the hands and feet.

There may be other evidence of an inadequate cardiac output such as drowsiness, confusion and an increased respiratory rate. If the diagnosis is uncertain additional dynamic bedside tests can be performed such as gentle head-down bed tilting, leg raising or the administration of a bolus of intravenous fluid. If the diagnosis of hypovolaemia is correct then the increase in venous return may result in a reduction in heart rate, narrowing of pulse pressure, reduction in respiratory rate and overall improvement in well-being. If the diagnosis remains uncertain, or coincidental medical problems such as heart or lung disease make performing or interpreting such tests difficult, then more complex investigations may be required.

With the exception of electrolyte and blood gas analysis the majority of laboratory investigations is of little use in the acute phase. Arterial blood gas analysis can be performed rapidly; hypovolaemic patients are commonly hypoxaemic and may have a metabolic acidosis as a consequence of an inadequate cardiac output. Urinalysis, as described above, may support the diagnosis of hypovolaemia but no single test is diagnostic. Rapid determinations of total blood volume are not yet available.

Except for extreme cases the clinical interpretation of CVP by examination of the jugular venous waveform is unreliable and has no place in the management of hypovolaemic patients. If there is any doubt about the diagnosis, particularly in patients with cardiorespiratory disease, the patient needs a CVP catheter. The insertion and, indeed, interpretation of the information available from central venous catheters carries a significant morbidity and mortality so they should only be inserted and managed by experienced clinicians. For a more detailed account of central venous catheterisation readers are referred to Rosen et al. As a general rule the right internal jugular approach is favoured. The subclavian vein may be particularly difficult to locate in the hypovolaemic patient and the risk of arterial cannulation, haemorrhage and
pneumothorax is then greatly increased. If during insertion steep head down tilt produces no adverse effects and it is difficult to visualise or palpate neck veins, the judicious administration of at least 500 ml of colloid by a peripheral route before proceeding is sensible and safe. In the unlikely event that fluid administration produces a deleterious effect the infusion can be stopped easily, the head-down tilt corrected and the patient sat up.

In cases of ventricular dysfunction and/or severe pulmonary disease there will be a misleading discrepancy between right and left atrial filling pressures. If the information obtained from the CVP catheter is confusing, it may be necessary to insert a pulmonary artery flotation (Swan-Ganz) catheter. The pulmonary artery occlusion pressure (PAOP) provides an index of left ventricular filling pressure and may help to clarify the situation. It is important to realise that right atrial pressure and PAOP are influenced not only by the circulating volume but also by the degree to which the circulation is constricted, the compliance of the right and left heart, as well as pain, agitation, etc., causing increases in sympathetic tone. Low values are sensitive indicators of hypovolaemia, but high values do not necessarily mean the patient is well filled.

Dynamic tests using fluid challenges give much more information and should always be tried in patients with evidence of an inadequate circulation. The administration of 200—500 ml of colloid over 5—10 minutes and comparison of the CVP or stroke volume (not the cardiac output) before the challenge and 5—10 minutes after the infusion has finished is the most useful guide. A sustained rise in CVP or PAOP of 3 mmHg and failure of the stroke volume to increase suggest the circulation is well filled.

**Decompensated hypovolaemia**

This is what many people refer to as shock. The degree of hypovolaemia is such that reflex redistribution of blood flow is insufficient to compensate and vital organs are no longer adequately perfused. The mean arterial blood pressure falls and may be difficult to record as peripheral pulses are often palpable. The blood supply to the heart and lungs is compromised, which further reduces cardiac output, causes ventilation/perfusion (V/Q) mismatching and compounds the problem. Tachycardia changes to bradycardia as myocardial oxygenation becomes critical and the conscious level is severely obtunded. If untreated this clinical state rapidly progresses to total circulatory arrest. No special equipment or investigations are needed to make the diagnosis of decompensated hypovolaemia and to start aggressive volume replacement therapy. Misdiagnosis and inappropriate over transfusion is an overrated problem. Delay in the treatment of hypovolaemic shock greatly reduces the chances of successful resuscitation. Most causes of hypovolaemic shock carry a far better prognosis than any condition that presents in a similar fashion but would be made worse by a fluid challenge.

The consequences of hypovolaemia

Decompensated hypovolaemia will result in endorgan damage and death if it is not treated rapidly and completely. Probably a far more common and insidious source of morbidity and mortality is the compensated hypovolaemias. As described above, a small reduction in circulating blood volume rapidly results in a far more significant reduction in splanchnic blood volume and in particular the supply to the innermost layer of the gut lumen, the mucosa. It is becoming increasingly clear that hyperperfusion of the gut mucosa is of fundamental importance in the pathogenesis of multiple organ dysfunction (see below).

Therefore, hypovolaemia is a potential killer in any disease process. The manifestations of persistent covert compensated hypovolaemia may not be seen for many days. Once a patient has overt hypovolaemia the chances of successful treatment are already significantly reduced with the exception of simple acute haemorrhage. Most patients are referred to intensive care units once they have progressed to decompensated shock with established organ failure. By that stage it is probably too late to make a significant difference to outcome. The early recognition and treatment of hypovolaemia is essential in any disease process.

**Treatment of hypovolaemia**

Very few patients benefit from fluid restriction; if there is evidence of hypovolaemia it should be treated. Inotropes should be used only when the circulating volume has been corrected.

Occult hypovolaemia is very difficult to diagnose. Therefore, in conscious patients who can drink the most rational approach is to be generous with fluids. Access is important, as is strength and volition. The patient with a full water jug and a raging thirst is commonplace. The aim should be an asymptomatic patient (i.e. no thirst) with good urine volumes (in excess of 0.5 ml/kg/hour) and normal urinalysis. The overriding principle is that fluid overload is easy to treat, whereas fully established organ failure is incurable.

Overt hypovolaemia should be considered a medical emergency and treatment is required urgently. The intravascular space must be resuscitated in minutes to hours not hours to days, as is currently common practice. Restoration of total body water and electrolytes will he slower. Treatment should be started following a presumptive diagnosis of hypovolaemia; by all means send laboratory investigations but do not wait for the results before starting treatment.

High-flow oxygen therapy should be given to all hypovolaemic patients until arterial blood gas analysis confirms normoxia. A pulse oximeter is useful if available. Venous access should be secured with short, large-bore cannulae, allowing large volumes to be infused rapidly. Ideally a 14G cannula in an arm vein should be used. These allow flow rates twice those of a 16G cannula. CVP catheters are of very limited use in the early phase of resuscitation, and are difficult and hence more dangerous to place. They should only be used if the diagnosis of hypovolaemia is in doubt or if no other access is available.

The initial choice of fluid in overt hypovolaemia should be a colloid for the reasons stated above. The need for blood (see below) should not delay initial resuscitation. Cardiac arrest due to a low haemoglobin concentration is very unusual; cardiac arrest due to hypovolaemia is relatively common. Resuscitation should he a continuous process with the doctor at the bedside re-evaluating the patient. Failure of a fluid challenge to secure improvement requires the use of more invasive monitoring. Each fluid challenge must be seen to produce a definite improvement. Precharted fluid regimens and remote management cost lives.

Just as patients compensate for volume loss in the early stages of hypovolaemia, so an apparently resuscitated patient may still have a significant volume deficit. The aim for immediate resuscitation should be normal measures of pulse, blood pressure and CVP, urine output > 0.5 ml/kg/hour with normal urinary osmolality and sodium concentration. Any metabolic acidosis should be seen to be correcting. Thereafter, one must try to maintain normovolaemia. This is a continuous process. Critically ill patients may have capillary leak and will therefore have a continuing colloid requirement. Gelatins, being small molecules, are poorly retained and can be replaced by hydroxyethyl starch, plasma or blood at this stage. In sepsis this requirement may be very large (see below).

The importance of blood in immediate resuscitation, the threshold at which one should transfuse urgently (i.e. con-sider using group compatible, uncross-matched blood or even Group O blood) and even the target haemoglobin level are controversial. Resuscitation should not be delayed whilst waiting for blood to be grouped; if acute anaemia is secondary to the bleeding resuscitation should be with Group 0 blood or group-compatible blood as it becomes available. Otherwise colloid should be used initially and cross-matched blood and relevant blood
products should be used when they are ready. Packed cells are not colloid and have little plasma expanding effect; transfusions with large amounts of packed cells will require supplementation with colloid. The age of the blood is important (old blood is acidic, with decreased oxygen-carrying capacity and poor red cell deformability) —use the youngest possible blood and whole blood if it is available.

**Hypovolaemia and the surgical patient**

Hypovolaemia is extremely common among patients undergoing surgery. It remains standard practice in the UK to deny patients food or drink for a minimum of 6 hours prior to elective surgery in an attempt to reduce the risk of pulmonary acid aspiration syndrome. It is not uncommon for this to extend to 10 or even 20 hours due to unforeseen delays. Preoperative fluid restriction is currently a matter of debate. Indeed, there is evidence suggesting that the administration of oral fluids to patients until 2 hours prior to elective surgery has produced a more favourable effect on gastric contents than total starvation. Yet no attempt is routinely made to maintain normal hydration in preparation for surgery, despite numerous previous studies demonstrating the benefits of fluid administration for even the most minor surgical procedures. Recently a study on fit young patients having elective laparoscopic sterilisation under general anaesthesia demonstrated a reduced morbidity by the administration of crystalloid during the operation. It is commonly taught that as part of the stress response to surgery patients have increased levels of ADH and aldosterone postoperatively and thus retain salt and water. As a result of this the overzealous administration of intravenous fluids is feared. Whilst it is probably true that ADH levels do rise in all postoperative patients, the presence of hypovolaemia per se may be responsible for much of the increase. A reduction in urine output in the first 24 hours after surgery may be acceptable, but a fall to oliguric levels (<0.5 ml/kg/hour) is not. Using the gastric tonometer, reduced splanchnic perfusion as a consequence of hypovolaemia has been demonstrated to be common during major surgery and associated with the development of postoperative organ failure. It is difficult to find any objective evidence to support the hypothesis that peripheral oedema or the accumulation of extravascular lung water, as opposed to pulmonary oedema due to left ventricular failure, has any significant adverse effects. On the contrary, the evidence supporting the prophylactic administration of intravenous fluids to patients having major surgery is impressive.

**Hypovolaemia and cardiogenic shock**

Conventional management of the patient with acute pulmonary oedema is still all too often based on diuretics. Unlike congestive cardiac failure, the usual problem in acute left ventricular failure is not an excess of total body salt and water but an acute redistribution of a normal quantity. This leads to an effectively hypovolaemic patient, particularly if they have been treated enthusiastically with diuretics. The most appropriate treatment is to reduce pre- and after-load with infused vasodilators such as GTN to encourage redistribution of fluid in a more normal fashion and to consider using ionotropes and even judicious colloid challenges guided by a pulmonary artery catheter if vasodilators do not produce a rapid improvement. This is particularly important in right ventricular infarction, where the effect of hypovolaemia and poor right ventricular function is to underfill the left ventricle which in itself is usually underperforming.

The treatment of patients with congestive cardiac failure is more difficult. The basic principle should remain the maintenance of an adequate circulation with the use of vasodilators to improve overall haemodynamics supplemented with diuretics as necessary. The fact that so many patients tolerate diuretic-based regimens so well reflects the inherent robustness of the average human being!
Therapeutic interventions aimed at preventing organ failure

The widespread use of blood and plasma for the first time during World War II resulted in the recognition of a new phenomenon — ‘irreversible shock’. It became apparent that numerous hypovolaemic casualties could have their vital signs restored with the administration of intravenous blood and plasma only to develop ‘secondary shock’, often days after the original insult, which rapidly became resistant to any form of treatment. Fifty years later the main thing that seems to have changed is the terminology used to identify the same condition. The terms multiple organ failure syndrome (MOFS), multiple systems organ failure (MSOF) and, most recently, multiple organ dysfunction syndrome (MODS) have all been used to describe ‘irreversible shock’ and organ failure. Rather like the elephant, it seems that we have difficulty describing it but we all know one when we see one.

In 1943 Blalock summarised the causes of irreversible shock seen in the Armed Forces as:

(1) haemorrhage uncomplicated by gross trauma; (2) burns; (3) trauma to large masses of muscle; and (4) the re-establishment of circulation in a damaged ischaemic area.

In the same dissertation he suggests that:

the initial phases (of shock) are certainly associated with and probably dependent upon a reduction in the volume of effective circulating blood ... Investigations have indicated that at some time in the development of irreversible shock there appear effects that may be ascribed either to toxic substances elaborated in areas of tissue damage or to a derangement of metabolism produced by a circulation which, either locally or generally, has been compromised over a long time. The currently proposed theories of the pathogenesis of organ failure differ mainly in the fine detail, in particular many of the ‘toxic substances’ or mediators have been iden-tified. Currently, we recognise and have tried to define more clearly the clinical conditions of the systemic inflammatory response syndrome (SIRS) and MODS.

It is postulated that, as a result of an insult, uncontrolled activation of inflammatory pathways may result in tissue destruction and subsequent organ failure. Inflammation is an essential component of the healing process. From a wide variety of stimuli (e.g. trauma, burns, infection) the final common pathway results in vasodilation, increased endothelial permeability, thrombosis, and leucocyte migration and activation. The systemic inflammatory response syndrome is the latest term proposed to describe a failure of localisation. MODS, due to tissue damage in organs distant to the site of the original injury, is the clinical manifestation of SIRS. Irrespective of the initiating stimulus (e.g. surgery, bacterial infection, pancreatitis), the morphology of necropsy specimens in both animal models and patients is remarkably constant. There is microvascular occlusion, endothelial destruction, interstitial oedema, leukostasis and thrombosis. Therefore, there would seem to be a dichotomy. Inflammation is essential for successful recovery from infection or injury, yet an excessive and uncontrolled inflammatory response can result in organ dysfunction or failure. One hypothesis is that there is a level of stimulation that, once exceeded, leads to uncontrolled activation of inflammatory pathways. There would appear to be a critical balance between activation and modulation (Fig 4.1).

Fully established multiple organ failure is almost always fatal. A greater understanding of the pathogenesis of MODS has provided the basis for treatment regimens currently being used clinically or tested experimentally for the prevention of organ damage. (Fig 4.2) See above) summarises the various stages that are thought to lead to the development of MODS and therefore are targets for intervention. The rationale behind the apparent success, or failure, of a cross-section of these regimens is discussed below.

The primary insult

As always, the earliest treatment is most effective and prevention is better than cure. If we assume that the primary insult is unavoidable, has been correctly diagnosed and treated, then all subsequent forms of treatment are aimed at limiting the degree of tissue damage.

Compounding insults

Avoiding tissue hypoxia — simple resuscitation with intravenous fluids

The commonest compounding insult is probably tissue hypoxia as a result of inadequate basic resuscitation. Treating the primary insult is almost a waste of time without restoration of an adequate circulating blood volume. The majority of patients will respond to the administration of intravenous fluids and supplementary oxygen via a face mask. There is little doubt that if the aim is to restore the intravascular volume then this can be done most efficiently using a colloid. As one of the central abnormalities in SIRS is thought to be endothelial leak, one might hope that a colloid with a larger molecular weight than albumin might be more effectively retained within the vascular compartment and therefore more likely to maintain microvascular flow and organ perfusion. However, there are no human data that demon-strate that any particular solution (colloid or crystalloid) is better than another in terms of outcome, even though there is approximately a 100-fold price difference between the cheapest and most expensive alternatives. There are, however, good data to suggest that to avoid tissue hypoperfusion you need to give enough of whatever you choose and you need to give it promptly with the appropriate level of monitoring. For rapid restoration of haemodynamic function a colloid does the job more efficiently than a crystalloid. Albumin has no demonstrable advantages over cheaper alternatives such as the modified gelatins.

Treating tissue hypoxia — the global approach

The rationale here is that patients with SIRS are thought to have an occult tissue oxygen debt in spite of apparently normal global cardiovascular variables such as blood pressure and urine output, and that by increasing total body oxygen delivery, commonly by the administration of ionotropes, this debt will be repaid and hypoxic tissue damage will be avoided. In patients undergoing high-risk major surgery and critically ill patients on the intensive therapy unit (ITU) there appears to be a positive correlation between a high oxygen delivery and survival. In patients undergoing high-risk major surgery prophylactically increasing cardiac output and oxygen delivery to predetermined supranormal levels has been associated with a decrease in subsequent organ dysfunc-tion and mortality. However, the same principles when applied to established critically ill patients on the ITU has met with very limited success. Once a critical degree of tissue hypoperfusion is established then the situation is apparently irreversible.

There is an ever increasing list of designer vasoactive drugs (e.g. dobutamine, dopexamine, enoximone, piroximone, milrinone, amrinone) that can be used to manipulate global haemodynamics in sepsis. They have attractive hypothetical advantages in terms of their effects on global oxygen flow variables that can be confirmed in animal models and humans. However, there is no evidence to suggest that they are any more effective than the cheaper alternatives such as adrenaline and noradrenaline in terms of outcome.

Treating tissue hypoxia — the regional approach

As a result of the enormous amounts of research that have focused on global oxygen delivery in SIRS and MODS, it has become evident that regional perfusion may be compromised in patients who have apparently adequate global oxygen delivery and consumption. Probably the most
commonly monitored end organ in the ITU has been the kidney, as urine output is easy to measure and relates crudely to function. The production of 0.5 ml/kg/hour of urine is accepted as an indicator of adequate regional perfusion. Unfortunately, although anuria carries a very poor prognosis the converse is not true. Many reno protective agents have failed to modify outcome in humans. In animal models the use of mannitol, fruseamide and low-dose renal dopamine infusions has been shown to protect the kidney, but this has not been demonstrated in the clinical environment. This may be because the infusion of a renal dose of dopamine, for example, may well produce a diuresis but cannot be expected to protect the kidney from coexisting hypoxia and hypovolaemia unless it is used as just a part of a total patient management regimen. Many believe that such agents used in isolation do more harm than good as they maintain an adequate urine output in the face of tissue hyperperfusion and also increase myocardial work.

More recently much attention has focused on the splanchnic region. In particular, the measurement of gastrointestinal luminal PCO2, using a gastric or sigmoid tonometer, and calculation of gastrointestinal mucosal pH have become fashionable as indices of splanchnic perfusion. Splanchnic perfusion and, in particular, that to the gut mucosa is compromised early and preferentially in shocked states. There is also a hypothesis that gut mucosal hyperperfusion may result in leakage of gut luminal contents into the bloodstream and that this may be a proinflammatory factor tipping the balance in favour of SIRS and MODS. In support of this hypothesis gut mucosal hyperperfusion, as determined by the presence of a murad acidosis measured with a tonometer, has been shown to be the most sensitive predictor of MODS and death in patients undergoing major surgery and on the ITU. Certain therapeutic manoeuvres have been demonstrated to improve gut mucosal perfusion both in animal models and in humans. These include the administration of intravenous fluids, dobutamine, dopexamine and donor blood.

Avoiding nosocomial infections.

Once a patient has some degree of organ dysfunction on an ITU they are thought to be at greater risk from nosocomial infection. In the prevention of secondary infection good hand washing and the avoidance of cross-infection carried by staff probably have the greatest impact. Assuming that such cross-infection is avoided then the patient is his or her own enemy and bacteria carried in the gastrointestinal tract provide the commonest source of secondary infection. Nosocomial pneumonia is thought to occur commonly as a result of spillage from the upper gastrointestinal tract into the lungs. It has been demonstrated that the administration of H2-receptor antagonists with the intention of reducing gastric acidity and avoiding stress ulceration also encouraged the growth of bacteria in the stomach and an increased incidence of nosocomial pneumonias. The use of sucralfate as stress ulcer prophylaxis has the advantage of also being bacteriostatic and has been associated with a decreased incidence of nosocomial pneumonia. Another approach to the problem of secondary infection from the gastrointestinal tract is selective decontamination of the digestive tract (SDD) with the aim of reducing the incidence of secondary infection, from both overspill and translocation. SDD involves the use of a variety of topical and intravenous anti-microbial agents with the aim of removing the pathogenic gut flora but maintaining the commensal anaerobes. Numerous studies have demonstrated that SDD and/or modifying the gastric intraluminal pH reduces the incidence of nosocomial pneumonia. However, reducing the incidence of nosocomial pneumonias has had a far lesser effect on outcome than one might anticipate for a true cause and effect relationship.

Treating endotoxaemia

Endotoxin is a recognised potent activator of various cellular and humoral pathways involved in the generalised inflammatory response. Endotoxins are mostly comprised of lipopolysaccharide, and most of their biological activity resides in the lipopolysaccharide section of the core region of lipopoly-saccharide is nearly identical for most strains of Gram-nega-tive bacterial endotoxins. Supranormal levels of naturally occurring endotoxin core antibodies have been associated with a reduction in organ failure in patients following high-risk surgery and on the ITU. However, in two large multicentre trials of patients with presumed Gram-negative infection, the results of giving donor antibodies against the core region of endotoxin have been inconclusive. Active immunisation would be an attractive alternative for patients scheduled for major surgery, and evidence from animal experiments has been encouraging. However, there is no currently available anti endotoxin vaccine. Other potential anti endotoxin strategies undergoing human testing include bactericidal/permeability-increasing protein (BPI), endo-toxin-neutralising protein and dextran—polymixin B conjugate, all of which have the ability to protect animals from endotoxin-mediated toxicity.

Systemic inflammatory response syndrome

The organo-protective therapeutic regimens cited above seem to work if used prophylactically, as is the case in major surgery. However, the results of adopting similar regimens in established MODS are rather disappointing. This would suggest that once a systemic inflammatory response is unresponsive to cardiovascular manipulations and antimicrobials then if the progression to MODS is to be avoided organ protection must come from a different line of attack. An increased understanding of the host-derived mediators of the tissue destruction seen in MODS has opened up a whole new field of therapeutic agents directed against them. It is hoped that specific manipulation of key mediators will at least halt the tissue damage in its tracks and hopefully be curative.

Cytokines

Protein cytokines play an important part in the mobilisation, localisation and subsequent activity of leucocytes in the inflammatory reaction. Tumour necrosis factor alpha (TNF-a) and the interleukins (IL) have emerged as prime targets for experimental manipulation. In animal models of septic shock, treatment with monoclonal antibodies to TNF-alpha and various interleukins (e.g. IL-1) have improved survival. There are ongoing trials of inhibitors of both TNF-alpha and IL in human sepsis. Unfortunately, the early reports have been inconclusive.

Decreasing cytokine synthesis and secretion

Corticosteroids reduce TNF-alpha mRNA translation in response to a stimulus and thus reduce secretion. Numerous studies have demonstrated the protective effects of corticosteroids in animal models of septic and haemorrhagic shock. The use of low-dose dexamethasone has been shown to improve outcome in paediatric patients with meningitis. From a purely hypothetical viewpoint, steroids should be the answer to the treatment of SIRS. However, two large multicentre, randomised trials of high dose dexamethasone used in the treatment of septic shock failed to demonstrate any improvement in survival.

Nitric oxide

In 1987 it was reported that the endothelium-derived relaxant factor was identical to the free radical nitric oxide (NO). NO is synthesised from l-arginine by a constitutive enzyme present in the endothelium, which has a physiological role in the control of blood pressure, and by an inducible nitric oxide synthase, which is expressed in vessel walls and phagocytic cells in response to endotoxin or cytokines. NO has a myriad of actions but is predominantly a vasodilator and can modify the neutrophil—platelet interactions that may result in the microvascular occlusion
seen in MODS. These effects create a therapeutic dilemma. Should you give NO in an attempt to restore microvascular flow or block its effects to restore the blood pressure in septic shock? In patients with severe acute respiratory distress syndrome inhaled NO has been demonstrated to reduce pulmonary artery pressure and improve pulmonary oxygenation without affecting systemic vascular resistance. However, it has also been demonstrated that blocking the production of NO from its precursor L-arginine is possible by the administration of arginine analogues such as NG-monomethyl-L-arginine (L-NMMA). In animal studies the administration of NO antagonists has been shown to restore the vascular response to catecholamines and improve survival.

**Arachidonic acid metabolites**

There is a multitude of animal and human evidence to suggest that metabolites of arachidonic acid play key roles in the pathogenesis of MODS, both protective (e.g. prostaglandin E₂) and deleterious ones (e.g. leukotrienes and thromboxane). Cyclo oxygenase inhibitors such as ibuprofen or indomethacin, which are nonsteroidal anti-inflammatory drugs, have been shown to reduce tissue damage and improve survival in animal models of sepsis.

**Neutrophils**

Degranulating neutrophils as part of a systemic inflammatory response are said to cause microvascular injury and promote organ dysfunction by the release of destructive enzymes and the generation of oxygen free radicals. Free radical scavengers such as superoxide dismutase, allopurinol and even vitamin C are universally successful in reducing the tissue damage seen in septic and haemorrhagic shock models. Provisional reports from at least two human studies claim success from free radical scavenging.

**Contact, coagulation and complement activation**

A common clinical feature of SIRS is a coagulopathy. Histologically the microvascular abnormality seen in MODS is not unlike clot. This has led to the assumption that there is a disturbance of the balance between procoagulant and anticoagulant pathways in SIRS that can manifest itself most vividly in the disseminated intravascular coagulation seen in meningococcal meningitis. There are preliminary results suggesting that the administration of clinical concentrates of inhibitors of the contact system such as antithrombin III and C1-esterase inhibitor may modify the outcome in established SIRS.

**Endogenous anti-inflammatory agents**

It is now recognised that most proinflammatory acute-phase reactants are balanced by the production of endogenous anti-inflammatory acute-phase reactants. For example, antagonists to soluble IL-1 and TNF-alpha are produced by hepatocytes and released into the circulation, thereby reducing the inflammatory response. The anti-inflammatory cytokine IL-10 is a potent macrophage-deactivating factor, and injection of recombinant IL-10 has been shown to protect mice from endotoxic shock. IL-10 is thought to regulate the effects of other cytokines (e.g. TNF-alpha), rather than block them completely, and therefore has the potential for maintaining optimal balance in the inflammatory system.

**Multiple organ dysfunction syndrome**

There are no animal or human data to suggest that fully established MODS is treatable. This does not mean that all patients who have MODS die. However, the small percentage who survive have probably done so because supportive care has given them a chance to get better.

**Conclusion**

Prevention of MODS by the prompt diagnosis and treatment of the primary insult coupled with cardiovascular resuscitation and supportive care has an extremely high success rate in patients who have some hope of long-term survival. However, once the same group of patients has established organ failure the outlook is extremely gloomy.

Nutrition

Malnutrition

In surgical practice malnutrition is common, being present before, or occurring after, operations in about 50 per cent of patients, possibly more in some parts of the world.

**Preoperative malnutrition** may be due to starvation or to a failure of digestion. Starvation is caused by:

- difficulty in obtaining food (poverty);
- difficulty in swallowing food (dysphagia);
- difficulty in retaining swallowed food (vomiting);
- self-neglect, e.g. in the elderly and in alcoholics.

Failure of proper digestion may, for example, be due to pancreatic or biliary disease (carcinoma or jaundice due to stones), and duodenal and jejunal conditions (fistula or blind-loop syndrome).

**Postoperative (post-traumatic) malnutrition** is, in most cases, of a transient nature consequent upon a short period of starvation and the stress reaction to trauma. Recovery from any nitrogen deficit (Table 5.1) due to protein catabolism will follow on return to normal feeding. Any delay in return to a normal diet, such as may be imposed by the dictates of the operation (oesophagectomy), or a complication (paralytic ileus from peritonitis), means that severe malnourishment is likely to occur.

**Hypercatabolic state.** Severe sepsis (subphrenic abscess), severe trauma (burns) and other severe disturbances of major viscera (pancreatitis) are accompanied by an accelerated and profound breakdown of tissue proteins.

In starvation, the metabolic changes are directed to minimising tissue loss and, in some circumstances, humans can survive for about 120 days. Glucose reserves are available only for 24 hours and thereafter are derived principally from muscle, so that catabolism begins almost immediately after food deprivation. In the first 72 hours, there is a rapid weight loss due to loss of sodium and water, then the resting metabolic expenditure falls and daily nitrogen losses over 2 weeks fall from about 10 g to 3—4 g. Progressively fat provides most of the energy requirements yielding 38 kJ/g while carbohydrate derived by gluconeogenesis in the liver from amino acids is utilised by the brain, adrenal glands and red cells — all obligatory glucose users. After about 21 days, the central nervous system adapts to using ketones derived from fat. The gluconeogenesis and ketosis of starvation may be easily inhibited by glucose intake.

Protein in lean tissue is constantly turned over and renewed. Normally the processes of protein synthesis and breakdown act in equal and opposite directions to keep the muscle mass in an adult constant — about 40 per cent of total body weight. It seems likely that under normal circumstances the provision of an adequate nutrient supply of amino acids allows protein synthesis to exceed breakdown during and after meals, whereas between meals the opposite pertains, thus maintaining a balance over a 24-hour period. Insulin and amino acids appear to stimulate muscle protein synthesis and insulin inhibits protein breakdown. Lean tissue may be lost by a variety of methods. In starvation, chronic illness and immobilisation, muscle protein synthesis is depressed below the level of protein breakdown. Such a pattern is found in patients suffering from heart failure, carcinoma, emphysema, hypothyroidism and cirrhosis, whereas a patient confined to bed will suffer an exacerbation of the process causing muscle wasting.

In sepsis, inflammation, trauma and burns, the muscle wasting results from a massive loss of amino acids from muscle tissue with depressed muscle protein synthesis and enhanced muscle breakdown. The mechanism is uncertain but injury and sepsis trigger a co-ordinated series of inflammatory and immune responses and the stimulation of macrophages to produce cytokines such as tumour necrosis factor and interleukin-1. These cytokines are associated with proteolysis, particularly the breakdown of myofibrillar proteins but only in the presence of elevated corticosteroid concentrations.

**After injury or surgical operation**

There is an increased oxygen and calorie consumption and a negative nitrogen balance (Cuthbertson). The increase in resting metabolic expenditure ranges from minimal after uncomplicated surgery to 30 per cent with multiple fractures, 45 per cent in peritonitis and up to 100 per cent in burns. An increase in metabolic rate and protein catabolism of more than 25 per cent is regarded as a hypercatabolic state.

The endocrine profile, activated by fear, apprehension and nervous stimuli from damaged tissues, is altered after stress with an increase in secretion of most hormones, in turn resulting in changes in substrate handling by the body.

Glycogen breakdown in muscle and liver is accelerated principally by adrenaline and glucagon, leading to increased blood glucose levels, while increased cortisol and glucagon induces gluconeogenesis from amino acids. Lipolysis — fat breakdown — is increased by growth hormone, glucagon and noradrenaline. Thus control of glucose levels is impaired and, together with depressed peripheral clearance, results in the diabetes of injury.

The stimulated protein breakdown in the postoperative period is associated with a change in synthesis rate in the body cell mass, and this results in a negative nitrogen balance indicating loss of protein derived from muscle and viscera. Larger losses are seen in muscular athletic men and the smallest losses in wasted patients. Epidural anaesthesia inhibits the normal postoperative increases in cortisol, adrenaline, aldosterone and growth hormone, and so may reduce the negative nitrogen balance. Nitrogen balance may be improved during enteral or parenteral feeding if the patient can be mobilised.

Studies following patients for up to 1 year following uncomplicated surgery suggest that the maximum weight loss occurs after 2 weeks and that normal body composition is restored after 6 months.

A particularly unpleasant effect of surgery is the period of mental and physical tiredness that follows it. It is not a particular problem in patients who feel well before surgery, but in those with preoperative tiredness, it is worst postoperatively at the end of the first week; at 4 weeks it is similar to the initial preoperative level, and it usually disappears after 3 months. Voluntary muscle functions deteriorate in a similar pattern to fatigue but postoperative nutrition, which restores muscle mass, does not influence postoperative fatigue, leading to speculation that the...
symptoms of fatigue have both a physiological and psychological basis.

Uncomplicated, minimally invasive surgery is believed to be associated with minimal postoperative fatigue and a shortened convalescence. Initial studies suggest that the neuroendocrine response is similar to a comparable open operation, and further studies are required to resolve this paradox.

Severe sepsis is characterised by an increased rate of whole body protein catabolism, and when prolonged the depletion of visceral protein results in multiple organ failure. In patients with sepsis, both protein synthesis and catabolism are increased with a much greater increase in catabolism resulting in protein loss. The increase in protein synthesis may be the result of increased hepatic protein synthesis of acute phase proteins. Intermediate metabolism in sepsis is directed at increasing substrate availability by lipolysis, glycogenolysis, protein catabolism and hepatic glucose production. Studies in septic patients have provided evidence that the myofibrillar proteins, retin and myosin, are particularly catabolised in sepsis. The principal mediators are tumour necrosis factor, interleukin-1 and glucocorticoids.

Fat oxidation increases with sepsis and is the principal source of energy in the patient with sepsis, while hepatic glucose production occurs despite hyperglycaemia and a low respiratory quotient. The increased substrate turnover is accompanied by an increase in resting energy expenditure.

The effects of malnutrition include poor wound healing manifesting as wound dehiscence (Chapter 3) and leaking anastomoses of bowel, delayed callus formation, disordered coagulation, reduced enzyme synthesis, impaired oxidative metabolism of drugs by the liver, immunological depression with increasing susceptibility to infection, decreased tolerance to radiotherapy and cytotoxic chemotherapy, all with the severe mental apathy and physical exhaustion of the patient.

Some clinical indications for nutritional support are:
- preoperative nutritional depletion;
- postoperative complications:
  - ileus more than 4 days,
  - sepsis,
  - fistula formation;
- intestinal fistula;
- massive bowel resection;
- management of:
  - pancreatitis,
  - malabsorption syndromes,
  - ulcerative colitis,
  - radiation enteritis,
  - pyloric stenosis;
- anorexia nervosa;
- intractable vomiting;
- maxillofacial trauma;
- traumatic coma;
- multiple trauma;
- burns;
- malignant disease;
- renal failure;
- liver disease;
- cardiac valve disease.

Assessment and management

It is essential for the clinician to be aware of the need to assess the state of nutrition of a patient and, if malnutrition is present or threatens, to consider the nutritional requirements, and then to use methods of sustaining normality or rectifying any deficiency. Between 1 and 2 per cent of elderly patients have serious subnutrition as a consequence of inadequate dietary intake.

Assessment

A malnourished patient has a characteristic appearance, lean and hungry in most cases of starvation, lean and apathetic in post-traumatic depletion, with a superimposed hectic flush around sunken cheeks and pinched nose in a hypercatabolic state. The clinician, when placing a comforting hand on the patient’s shoulder, discerns the bony scapula bereft of almost all its muscle. However, these clinical observations only detect gross malnutrition and therefore measurement of the nutritional status is essential (Goode). The following parameters are included.

1. **Body weight.** Careful weighing on a bed weighing machine is the obvious way of detecting the progress or otherwise of the patient. The desirable weight of the patient can be checked by reference to the appropriate tables, or by applying the body mass index (BMI) = weight (kg)/height² (in). A woman should have an index of 20, 21 or 23, and a man 20.5, 22 or 23.5 according to size of frame (small, medium or large).

2. **Upper arm circumference.** Feeding is indicated if the circumference is less than 23 cm in females and 25 cm in males.

3. **Triceps skin fold thickness.** Using a skin fold caliper, the minimum is 13 mm in females and 10 mm in males.

4. **Serum albumin** should not be less than 35 g/litre.

5. **Lymphocyte count.** Less than 1500/mm³ indicates an impaired cellular defence mechanism.

6. **Candida skin test.** A negative reaction also means defective cell-mediated immunity.

7. **Nitrogen balance studies.** The total nitrogen intake is compared with the loss from all sources, such as urine, fistula drainage and nasogastric aspirate (1 litre = 1 g nitrogen). A greater loss than intake indicates a negative balance and tissue breakdown. A positive balance means anabolism—tissue synthesis.

Other measurements include those determining the rate of muscle breakdown, such as urinary creatinine excretion, or 3-methylhistidine excretion. Body potassium and nitrogen are used to assess the absolute size of the body cell mass. [¹⁴C] Leucine incorporation is a measure of
the synthesis rate, while serum transferrin is used as a measure of visceral protein synthesis (needs to be more than 1.5 g/litre).

**Nutritional requirements**

These include carbohydrate, fat, protein, vitamins, minerals and trace elements (Table 5.2).

Energy is provided by carbohydrate and fat. A healthy adult at rest requires 6300—8400 nonprotein kilojoules per day for energy (1500—2000 calories). Carbohydrate provides 16.8 kJ/g (4.1 kcal/g) and fat 37.8 kJ/g (9.1 kcal/g). The number of nonprotein kilojoules given should bear a definite relationship to the nitrogen intake. A typical regime would feature 8400 kJ (2000 kcal) to 13 g N (about 150 to 1).

**Nitrogen requirements.** The minimum for dynamic tissue turnover, and so to keep a healthy adult in positive nitrogen balance, is about 35—40 g of protein or 5.5—6.5 g of nitrogen per day. The hypercatabolic patient requiring hyperalimentation may need three or four times this amount of protein. A daily negative nitrogen balance of 10 g is not unusual and is equivalent to a loss of 62.5 g of protein or 300 g of muscle tissue.

**Vitamins.** Whatever the method of feeding, vitamins are necessary as supplements, as they are essential for the maintenance of normal metabolic function.

The water-soluble vitamins B and C act as coenzymes in collagen formation and wound healing. Postoperatively, the vitamin C requirement increases to 60—80 mg/day. Preoperative depletion is exacerbated by anorexia, smoking and barbiturate therapy. Vitamin B₁₂ is given 500 micro gram intramuscularly (i.m.) weekly, particularly to those with initial low levels (celiac disease, Crohn’s disease, ileal resection or bypass, blind-loop syndrome, tapeworm infestation, reduced pancreatic secretion, tropical sprue, excess alcohol intake, anticonvulsant therapy and after gastric surgery). As the serum folate falls, especially in those on parenteral nutrition, folic acid is required daily in doses of 3—6 mg i.m.

The fat-soluble vitamins A, D, F and K are reduced in steatorrhoea and the absence of bile. Vitamin A, 5000 units per week, is required after surgery and, when appropriate, it enhances the antitumour effect of cyclophosphamide. Vitamin K 5—10 mg i.m. weekly reduces any bleeding tendency. If commercially available vitamin additives are put into an infusion, the container should be protected from the light.

**Minerals and trace elements**

Sodium, potassium, iron, calcium and magnesium deficiencies must be identified and made good (Chapter 4). Zinc deficiency is manifest as a rash on the face and perineum which does not respond to antifungal therapy, stomatitis which causes disturbance of taste (dysgeusia) and alopecia. Copper deficiency results in leucopenia and anaemia, while lack of chromium may give rise to glucose intolerance. The 14 trace elements that are considered essential for normal enzyme activities include manganese, cobalt, molybdenum and vanadium. It is to be remembered that long-term parenteral nutrition can result in depletion.

Methods of feeding. These are predominantly enteral and less commonly parenteral.

**Enteral nutrition**

**By mouth**

Obviously, as this is the natural way, it should always be attempted. Only when it is known that this route cannot be used or is ineffective are other methods considered.

Feeding by mouth demands common sense, cleanliness and compassion on the part of the medical attendants. It is common sense to ensure that an adequate, palatable and varied diet, including all the nutritional requirements, is provided at regular intervals, more frequently than regular meal times if necessary. It is common sense to begin with a liquid diet as soon as bowel sounds return after an abdominal operation, and not, for example, to allow a plate of fish and chips to be put in front of a patient the day after a gangrenous appendix has been removed. Promotion to semisolid (light) and then to more solid food (full diet) follows in steps of 3—7 days according to progress.

**Cleanliness** in the preparation and serving of food and of the utensils used is of paramount importance in avoiding gastrointestinal infection causing vomiting and diarrhoea. A salmonella infection among elderly patients and children may be a mortal blow.

**Compassion** is needed to ensure that the patient actually receives and ingests the proffered food. Food must be placed within reach of an enfeebled patient. Assistance is often required and should be freely given. Dental care may be necessary to facilitate oral intake and false teeth may need consideration. Table 5.3 shows a representative range of the enteral diets available. Dieticians and pharmacists should be involved in the prescribing of enteral feeding regimes in much the same way as they are involved in parenteral feeding.

**By nasogastric tube**

A nasogastric tube which has been passed to allow regular gastric aspiration to be performed may also be used for feeding liquidized diets. Fine-bore tubing can be used instead, being favorably received by most patients as less irritating than the larger tube. It is invaluable when passed with the aid of an endoscope through an oesophageal stricture into the stomach, enabling the effects of starvation to be reversed. In some patients, the tube can be sited in the duodenum, especially if there are problems of gastric stasis or oesophagogastric reflux.

**Technique of fine-bore tube insertion and usage**

The patient may be sitting or lying, preferably the former. The introducer wire is lubricated with water and inserted into the fine-bore tube. Pass the tube through the nose via the nasopharynx and oesophagus into the stomach. Withdraw the wire and tape the tube to the patient. Check the position of the tube by radiography as passage into a bronchus can occur quite easily. Alternatively, a quick check can be made by injecting 5ml of air down the tube and listening through a stethoscope for its bubbling entry into the stomach.

Administration of the feeds is either by gravity or by means of an infusion pump.

**Problems of tube feeding**

Gastric emptying should be normal. In ill patients ensure that the stomach empties by injecting 60 ml water down a nasogastric tube and aspirate 4-hourly. If after 24 hours fluid is passing through the stomach, commence feeding for the first day and aspirate intermittently to ensure that the stomach empties. Then remove the tube and introduce the fine-bore tube.
Blockage of a 1-mm bore tube is cleared by flushing through with 2 ml water — do not add effervescent potassium to the feed as curdling will follow.

Most fine-bore tubes incorporate a male ‘luer’ lock connector making the nasogastric drip system incompatible with intravenous lines.

Check the drip rate hourly.

All feeds should be stored at 4°C until use, not exposed to room temperature for more than 8 hours and discarded if not used after 12 hours. As diet kitchens may be a source of Klebsiella infection, the bacteriological monitoring of feeds is desirable.

Unwanted effects. Nausea, vomiting and pulmonary aspiration are avoided by regulation of the infusion rate and ensuring initial gastric emptying. Diabetics and hyperosmolar states are related to high carbohydrate intake with particular hazard for the established diabetic. Diarrhoea is common and the pathogenesis is not fully understood, but fluid and electrolytes are secreted into the bowel in response to a high osmotic load. The use of broad-spectrum antibiotics is also associated with diarrhoea. Recent studies suggest that osmolality, electrolyte content and volume of the feed are not implicated in the onset of diarrhoea. It is now probable that the bypassing of the cephalic phase of feeding when a tube is in situ results in suppression of distal colonic motor activity with the onset of diarrhoea. Commence with half strength feed and increase slowly to standard concentration over days given at a slow, constant rate, avoiding milk because of possible lactose intolerance and a high fat content giving steatorrhoea. Mild disturbances of liver function can be associated with both enteral and parenteral feeding, due to intrahepatic cholestasis. Metronidazole 500 mg twice daily may prevent overgrowth of the anaerobic bacteria responsible.

By tube enterostomy

Tube enterostomy is the operative placement of a tube or catheter into the gastrointestinal tract. It is indicated when the passage of a fine-bore nasogastric tube is not possible or when more than 4 weeks of enteral feeding is anticipated. The common contraindications include complete or partial gastric or intestinal obstruction. The tube is usually placed as a specific surgical procedure or as an adjunct to intra-abdominal surgery.

A choice of procedure is to fashion either a gastrostomy or jejunostomy. The contraindications to the former are:

- gastric disease;
- impaired gastric emptying;
- significant gastro-oesophageal reflux;
- loss of the gag reflex.

Jejunostomy is the procedure of choice for the ease of placement of the tube, the initiation of early postoperative feeding, and the avoidance of the risk of pulmonary aspiration.

By gastrostomy (Fig 5.1 and Fig 5.2)

There are two long-term types of gastrostomy: Stamm and Janeway. An upper abdominal (midline) incision is optimal for giving the best exposure and the catheter can be placed laterally away from the incision. The Stamm gastrostomy is the simplest to perform and is particularly valuable as a temporary procedure or in the patient who is a poor postoperativesk. Inadvertent removal of the tube is followed by rapid shrinkage of the cutaneous orifice. To preserve the established gastrostomy a tube must be promptly reinserted. Caution must be exercised to ensure that the new tube is in situ before feeding is recommenced. A Janeway gastrostomy is preferred if there is a need for permanent tube feeding.

When a quick temporary measure is necessary, the ink-well (Kader—Senn) technique is valuable. The tube should be large and, as in all gastrostomies, the end of the tube should be directed towards the fundus.

Complication rates as high as 30 per cent have been associated with gastrostomy procedures, reflecting poor nutritional status, impaired wound healing and pulmonary complications because of immobility. Leakage around the tube can be controlled by inserting a larger catheter with a balloon and taping the tube with gentle traction.

The endoscopic placement of gastrostomy tubes in therapeutic endoscopy is an innovation during the last decade (Fig 5.3 and Fig 5.4). Percutaneous endoscopic gastrostomy has reduced the need for the surgical fashioning of a feeding gastrostomy under general or local anaesthesia. Thus, whenever a surgical gastrostomy is indicated, a percutaneous endoscopic technique may be used. As the gastroscopy must be passed into the stomach, a complete oesophageal obstruction will be an absolute contraindication, as are ascites, sepsis, abnormal clotting and peritoneal dialysis. The patient should have no intake for 8 hours before the procedure. The basic gastrostomy is fashioned in a retrograde manner from within the stomach. A suture is placed through the anterior abdominal and gastric wall and brought out through the mouth. A catheter with a tapered tip is then fixed to the oral end of the suture from the abdominal wall. The catheter is then delivered through the abdominal wall. The holding sutures are removed from the abdominal wall after 1 week.

There is a 3 per cent incidence of major complications, sepsis, puncture of another viscus such as the colon or the need for a laparotomy. Minor complications in 7 per cent of cases include wound infection and circum stomal drainage.

A tract forms within 2 weeks and, if the catheter is removed, another of similar size may be inserted within a few hours.

By jejunostomy (Fig 5.5 and Fig 5.6)

There are two types of feeding jejunostomy: a Witzel jejunostomy with formation of a serosal tunnel, and a needle jejunostomy using a catheter of a small gauge. The ease of jejunostomy as an adjunct to an extra-abdominal surgical procedure has increased in popularity.

It is of importance to control infusion rates of nutrients, particularly with a jejunal feed. The perceived benefits of an enteral pump infusion system include:

- more efficient nutrient delivery;
- reduced abdominal discomfort;
- decreased incidence of osmotic diarrhoea.

A particular advantage is the pump alarm system indicating an empty bag, line occlusion or a failing pump battery system. This safety
mechanism promotes mobility for the patient, a more continuous energy intake than an intermittent feeding regimen and a mechanism providing security and confidence for the patient, and nursing and medical staff.

Parenteral nutrition

Parenteral nutrition by intravenous feeding is used in less than 4—5 per cent of all hospital admissions, either when enteral feeding is not possible, or to supplement deficient enteral feeding. It has been suggested that although the incidence of serious, noninfectious complications is lower in patients receiving total parenteral nutrition, the incidence of septic complications is substantially higher and only in severely malnourished patients do the benefits outweigh the risks.

Total parenteral nutrition is particularly complicated by displacement of the catheter, sepsis, mechanical problems and metabolic derangements — which occur in up to 10 per cent of postoperative patients.

Intravenous (i.v.) fat has many immunosuppressive effects:

i.v. long-chain triglycerides reduce the functions of the reticuloendothelial system and neutrophils and the ratio of T-helper to T-suppressor cells. Contraindications include cardiac failure, severe liver disease, disorders of fat metabolism, uncontrolled diabetes, shock and severe blood dyscrasias. It must be remembered that total parenteral nutrition is not to be undertaken lightly. It is potentially hazardous and can be dangerous in inexperienced hands. The formation of multidisciplinary nutritional care teams including dieticians and pharmacists is a major advance and their advice should be sought.

When planning an intravenous feeding regimen, first weigh the patient and calculate the fluid needs for the next 24 hours. Energy and nitrogen intake should be calculated on a body weight basis, remembering that daily needs may change.

Daily biochemical patient monitoring is essential (Table 4.5).

Most feeding teams decide on the nitrogen and energy requirements of their patients, and tailor-make the feeds from the wide variety of amino acid solutions with and without electrolytes, and the various concentrations of dextrose and fat available (Table 5.9). Typically, these are mixed under laminar flow sterile conditions in the pharmacy into 3-litre bags giving sufficient for 24 hours or, better still, supplied to specifications by one of the companies involved in the manufacture of i.v. solutions. Twenty per cent glucose is equivalent to 3200 kJ/litre (770 kcal/litre) and Intralipid 20 per cent (KabiVitrum) is equivalent to 8400 kJ/litre (2000 kcal).

As most glucose solutions are hypertonic and irritant, they are usually given through central veins, the cannulation of which requires technical finesse. In the short term, the nutritional requirements in aseptic patients can be adequately met with mixtures of amino acids, fat and glucose given peripherally. Fat buffers the vein wall and sometimes subtherapeutic doses of heparin and hydrocortisone are given to act locally in the prevention of thrombophlebitis. The energy requirements of surgical patients have often been overestimated; few will require more than 8400 kJ (2000 kcal) per day (Macfie).

Technique for central venous catheter insertion with a skin tunnel (Fig. 5.7)

Percutaneous catheter insertion requires expertise to prevent the complications which may occur in one in five attempts. These are air embolism, pneumothorax and injury to the subclavian artery or brachial plexus because of significant variation in relationship of the subclavian vein to the clavicle and first rib. A subclavian vein cutdown technique may be employed to allow cannulation of the vein under direct vision. A silicone rubber catheter of 1 mm diameter (Vygon, Vygon UK Ltd, Uxbridge, UK) is inserted by intraclavicular approach, the introducer inserted under local anaesthetic through a 1-cm skin incision (A) 2 cm below the clavicular point. The position of the catheter is checked radiologically, ensuring the tip is in the superior vena cava or right atrium. The catheter hub is removed and the introducer withdrawn. The introducer is now inserted through the skin puncture at (B) about 7 cm below and medial to (A); it is passed through the subcutaneous tissue to emerge at (C) and the catheter threaded through the introducer at (A) until it is seen within the transparent introducer at (B). The introducer is partially withdrawn and cut at X—X so that 2 cm remains in the tunnel and 2 cm protrudes, and the catheter pushed fully through the 4-cm sleeve, avoiding kinks at (A). (A) and (B) are cleaned with chlorhexidine in alcohol and sprayed with povidone iodine powder. Incision (A) is closed with a stitch and covered with a sterile dressing. Caution: it is possible for the catheter tip to perforate the vein wall. If this occurs in the pleural cavity a pneumothorax can be caused. Before the infusion is started, it is essential to confirm by a free backflow of blood that the catheter remains in the lumen of the vessel.

Commence feeding using half-strength solution and increase to the desired daily intake over days. Additives to solutions should be avoided and given through a separate line, although central mixing in pharmacy allows addition under sterile conditions into a 3-litre bag delivery system.

Catheter-related sepsis may occur in up to a third of patients fed parenterally. Skin flora are important in the pathogenesis of this sepsis and the skin at the site of the catheter insertion should be swabbed on alternate days. Bacteriological skin culture shows a strong association between microbial growth, usually Staphylococcus epidermidis, and the development of catheter-related infection. Factors known to increase the risk of infection include variation from the strict nursing protocol for care of the catheter, the age of the patient and the duration of hospital stay before the institution of parental nutrition.

Home parenteral nutrition

Chronic intestinal failure results in a failure of adequate nutrient absorption from the gut to maintain body weight. This may follow extensive bowel resection, multiple high output fistulas, motility disorders and extensive Crohn’s disease. Such patients require prolonged nutritional management by a skilled and experienced team. Long-term home parenteral nutrition depends upon suitable case selection and extensive patient training by experienced nurses, together with a comprehensive hospital pharmaceutical service: the patient will live at home and manage his or her own parenteral feeding. With successful treatment, many patients are able to return to work or care for the home and family unaided or with minimum help.

Notes on solutions. Fructose, sorbitol or alcohol solutions are poten-tially disadvantageous owing to an associated lactic acidosis or hepato-cellular damage. Fat, isotonic preparations of vegetable oils in water with an emulsification agent or purified egg phospholipid in
Intralipid (to stabilise the mixture) should not be used 12 hours before blood sampling as they interfere with analysis. The rate of clearance of intravenous fat is increased after surgery or when energy demands are high (Feggetter).

The nitrogen sources are either casein hydrolysates, or laevorotatory isomers of amino acids. In such solutions, all essential amino acids should be present with a broad spectrum of the nonessential amino acids. No single amino acid should predominate since, if its use is inefficient, this will interfere with the use of the others (Tweedle). In sepsis, renal failure and hepatic failure, the use of solutions containing only essential amino acids, isoleucine, leucine, valine, phenylalanine, lysine and tyrosine is under investigation.

Complications. The initial complications of parenteral feeding arise from malposition of the catheter tip and radiographic confirmation of the site of the catheter tip is mandatory before infusion. infection, particularly septicaemia, arises from continuous direct vascular access and immune depression in malnourished patients, together with the solutions being ideal bacterial and fungal culture media. Catheter insertion with strict asepsis, daily care of the entry site cleaned with 1—2 per cent tincture of iodine and alcohol solutions, and the strict use of the line only for nutrient solutions all contribute to prevention. However, if a patient develops an unexplained fever, hypotension, vomiting, diarrhoea, confusion or seizures, a full clinical examination with appropriate radiology and bacteriological culture of blood, sputum, urine and swabs of the catheter site are indicated. If a source of infection is discovered it is treated, but if no source is found and the fever persists for 24 hours, remove the catheter and send the tip for bacteriological and fungal culture, *Candida albicans*, staphylococci or *Klebsiella* frequently being isolated. Recommend the parenteral regimen using a new catheter at a fresh site.

Prolonged use of amino acids and glucose alone will result in essential fatty acid deficiency, with dermatitis, anaemia and increased capillary permeability, a complication avoided by the use of intravenous fat solutions or essential fatty acids rubbed into the skin weekly. Similarly, hypophosphataemia is seen with such regimens and accentuated by the use of insulin, resulting in enzyme defects, adenosine-5'-triphosphate (ATP) deficiency and a shift to the left in the oxygen dissociation curve. This is prevented by a daily intake of 13 mmol of potassium dihydrogen phosphate. Table 5.6 lists some clinical syndromes and biochemical disorders resulting from drug—nutrient interactions and Table 5.7 lists other biochemical complications. Jaundice occurring during parenteral nutrition is cholestatic, perhaps the result of sepsis, malnutrition and hypoxia.

Severe hepatic steatosis is rare during total parenteral nutrition. However, transient hepatic abnormalities are so common that some authorities regard it as the most frequent metabolic complication. A cholestatic picture tends to predominate with increases in alkaline phosphatase and bilirubin. Elevations of serum transaminases may also be found. Hepatic biopsy performed in the jaundice phase shows histological evidence of fatty infiltration, periportal lymphocytic infiltration with bile duct proliferation and intrahepatic cholestasis or biliary sludging resulting in extrahepatic obstruction.

The syndrome differs somewhat between infants and adults. In the former, typical morphological changes and jaundice, fatty meta-morphosis and even cirrhotic transformation are described, whereas older patients predominantly have enzyme derangements.

The pathophysiology of hepatic dysfunction is not entirely understood.

Up to 40 per cent of surgical patients have an elevation of alkaline phosphatase, particularly if the feeding solution contains more than 214 kJ/kg daily, while it has been suggested that reduction in carbohydrate intake by increased use of a fat solution reduces liver dysfunction. In the vast majority of patients, hepatic function disturbance is both mild and self-limiting and spontaneous recovery is invariable after cessation of total parenteral nutrition.

In the patient with jaundice, it is proposed that cyclical nocturnal total parenteral nutrition reverses abnormalities when replacing continuous parenteral nutrition. Metabolic acidosis, much less common if fructose and alcohol are avoided, may arise from infusion of available hydrogen ions in amino acid solutions and is simply corrected with sodium bicarbonate solution.

Steroids. Anabolic steroids (e.g. Durabolin 25 mg i.m. weekly) may be used to improve nitrogen balance, but the effect may not be observed for some days.
Rehabilitation

It is not enough to save the patient’s life or to carry out a successful operation for a benign condition: whenever possible, the patient should be restored to full social and work capacity. This aim demands more than surgical ‘cure’. Rehabilitation will be required in many cases. The importance of this can be judged by the well-documented fact that a patient who suffers a severe and incapacitating injury or accident that keeps him or her from returning to work for 12 months is unlikely ever to return to full employment, however good his or her recovery from the injury appears to be. While orthopaedic and neurosurgical centres provide the bulk of surgical patients requiring a programme of active physical rehabilitation, such centres should be equipped to assist patients recovering from medical disorders as well, e.g. cardiac and ‘stroke’ patients. With the steadily enlarging proportion of elderly patients surviving, there is an increasing demand for facilities for vascular patients (amputees) and patients with gastrointestinal diseases, principally cancer of the lower bowel (colostomised cases).

Motivation is an important element in rehabilitation. In the USA, a company employee or union-supported victim of trauma takes five times longer to resume his or her normal work than a self-employed person. Therefore, rehabilitation should include a programme of psychological and emotional readjustment in which the family should play an active supportive role. Although rehabilitation can involve the surgeon, pastor, marriage counsellor, occupational therapist, physio therapist, vocational training assistance scheme, prosthetic counsellor, psychiatrist, health visitor and the family doctor, in many cases practical guidance and effective support should emanate from the surgeon who carried out the primary care. Nothing is more important than the timely recall by the surgeon at the time of the initial surgical procedure that his or her patient will require appropriate rehabilitation to achieve the best result.

While maintaining a caring and human approach, the surgeon must be prepared to be firm with patients who play for sympathy as they try to avoid achieving independent status during their rehabilitation programme.

Preparation for anaesthesia

Recognition of general medical and specific anaesthetic risk factors facilitates the implementation of pre-emptive measures and improves patient safety. Early assessment, liaison with the anaesthetist and appropriate investigations avoid unnecessary delays. In any case, the anaesthetist who is to be present during the operation should assess the patient preoperatively and participate in the preparation for surgery.

Preoperative evaluation and management

Investigation of the general condition of the patient before surgery should be specific according to the general history and clinical signs. Investigations in fit people are unnecessary and uneconomic, but indicated tests should be performed as early as possible, preferably before admission. Routine haematological and biochemical screens, with electrocardiography and chest radiography, are prudent investigations in elderly people receiving general anaesthesia for all but minor surgery. The saving of a serum sample for transfusion cross-match, a check for hepatitis antigen and a sickle-cell screen, if indicated, should not be forgotten.

Cardiovascular disease

Uncontrolled hypertension and angina, dysrhythmias and cardiac failure are common reasons for postponement of elective procedures. Correction of hypertension and ischaemic heart disease is essential and needs to be continued through the operative period, even though the patient may be unable to take oral drugs. Fast atrial fibrillation needs to be controlled before anaesthesia. Symptomatic disorders of sinoatrial conduction require pacemaker insertion before anaesthesia, as do all cases of either Mobitz type 2 second-degree block or third-degree heart block. In an emergency, transvenous temporary pacing wires or external pacing can be used. Modern variable-rate demand pacemakers may require resetting to fixed rate mode, but are generally stable during anaesthesia. However, a cardiological opinion should be sought, bipolar diathermy employed if possible and the diathermy plate should be positioned so that the current does not cross the heart or pacemaker wires.

Recent myocardial infarction is a strong contraindication to elective anaesthesia. There is a significant mortality from anaesthesia within 3 months of infarction, and elective procedures should ideally be delayed until at least 6 months have elapsed.

Patients with valvular disease will need corrective treatment of any preoperative infections, and appropriate perioperative prophylactic antibiotic cover, to avoid subacute bacterial endocarditis.

Patients with cardiac disease need careful preoperative evaluation. Much can be derived from a detailed history including exercise tolerance and drug history. Echocardiography has enabled noninvasive assessment of cardiac function. Any electrolyte abnormality (especially hypokalaemia) or anaemia should be corrected and the circulatory volume should be maintained at normal level. Perioperatively, the presence of an adequate urine output is a useful indicator of adequacy of the circulating volume.

Operative procedures create an increased demand for oxygen due to pain, surgical stress and temperature loss. Patients with cardiac disease may need a period of elective postoperative mechanical pulmonary ventilation after surgery, until the period of raised oxygen consumption has passed. The careful anaesthetist and surgeon plan such care before surgery.

Respiratory disease

Thoracical surgical procedures demand specific preoperative tests of respiratory function including spirometry and blood gas analysis. In general surgical practice, respiratory infection and asthma are the common problems needing treatment before anaesthesia. In chronic respiratory failure, careful attention should be given to perioperative physiotherapy, early mobilisation and treatment of infection. Measurement of oxygen saturation and blood gas tensions preoperatively give a very useful guide to future values on recovery. The need for postoperative ventilatory support should be anticipated. Regional anaesthesia as appropriate is advantageous in respiratory disease. Upper abdominal and thoracic procedures are unsuited to regional anaesthesia alone, as positive pressure ventilation under general anaesthesia is necessary.

Gastrointestinal disease

Aspiration of gastric contents carries a high risk of acid pneumonitis, pneumonia and death. Regurgitation in the presence of a hiatus hernia, or from ‘the full stomach’, may result from emergency (nonstarved) cases, bowel obstruction or paralytic ileus and indicates mandatory precautions during anaesthesia. A rapid sequence induction is conducted, in which the patient is ‘preoxygenated’ and cricoid pressure is applied from loss of consciousness until the lungs are protected by tracheal intubation. Bowel obstruction requires preoperative nasogastric aspiration and careful correction of fluid and electrolyte balance before anaesthesia is induced.

H₂-receptor blocking agents such as ranitidine are administered if there is an increased risk of regurgitation, ideally at least 2 hours preoperatively.

Anaesthesia in the presence of jaundice carries a high risk of renal damage. The anaesthetist should ensure that no hypovolaemia occurs and that a good urine output is present before induction, by the preoperative infusion of intravenous crystalloid solutions. A diuretic agent should only be used if the circulating volume is first assessed to be adequate.

Metabolic disorders

Familial porphyria and hyperpyrexia are hereditary metabolic disorders associated with high anaesthetic risks. Phaeochromocytoma is also associated with severe anaesthetic complications. The presence of these disorders requires highly specific preanaesthetic planning. Diabetes and adrenal suppression from steroid therapy are also common metabolic disorders which complicate anaesthesia.

Non insulin-dependent diabetic patients on diet and oral hypoglycemic agents will need blood sugar measurement during anaesthesia. An intravenous infusion of glucose may be required if the long-acting hypoglycemic effects persist even if the agent was omitted on the day of surgery.

Except for minor surgery, an intravenous infusion of glucose with soluble insulin is likely to be necessary with close monitoring and control of blood sugar levels. Insulin-dependent diabetes always needs preoperative conversion to control with rapidly acting soluble insulin by intravenous infusion on the operative day, and this is continued until the patient has recovered from the operation. In practice, for maintenance of blood sugar levels, it is best to keep a constant infusion of 5—10 per cent glucose with potassium supplementation through a separate intravenous channel at about 2 litres/24 hours. Soluble short-acting insulin is given continuously by intravenous syringe pump, with the rate indicated by frequent (1—4-hourly) measurement of blood glucose concentration. The plasma potassium level needs careful control. The circulating volume should be manipulated independently via a separate infusion of normal saline, blood or colloid. In this way a steady control of blood glucose concentration can be easily achieved by an experienced nurse. Patients who are receiving corticosteroids or who have received them in the past 2 months require supplementation with hydrocortisone during and after surgery to avoid adrenal insufficiency.

Preparation for anaesthesia

Recognition of general medical and specific anaesthetic risk factors facilitates the implementation of pre-emptive measures and improves patient safety. Early assessment, liaison with the anaesthetist and appropriate investigations avoid unnecessary delays. In any case, the anaesthetist who is to be present during the operation should assess the patient preoperatively and participate in the preparation for surgery.

Preoperative evaluation and management

Investigation of the general condition of the patient before surgery should be specific according to the general history and clinical signs. Investigations in fit people are unnecessary and uneconomic, but indicated tests should be performed as early as possible, preferably before admission. Routine haematological and biochemical screens, with electrocardiography and chest radiography, are prudent investigations in elderly people receiving general anaesthesia for all but minor surgery. The saving of a serum sample for transfusion cross-match, a check for hepatitis antigen and a sickle-cell screen, if indicated, should not be forgotten.

Cardiovascular disease

Uncontrolled hypertension and angina, dysrhythmias and cardiac failure are common reasons for postponement of elective procedures. Correction of hypertension and ischaemic heart disease is essential and needs to be continued through the operative period, even though the patient may be unable to take oral drugs. Fast atrial fibrillation needs to be controlled before anaesthesia. Symptomatic disorders of sinoatrial conduction require pacemaker insertion before anaesthesia, as do all cases of either Mobitz type 2 second-degree block or third-degree heart block. In an emergency, transvenous temporary pacing wires or external pacing can be used. Modern variable-rate demand pacemakers may require resetting to fixed rate mode, but are generally stable during anaesthesia. However, a cardiological opinion should be sought, bipolar diathermy employed if possible and the diathermy plate should be positioned so that the current does not cross the heart or pacemaker wires.

Recent myocardial infarction is a strong contraindication to elective anaesthesia. There is a significant mortality from anaesthesia within 3 months of infarction, and elective procedures should ideally be delayed until at least 6 months have elapsed.

Patients with valvular disease will need corrective treatment of any preoperative infections, and appropriate perioperative prophylactic antibiotic cover, to avoid subacute bacterial endocarditis.

Patients with cardiac disease need careful preoperative evaluation. Much can be derived from a detailed history including exercise tolerance and drug history. Echocardiography has enabled noninvasive assessment of cardiac function. Any electrolyte abnormality (especially hypokalaemia) or anaemia should be corrected and the circulatory volume should be maintained at normal level. Perioperatively, the presence of an adequate urine output is a useful indicator of adequacy of the circulating volume.

Operative procedures create an increased demand for oxygen due to pain, surgical stress and temperature loss. Patients with cardiac disease may need a period of elective postoperative mechanical pulmonary ventilation after surgery, until the period of raised oxygen consumption has passed. The careful anaesthetist and surgeon plan such care before surgery.

Respiratory disease

Thoracical surgical procedures demand specific preoperative tests of respiratory function including spirometry and blood gas analysis. In general surgical practice, respiratory infection and asthma are the common problems needing treatment before anaesthesia. In chronic respiratory failure, careful attention should be given to perioperative physiotherapy, early mobilisation and treatment of infection. Measurement of oxygen saturation and blood gas tensions preoperatively give a very useful guide to future values on recovery. The need for postoperative ventilatory support should be anticipated. Regional anaesthesia as appropriate is advantageous in respiratory disease. Upper abdominal and thoracic procedures are unsuited to regional anaesthesia alone, as positive pressure ventilation under general anaesthesia is necessary.

Gastrointestinal disease

Aspiration of gastric contents carries a high risk of acid pneumonitis, pneumonia and death. Regurgitation in the presence of a hiatus hernia, or from ‘the full stomach’, may result from emergency (nonstarved) cases, bowel obstruction or paralytic ileus and indicates mandatory precautions during anaesthesia. A rapid sequence induction is conducted, in which the patient is ‘preoxygenated’ and cricoid pressure is applied from loss of consciousness until the lungs are protected by tracheal intubation. Bowel obstruction requires preoperative nasogastric aspiration and careful correction of fluid and electrolyte balance before anaesthesia is induced.

H₂-receptor blocking agents such as ranitidine are administered if there is an increased risk of regurgitation, ideally at least 2 hours preoperatively.

Anaesthesia in the presence of jaundice carries a high risk of renal damage. The anaesthetist should ensure that no hypovolaemia occurs and that a good urine output is present before induction, by the preoperative infusion of intravenous crystalloid solutions. A diuretic agent should only be used if the circulating volume is first assessed to be adequate.

Metabolic disorders

Familial porphyria and hyperpyrexia are hereditary metabolic disorders associated with high anaesthetic risks. Phaeochromocytoma is also associated with severe anaesthetic complications. The presence of these disorders requires highly specific preanaesthetic planning. Diabetes and adrenal suppression from steroid therapy are also common metabolic disorders which complicate anaesthesia.

Non insulin-dependent diabetic patients on diet and oral hypoglycemic agents will need blood sugar measurement during anaesthesia. An intravenous infusion of glucose may be required if the long-acting hypoglycemic effects persist even if the agent was omitted on the day of surgery.

Except for minor surgery, an intravenous infusion of glucose with soluble insulin is likely to be necessary with close monitoring and control of blood sugar levels. Insulin-dependent diabetes always needs preoperative conversion to control with rapidly acting soluble insulin by intravenous infusion on the operative day, and this is continued until the patient has recovered from the operation. In practice, for maintenance of blood sugar levels, it is best to keep a constant infusion of 5—10 per cent glucose with potassium supplementation through a separate intravenous channel at about 2 litres/24 hours. Soluble short-acting insulin is given continuously by intravenous syringe pump, with the rate indicated by frequent (1—4-hourly) measurement of blood glucose concentration. The plasma potassium level needs careful control. The circulating volume should be manipulated independently via a separate infusion of normal saline, blood or colloid. In this way a steady control of blood glucose concentration can be easily achieved by an experienced nurse. Patients who are receiving corticosteroids or who have received them in the past 2 months require supplementation with hydrocortisone during and after surgery to avoid adrenal insufficiency.
Coagulation disorders

Whether iatrogenic (including therapeutic) or pathological in origin, coagulation disorders need careful assessment before surgery with a coagulation screen, or clotting factor and platelet measurements. In acquired disorders, such as disseminated intravascular coagulation, fresh frozen plasma or cryoprecipitate and platelets may be given to the patient by the anaesthetist perioperatively to control haemorrhage. Patients receiving therapeutic warfarin need to cease treatment several days preoperatively and have prothrombin time (PT) measurement until the International Normalised Ratio (INR) falls to about 1.5 from the therapeutic range of 2.0—4.2. At an INR of 1.5, surgical haemostasis should be achieved. Vitamin K can be used to hasten the reversal of warfarin but it is a long-acting agent and can cause weeks of resistance to warfarin after surgery, so it is better to avoid it. When the risk of thrombosis and embolism is high, an intravenous infusion of heparin can be used to replace warfarin. The heparin can be stopped or reversed with protamine for the period of surgery. Rapid control of heparin activity is easy, but it is not so with warfarin.

Neurological disease

In cerebral disease and trauma, hypoxia, hypercarbia and respiratory obstruction raise intracranial pressure and can cause cerebral damage. In the presence of deteriorating consciousness, management of the airway and ventilation is of prime importance, and especially so in traumatic injury in which early endotracheal intubation and pulmonary ventilation should precede supine positioning for computed tomography (CT) of the brain. Particular care of the neck during intubation is necessary if a cervical fracture is suspected. Skull traction and awake intubation under local anaesthesia are sometimes used.

Anticonvulsant drugs must be continued during surgery on epileptic patients, and this may necessitate using intravenous administration.

Anaesthesia and psychiatric disease

General, rather than regional, anaesthesia is usually necessary. Tricyclic antidepressants and monoamine oxidase inhibitor drugs potentiate sympathomimetic agents so adrenalin and cocaine must be avoided. Pethidine can also cause hypertension with these drugs. Other narcotic analgesic agents can be used but caution is necessary as their side effects can be potentiated, especially with monoamine oxidase inhibitors.

Starvation before surgery

Standard practice for many years has been 6 hours’ abstinence from food and 4 hours’ abstinence from fluids. Recently, there has been a shift to permit clear, nonfizzy fluids up to 2 hours preoperatively. These rules apply whenever loss of protective laryngeal reflexes may pertain, as during regional anaesthesia and sedation. Small children are usually given a glucose drink about 4 hours preoperatively to prevent perioperative hypoglycaemia.

Consent for surgery and anaesthesia

Informed consent should be obtained by the surgical team, preferably the operating surgeon, before any sedation is given, but the anaesthetist should still explain anaesthetic procedures, especially regional and spinal techniques, and discuss potential sequelae.

Preoperative drugs and treatment

Preoperative sedative and analgesic medication is becoming much less common. Heavy sedative, antiemetic, antitussive, amnesic medication was previously used for the relatively unpleasant inductions of anaesthesia with pungent inhalational agents. Except for patients who are already in pain, opioid analgesic agents are generally first given during induction of anaesthesia, administered intravenously for rapid onset of action prior to surgery. For reduction of anxiety, oral short-acting benzodiazepines are now more commonly used 1—2 hours preoperatively, especially for children. Oral trimeprazine is also still popular for children.

For the increasing numbers of day-case procedures, preoperative sedation is avoided so as to promote rapid emergence from anaesthesia and mobilisation.

The anticholinergic agents, atropine, glycopyrronium and hyoscine, are used to reduce respiratory and oral secretions. They are not essential with modern anaesthetic agents, but still useful for airway surgery and endoscopy. Atropine and glycopyrronium also protect against vagal dysrhythmias, for which administration at induction is just as effective, and can cause alertness and tachycardia. Hyoscine is pleasantly sedative without the cardiac effects of atropine, but it can cause excessive sedation in infants or the elderly.

Antithrombotic prophylaxis is usually initiated preoperatively in major surgery, commonly by subcutaneous heparin injection. Particular attention must be given to higher risk patients such as women taking contraceptive and hormone replacement drugs, and those undergoing pelvic, hip, knee and cancer surgery. Low dose progesterone preparations may be effectively covered by subcutaneous heparin, but other less commonly prescribed forms of contraceptive hormone treatment may need to be stopped 1 month before major surgery.

Preoperative chest physiotherapy, possibly with bronchodilator treatment, may be indicated.

If indicated, prophylactic antibiotic agents are given by the anaesthetist in concert with the surgeon, either with the premedication or intravenously at induction of anaesthesia.
General anaesthesia

Induction of anaesthesia

Intravenous anaesthesia is most common in contemporary practice, although the recent introduction of nonpungent sevoflurane has led to renewed use of inhalational induction. Inhalational induction is useful in young children, or ‘needle phobic’ adults, and may also be used in patients who are at risk of airway obstruction or pulmonary aspiration (of, for example, blood) when the patient is put into the lateral position with head down tilt to drain the fluid away from the trachea. For intravenous induction, propofol with its rapid recovery is replacing the long-standing barbiturate agent, thiopentone. Analgesic agents are frequently also injected at the time of anaesthetic induction.

Maintenance of anaesthesia

Following the induction of anaesthesia, inhalational volatile or intravenous anaesthetic agents are continuously administered to maintain an adequate depth of anaesthesia. Adding nitrous oxide contributes analgesic and weak anaesthetic effects, which reduce the concentration of volatile anaesthetic agent required for maintenance. To provide a safety margin, at least 30 per cent oxygen is added to the inspired mixture. Although still employed in some parts of the world, ether has generally been replaced by halothane, enflurane and isoflurane. Desflurane and sevoflurane are the most recently introduced agents, conferring the advantages of fewer side effects and more rapid recovery.

The use of nitrous oxide is slowly waning, as oxygen-enriched air with volatile or intravenous maintenance gains popularity.

If compressed sources of oxygen, nitrous oxide or air are scarce, then air may be drawn into the anaesthetic circuit, either by the (unparalysed) patient’s own respiratory effort or by a mechanical ventilator.

Total intravenous anaesthesia, a technique undergoing contemporary resurgence, avoids the use of inhalational anaesthetic agents and is claimed to provide enhanced quality and rapidity of recovery. It is also used when inhalational anaesthesia may be impractical, such as during airway laser surgery or endoscopy, and is popular for cardiopulmonary bypass. It is also indicated in spinal surgery during neurophysiological monitoring of cord integrity, as evoked potential signals are suppressed by inhalational anaesthesia. Intravenous anaesthesia avoids atmospheric pollution, and is usually conducted by infusing propofol and a short acting opioid analgesic agent, such as fentanyl or alfentanil, in combination with neumromuscular block and pulmonary ventilation with a mixture of air and oxygen.

Management of the airway during anaesthesia

General anaesthesia reduces the tone of the muscles required to preserve airway patency, and hence the need for manual methods (e.g. jaw thrust), or devices such as the Guedel or laryngeal mask airways, or endotracheal tubes.

Sir Ivan Magill developed the endotracheal tube during World War I to facilitate plastic surgery around the mouth without a face mask. The addition of a cuff to the tube allowed a seal of the trachea to protect the lungs from aspiration of blood or secretions, and later mechanical positive pressure pulmonary ventilation.

The following means of airway control in the anaesthetised or unconscious patient are used (Fig. 6.1).

Positioning of the tongue and jaw

The anaesthetist thrusts the jaw forward, from behind the temporomandibular joints, thereby elevating the tongue off the posterior pharyngeal wall, which may also be achieved by inserting an artificial oropharyngeal airway such as the ‘Guedel’. The anaesthetic gases are given through a face mask.

The laryngeal mask airway (LMA) (developed by Archie Brain) is also inserted via the mouth, and is positioned with the mask over the larynx, sealed by an inflatable cuff. It frees the anaesthetist’s hands from holding the patient’s jaw or face mask. Its placement is less stimulating than endotracheal intubation. It has proved to be a reliable means of maintaining a patent airway, and is a technique readily taught to nonanaesthetists for emergency airway management. It is likely to replace the face mask for immediate care prior to endotracheal intubation.

The endotracheal tube may be passed into the trachea via either the mouth or the nose. It is usually placed by direct laryngoscopy, using a laryngoscope, but it is occasionally impossible to visualise the larynx. A fibreoptic technique may be used in which the tracheal tube is ‘rail-roaded’ over the flexible laryngoscope, once the tip has been steered into the trachea.

A cuffed endotracheal tube is used to facilitate artificial ventilation or surgery around the face or airway, and to protect the lungs if there is a risk of pulmonary aspiration. If fluid may collect in the mouth from above (as in nasal surgery), a throat pack is placed in the oropharynx.

Although endotracheal intubation is generally straight forward, complications do occur:

- accidental and unrecognised oesophageal intubation;
- accidental intubation of a main bronchus;
- trauma to larynx, trachea or teeth;
- aspiration of vomitus during neuromuscular blockade for intubation;
- failure to intubate and loss of airway control;
- disconnection or blockage of the tube;
- delayed tracheal stenosis, in children or after prolonged intubation.

Careful observation of physical signs and constant vigilance, aided by pulse oximetry, capnography of the expiratory gases, inspiratory oxygen concentration measurement and ventilator disconnection alarms are mandatory to minimise these risks.

Tracheostomy tube

Anaesthesia can safely be conducted through a tracheostomy tube but it should have an inflatable cuff for airway control. Silver or fenestrated
Accurate monitoring of vitals functions during anaesthesia is now regarded as obligatory in all parts of the world. Surgery should not be practised where proper facilities for monitoring and cardiopulmonary resuscitation are not available. The basic parameters monitored are inspiratory oxygen concentration, oxygen saturation by pulse oximetry, expiratory carbon dioxide tension measurement, blood pressure and the electrocardiogram. For major surgery, invasive, direct monitoring of the circulation is used, but the potential value of information gained must be weighed against the possible dangers of placing intra arterial or central venous or pulmonary artery catheters. Hourly observation of urine output via a urinary catheter is most helpful in assessing renal perfusion. Ventilators should all have airway pressure monitors and be weighed against the possible dangers of placing intra arterial or central venous or pulmonary artery catheters.

Management of temperature during anaesthesia

Hypothermia develops quickly during anaesthesia and surgery due to vasodilation, cold infusions of fluid, and loss of body heat by radiation and fluid evaporation from open body cavities. It is a particular hazard in children because of the high ratio of body surface area to body mass. The elderly are also at particular risk as hypothermia and shivering increase oxygen consumption and vascular resistance, predisposing to myocardial infarction. In high-risk patients and for long operations, warm air blowers and warming blankets should be used, and fluids for intravenous infusion, or irrigation of body cavities or organs (such as the bladder and renal pelvis), should be warmed to body temperature. Careful intraoperative temperature control greatly reduces postoperative morbidity.

In the UK, the Association of Anaesthetists recommends the following standards of routine monitoring in the anaesthetised patient (Fig. 6.3):

- the continuous presence of an adequately trained anaesthetist;
- regular blood pressure and heart rate measurements (recorded);
- continuous monitoring of the electrocardiography (ECG) throughout anaesthesia;
- continuous analysis of the oxygen content in the inspiratory gas mixture;
- oxygen supply failure alarm;
- ventilator disconnection alarm;
- pulse oximeter;
- capnography (measurement of end-tidal carbon dioxide content);
- temperature measurement availability;
- neuromuscular monitoring availability.

Endobronchial tube

In pulmonary and open oesophageal surgery, selective intubation of either bronchus is usual to facilitate deflation of the lung on the operated side. Its use is essential to protect the normal lung in the presence of a bronchopleural fistula.

Ventilation through a bronroscope

The lungs can be ventilated during bronchoscopy by intermittent jets of oxygen down a cannula within the bronchoscope. The oxygen entrains air by the Venturi effect to generate enough pressure and flow to inflate the lungs.

The technique demands constant observation of the patient’s chest movement.

Neuromuscular blockade during surgery

Pharmacological blockade of neuromuscular transmission provides relaxation of muscles to facilitate surgery and mechanical positive pressure ventilation. Muscle tone may also be reduced by very deep anaesthesia, but may compromise the circulation. Neuromuscular blockade demands complete control of the airway and ventilation by the anaesthetist. The depolarising muscle relaxant, suxamethonium, rapidly provides excellent intubating conditions of brief duration, but commonly causes postoperative diffuse muscle pains, and rarely may cause a prolonged block if the patient is deficient in plasma pseudocholinesterase.

The competitive neuromuscular blocking agents such as curare and its modern successors produce a prolonged effect which may persist into the postoperative period. Atracurium, cisatracurium, vecuronium and rocuronium share more predictable activity profiles and are less dependent on hepato renal function. A peripheral nerve stimulator is also used to check for adequate depth of blockade during surgery, and to confirm satisfactory recovery of neuromuscular function prior to extubation of the trachea. The advent of neuromuscular blockade in the 1940s facilitated many advances in abdominal and thoracic surgery, but introduced the risk of accidental patient awareness during surgery.

Haemostasis and blood pressure control

Although the dangers of profound hypotension are nowadays well accepted, a 20—30 per cent reduction of mean arterial blood pressure from the awake preoperative level in fit patients is still deemed acceptable, and can greatly improve the quality of the operative field and reduce total blood loss. Reduction of venous pressure at the wound by correct patient positioning and avoidance of any causes of venous obstruction (Fig. 6.2), and maintenance of satisfactorily deep anaesthesia and slightly reduced arterial carbon dioxide tension, further contribute to providing a dry surgical field.

Hypotensive drugs may be used to produce deliberate controlled hypotension if there is a clear surgical benefit to be obtained, although preservation of cerebral perfusion and oxygenation remains paramount. The surgeon must be aware of the prevailing blood pressure, particularly at the time of ensuring satisfactory haemostasis prior to wound closure. Usually, the anaesthetist will attempt to bring the blood pressure back to the normal level at this stage of the procedure.

Endobronchial tube

In pulmonary and open oesophageal surgery, selective intubation of either bronchus is usual to facilitate deflation of the lung on the operated side. Its use is essential to protect the normal lung in the presence of a bronchopleural fistula.

Ventilation through a bronroscope

The lungs can be ventilated during bronchoscopy by intermittent jets of oxygen down a cannula within the bronchoscope. The oxygen entrains air by the Venturi effect to generate enough pressure and flow to inflate the lungs.

The technique demands constant observation of the patient’s chest movement.

Neuromuscular blockade during surgery

Pharmacological blockade of neuromuscular transmission provides relaxation of muscles to facilitate surgery and mechanical positive pressure ventilation. Muscle tone may also be reduced by very deep anaesthesia, but may compromise the circulation. Neuromuscular blockade demands complete control of the airway and ventilation by the anaesthetist. The depolarising muscle relaxant, suxamethonium, rapidly provides excellent intubating conditions of brief duration, but commonly causes postoperative diffuse muscle pains, and rarely may cause a prolonged block if the patient is deficient in plasma pseudocholinesterase.

The competitive neuromuscular blocking agents such as curare and its modern successors produce a prolonged effect which may persist into the postoperative period. Atracurium, cisatracurium, vecuronium and rocuronium share more predictable activity profiles and are less dependent on hepato renal function. A peripheral nerve stimulator is also used to check for adequate depth of blockade during surgery, and to confirm satisfactory recovery of neuromuscular function prior to extubation of the trachea. The advent of neuromuscular blockade in the 1940s facilitated many advances in abdominal and thoracic surgery, but introduced the risk of accidental patient awareness during surgery.

Haemostasis and blood pressure control

Although the dangers of profound hypotension are nowadays well accepted, a 20—30 per cent reduction of mean arterial blood pressure from the awake preoperative level in fit patients is still deemed acceptable, and can greatly improve the quality of the operative field and reduce total blood loss. Reduction of venous pressure at the wound by correct patient positioning and avoidance of any causes of venous obstruction (Fig. 6.2), and maintenance of satisfactorily deep anaesthesia and slightly reduced arterial carbon dioxide tension, further contribute to providing a dry surgical field.

Hypotensive drugs may be used to produce deliberate controlled hypotension if there is a clear surgical benefit to be obtained, although preservation of cerebral perfusion and oxygenation remains paramount. The surgeon must be aware of the prevailing blood pressure, particularly at the time of ensuring satisfactory haemostasis prior to wound closure. Usually, the anaesthetist will attempt to bring the blood pressure back to the normal level at this stage of the procedure.

Management of temperature during anaesthesia

Hypothermia develops quickly during anaesthesia and surgery due to vasodilation, cold infusions of fluid, and loss of body heat by radiation and fluid evaporation from open body cavities. It is a particular hazard in children because of the high ratio of body surface area to body mass. The elderly are also at particular risk as hypothermia and shivering increase oxygen consumption and vascular resistance, predisposing to myocardial infarction. In high-risk patients and for long operations, warm air blowers and warming blankets should be used, and fluids for intravenous infusion, or irrigation of body cavities or organs (such as the bladder and renal pelvis), should be warmed to body temperature. Careful intraoperative temperature control greatly reduces postoperative morbidity.

Monitoring during anaesthesia

Accurate monitoring of vital functions during anaesthesia is now regarded as obligatory in all parts of the world. Surgery should not be practised where proper facilities for monitoring and cardiopulmonary resuscitation are not available. The basic parameters monitored are inspiratory oxygen concentration, oxygen saturation by pulse oximetry, expiratory carbon dioxide tension measurement, blood pressure and the electrocardiogram. For major surgery, invasive, direct monitoring of the circulation is used, but the potential value of information gained must be weighed against the possible dangers of placing intra arterial or central venous or pulmonary artery catheters. Hourly observation of urine output via a urinary catheter is most helpful in assessing renal perfusion. Ventilators should all have airway pressure monitors and disconnection alarms.
In the USA, spirometry during anaesthesia is regarded as necessary.

**Recovery from general anaesthesia**

Recovery from general anaesthesia should be closely supervised by trained nursing staff in an area equipped with the means of resuscitation and with adequate monitoring devices. An anaesthetist should be readily available. For the seriously ill patient, a high dependency unit or intensive care unit may be necessary until the patient’s condition is satisfactory and stable. The transition from tracheal intubation with ventilatory support to spontaneous breathing with an unprotected airway is a time of increased risk, when respiratory arrest or obstruction may occur.

The common causes of failure to breathe after general anaesthesia are:

- obstruction of the airway;
- central sedation from opioid drugs or anaesthetic agents;
- hypoxia or hypercarbia of any cause;
- hypocarbia from mechanical overventilation;
- persistent neuromuscular blockade;
- pneumothorax from pleural damage during anaesthesia or surgery;
- circulatory failure leading to respiratory arrest.

**Management of blood pressure in the recovery room**

**Hypotension**

This may be due to hypovolaemia, prolonged vasodilation or myocardial depressant effects of anaesthetic, drugs, cardiac dysrhythmia or hypoxaemia. Management is by treatment of the cause.

**Hypertension**

Hypertension is common postoperatively, usually of brief duration and associated with peripheral vasoconstriction due to pain, fear, cold or shivering, or pre-existing hypertensive disease. Hypertension predisposes to cerebral and myocardial damage, and needs active management. If it persists in the presence of adequate pain relief, sublingual rifedipine and intravenous labetalol or hydralazine are useful. Rarely, control with more powerful intravenous drugs such as sodium nitroprusside or glyceryl trinitrate is necessary, in conjunction with direct intra-arterial blood pressure monitoring.

**General anaesthesia for day-case surgery**

Day-case management already accounts for about 40 per cent of procedures in UK hospitals and is intended to reach over 60 per cent. While the principles remain the same, it is even more necessary for the day-case patient to recover rapidly from general anaesthesia and mobilise with the minimum of side-effects. Longer and more complex operations are now conducted as day cases, demanding high-quality anaesthesia and effective analgesic strategies.

Careful selection of patients is essential with regard to coexisting diseases, the nature of the proposed surgery, the availability of a suitable escort and transport home, and domiciliary care. Well-controlled nondebilitating chronic diseases do not preclude day care, but may require a longer period of postoperative supervision before permitting discharge home.

General anaesthesia combined with regional anaesthesia, as for inguinal hernia repair, is often suitable. Anaesthetics which promote rapid recovery such as propofol, sevoflurane and desflurane are used. Drugs with prolonged depressant central action, including premedicant drugs, are avoided and, where possible, analgesics should act peripherally or be of short duration if centrally acting. Where possible, patients are managed with a laryngeal mask or face mask, although endotracheal intubation is the necessary airway control for many day cases such as oral or ear, nose and throat (ENT) procedures, and is generally uncomplicated.

With the patient relatively isolated from immediate medical supervision and advice, postoperative analgesia must be carefully tailored to the procedure, especially in the case of the more painful procedures (such as hernia repair, haemorrhoidectomy, tubal surgery, meniscectomy) for which stronger analgesics and combinations should be provided. Regular postoperative dosing is recommended to avoid breakthrough pain, as may particularly occur following the initial benefits of local anaesthetic.

**General anaesthesia and cardiopulmonary bypass**

The technique is discussed in Chapter 48 of this book.

Anaesthetic agents and oxygen cannot be delivered to the circulation through the lungs when the lungs are bypassed, so all drugs are given directly into a vein or into the blood while it passes through the oxygenator.
Local anaesthesia

Choice of a local anaesthetic technique depends upon its feasibility for a particular procedure and the patient’s willingness and ability to co-operate, as well the surgeon’s and anaesthetist’s preference. Local anaesthesia may be the reliable and traditional method for some minor surgical procedures which do not warrant general anaesthesia. One of the main advantages is the continuation of pain relief into the postoperative period, by either drugs with a prolonged duration of action or delivery of further local anaesthetic increments via a catheter.

However, local anaesthesia is not infallible, and may be contraindicated by allergy or local infection. Epidural and intrathecal anaesthesia includes sympathetic blockade which may result in vasodilatation and systemic hypotension, and may confer greater intraoperative risk than a carefully managed general anaesthetic.

Complications may be local, such as infection or haema-toma, or systemic if overdosage or accidental intravascular injection leads to toxic blood levels. The latter may manifest as depressed conscious level, convulsions and/or cardiac arrest (particularly bupivacaine), and may be heralded by circum-oral paraesthesia and light-headedness. Addition of adrenaline to the local anaesthetic solution increases the risk of cardiac arrhythmia associated with accidental intravascular injection. Prilocaine overdosage causes methaemoglobinemia. Recently introduced local anaesthetics such as ropivicaine and laevobupivacaine are claimed to have enhanced safety profiles.

Addition of adrenaline (commonly 1:200 000—1:125 000 concentration) to the local anaesthetic solution hastens the onset and prolongs the duration of action, and permits a higher dose of drug to be used as it is more slowly absorbed into the circulation. Adrenaline should not be used in hypertensive patients, or for patients taking either monoamine oxidase inhibitor or tricyclic antidepressant drugs, as its cardiovascular effects are potentiated. It should not be used in end arterial locations, where there is no collateral circulation, such as fingers and toes, or around the retinal artery.

The potential risk of life threatening sequelae mandates the availability of appropriately skilled personnel and resuscitation equipment including oxygen, as prerequisites if local anaesthesia is practised.

The following exemplify sensible upper dose limits suitable for a 70 kg adult.

- Lignocaine 200 mg (10 ml of 2 per cent) or lignocaine with adrenaline (1:200 000) 500 mg. Lignocaine 1 per cent is effective for most sensory blocks and addition of adrenaline enables a greater volume to be used. Thus, up to 50 ml of lignocaine 1 per cent with adrenaline (1:200 000) can be infiltrated into the tissues.

- Bupivacaine 150 mg (30 ml of 0.5 per cent). Addition of adrenaline would enhance the safety of this high dose. Bupivacaine is more cardiotoxic than lignocaine. Bupivacaine 0.25 per cent is effective for sensory block against moderate stimulus. Bupivacaine must never be injected into a vein, and is absolutely contraindicated from use for intravenous regional anaesthesia. (Bier’s block is com-monly used for procedures such as reduction of Colle’s fracture and carpal tunnel decompression.) Bupivacaine is a long-acting drug lasting for about 6 hours.

- Prilocaine 400 mg (40 ml of 1 per cent). The presence of blue—brown skin colour indicates methaemoglobin toxicity.

Topical anaesthesia

Topical anaesthetic agents are used on the skin, the urethral mucosa, nasal mucosa and the cornea. The agents used are amethocaine, because it is well absorbed by mucosa, cocaine for its vasoconstrictive properties, lignocaine and prilocaine. A lignocaine and prilocaine eutectic mixture (‘EMLA’ cream) is commonly used on the skin of children before venepuncture.

Local infiltration

This is the method most commonly used by both surgeons and physicians. It is not necessary to starve the patient preoperatively unless the procedure carries a high risk of intravascular or intrathecal injection. Infiltration of local anaesthetic drug may be into or around a wound, ideally with particular attention to neuroanatomical territories and boundaries. Contraindications are local infection and clotting disorder. Not only will local infiltration spread the infection, but local anaesthetic drugs are ineffective in conditions of acidity as produced by infection. Local infiltration in the presence of a clotting disorder may result in haemorrhage, or may produce haematoma, potentially fatal in the airway, as in dentistry.

Regional anaesthesia (without general anaesthesia)

Regional anaesthesia involves blockade of major nerve trunks which innervate the site of surgery. It is usually performed by an anaesthetist with the necessary skills. However, both ultrathecal (spinal) and epidural anaesthesia should only be con ducted by experienced practitioners using full aseptic techniques.

It is in any case required that a doctor other than the operator is present to monitor continuously and resuscitate the patient if necessary. If regional anaesthesia fails, general anaesthesia may be necessary. Compensation for an inadequate regional block by heavy sedation carries great dangers including airway obstruction and pulmonary aspiration of gastric contents. These may easily go unrecognised by a single-handed operator. All patients should be starved preoperatively and monitored. In emergency surgery, regional anaesthesia carries the advantage of preservation of the protective laryngeal reflexes, particularly in emergency obstetric anaesthesia, for which epidural or spinal regional anaesthesia is commonly the method of choice. The reduction in blood pressure with spinal and epidural anaesthesia can be advantageous in reducing intraoperative blood loss, but only if the surgeon strives to achieve haemostasis prior to wound closure and restoration of normal blood pressure.

When sedation has been used for surgery under regional anaesthesia, respiratory obstruction may occur postopera-tively when the surgical stimulus has ceased. Oxygen saturation measurement by pulse oximetry is required monitoring during regional anaesthesia.

Regional anaesthesia had a very clear advantage over general anaesthesia when general anaesthetic agents carried high morbidity and mortality rates. In contemporary practice this advantage is less pronounced or even reversed. However, regional anaesthesia may be advantageous for patients who have debilitating respiratory disease. In cardiovascular dis-ease, general anaesthesia with support of the circulation and pulmonary ventilation is often more advantageous than risking hypotension and tachyarythmias exaerobating ischaemic heart disease and resultant angina, which may occur with regional anaesthesia. Regional anaesthesia does provide excellent analgesia into the postoperative period, reducing the need for centrally acting analgesic agents.

The most clear indications for spinal and epidural anaesthesia are in obstetric practice to spare the mother from the risk of pulmonary aspiration because of the full stomach usually present in labour, and also to spare the newborn from the depressant action of the general
anaesthetic and analgesic drugs.

General and regional anaesthesia combined

Combining the two methods of anaesthesia in well-balanced measure enables a patient to receive a lighter general anaesthetic and to have the advantage of good postoperative analgesia. At its simplest, the infiltration of an abdominal wound with local anaesthetic agent will facilitate comfortable breathing in the recovery room.

Regional local anaesthetic techniques

Spinal, plexus and major nerve local anaesthetic blockade may be employed alone or in combination with sedation or general anaesthesia. It is most commonly used for limb, abdominal and thoracic surgery, and obstetric analgesia and surgery.

It is imperative that a second medical practitioner, and not the surgical operator, is responsible for supervision and monitoring of the patient during the procedure.

Preoperative patient preparation for elective regional anaesthesia includes that required for general anaesthesia, with explanation of the local anaesthetic procedure. In emergency, it is safer to use regional anaesthesia on an unstarved patient rather than general anaesthesia, for the risk of aspiration of gastric contents is much reduced although not absent. Some forms of regional anaesthesia with long acting drugs, such as epidural bupivacaine anaesthesia, result in prolonged motor block and may be unsuitable if the patient is expected to be an ambulant day case.

The recently introduced subcutaneous low-molecular-weight heparins (LMWH) for prophylaxis for deep venous thrombosis are longer acting than heparin, and appear to have increased the risk of intraspinal haematoma. Epidural and spinal injections (and catheter insertion or removal) should only be performed at least 12 hours after a LMWH dose, and the next LMWH dose delayed for at least 2 hours. The LMWH doses must therefore be timed appropriately. As with many perioperative management issues, optimal care depends upon close liaison between anaesthetist and surgeon.

Electrocardiogram, pulse oximetry and blood pressure measurements should be performed during regional anaesthesia. Oxygen by face mask should be given to frail or sedated patients during surgery.

Common local anaesthetic techniques

In awake patients the nerve blocks must provide comprehensive numbness throughout the surgical field. The following field blocks are commonly used.

- Brachial plexus block for surgery on the arm or hand.
- Field block for inguinal hernia repair. The iliohypogastric and ilioinguinal nerves are blocked immediately infero-medial to the anterior superior iliac spine. The genito-femoral nerve is infiltrated at the inguinal point and at the pubic tubercle. If a large volume of local anaesthetic is used, the peritoneal sac can be anaesthetised before the incision, but care must be taken to avoid drug toxicity.

Local anaesthetic with 1:200 000 adrenaline prolongs the duration of action and reduces toxicity by producing vasoconstriction. The line of the skin incision should be infiltrated with the mixture.

- Regional block of the ankle. This can be used for surgery on the toes and minor surgery of the foot.

Intravenous regional anaesthesia

The arm to be operated on is exsanguinated by elevation and/or compression, and then isolated from the general circulation by the application of a tourniquet inflated to a pressure well in excess of the systolic arterial pressure. The venous system is then filled with local anaesthetic agent, injected via a previously placed indwelling venous cannula. The drug diffuses from the bloodstream into the nerves to produce an effective block. The arm is more suitable for this procedure (Bier’s block) than the leg because the large volume of drug required for the latter can easily lead to toxicity. The tourniquet must only be deflated after adequate time has elapsed (at least 20 minutes) to allow for the residual venous drug load to fall to a safe level, before it is washed back into the general circulation. Cardiac arrest or convulsions may well occur if the tourniquet is accidentally released before the drug is fixed; this was particularly noted with bupivacaine, which has been banned from use in this procedure after reports both of a number of deaths and of directly toxic effects on the heart. Prilocaine 0.5 per cent up to 50 ml is recommended as the safest agent to use. As above, a separate medical practitioner should supervise the block and monitor the patient, while the surgeon operates.

Intrathecal anaesthesia

Spinal anaesthesia in the awake patient is useful for some forms of surgery in the pelvis or lower limbs. Hyperbaric solutions of bupivacaine are injected as a ‘single shot’ into the cerebrospinal fluid, to produce rapidly an intense blockade, usually within 5 minutes. Autonomic sympathetic blockade results in hypotension, necessitating prior intravenous fluid loading and titration of vasoconstrictor drugs. If the hyperbaric solution is allowed to ascend too high, severe hypotension and ventilatory failure occur. This factor limits the use of spinal anaesthesia to surgery below the segmental level of Tb.

Postoperative headache, due to cerebrospinal fluid leakage through the dural perforation, is nowadays much less common as a result of modern needles (very fine with a round or pencil point tip and side aperture) designed to split rather than cut the dural fibres.

Spinal anaesthesia is much used for Caesarean section, prostatectomy and lower limb surgery. Intrathecal opioid drugs are used to produce postoperative analgesia but there is a significant risk of respiratory depression.

Epidural anaesthesia

Epidural anaesthesia is slower in onset than intrathecal anaesthesia, but has the advantage of multiple dosing and hence prolonged use, as an indwelling catheter may be threaded into the epidural space. Hence, epidural anaesthesia can provide good pain relief extending into the postoperative period. Urinary retention is common, necessitating catheterisation of the bladder. Epidural anaesthesia also includes sympathetic blockade, but it is of slower onset, as is the resulting hypotension, which may be easier to control and can be used to advantage for the surgery, in reduction of blood loss. If a weak solution of bupivacaine or the newer ropivicaine is chosen, epidural anaesthesia can be used to produce a predominantly sensory block for analgesia after upper abdominal or thoracic surgery. The contemporary trend is to
combine weak solutions of local anaesthetic with opioid agents such as the lipid-soluble diamorphine or fentanyl, the latter producing analgesia by their action on the opioid receptors in the spinal cord. However, the potential complication of epidural opioid analgesia is delayed respiratory arrest from rostral spread and central depression, as late as 24 hours after the last dose. Hence, regular monitoring of conscious level and respiratory rate, and facility to immediately reverse the opioid with intravenous naloxone or to resuscitate, are essential prerequisites.

Epidural anaesthesia (with bupivacaïne or ropivacaïne) remains the standard method of anaesthesia during labour and interventional delivery. In contrast to local anaesthetic agents, epidural opioid agents alone do not produce hypotension, so they are preferable for patients who are mobile. There is a current trend towards their use in labour for this reason, but alone they would not produce adequate analgesia for surgical intervention.

Caudal epidural anaesthesia is produced by injection of local anaesthetic agent through the sacrococcygeal membrane. Its main uses are to supplement general anaesthesia and for very effective postoperative pain relief. This analgesic technique is much used in paediatric surgery.
Perioperative pain relief

(acute pain management)

Optimal management of acute postoperative pain requires planning, patient and staff education, and tailoring to the type of surgery and the needs of the individual patient. Patients vary greatly (up to eight-fold) in their requirement for analgesia, even after identical surgical procedures. Under-treatment results in unacceptable levels of pain with tachycardia, hypertension, vasocostriction and 'splinting' of the affected part. Painful abdominal and thoracic wounds restrict inspiration, leading to tachypnoea, small tidal volumes, and inhibition of the patient from effective coughing and mobilisation. This predisposes to chest infection, delayed mobilisation, deep venous thrombosis, muscle wasting and pressure sores.

However, analgesic administration above the patient’s requirement increases the risks of side effects such as nausea, vomiting, somnolence and dizziness or, if greatly in excess, severe central effects including depressed consciousness and respiration. This is fortunately rare, and can be avoided by sensible initial dosing followed by titration until the patient is comfortable. Exaggerated fears of opioid induced central depression and addiction have led all too commonly to inhibition amongst staff from prescribing and administering adequate doses of opioids. Intermittent intramuscular dosing also leads to delays in administration of the ‘controlled’ opioids compounded by the time to onset of action of action.

As a result of these common deficiencies, a Joint Working Party of the Royal Colleges of Anaesthetists and Surgeons was convened, which published the report Pain after Surgery in 1990. It recommended the establishment of acute pain teams, comprising medical and nursing specialists, to oversee the implementation of guidelines for practice including routine recording of pain levels, and educating both staff and patients. Combinations of analgesic methods [local anaesthesia and nonsteroidal anti-inflammatory drugs (NSAIDs) with opioid drugs] were advocated, as were the more sophisticated methods of pain management such as ‘patient-controlled analgesia’.

The Working Party report also encouraged further use of combined treatments (termed balanced analgesia) such as with:

• local anaesthetic blocks — excellent short-term analgesia, but requires skill and has a small failure rate. Continuous catheter techniques prolong pain relief but are only appro-priate for inpatients;

• spinal opioids — generally very useful for appropriate types of surgery, but again requires skill, and is limited by concerns over severe respiratory depression;

• NSAIDs — in combination reduce requirement for opioids and alone are useful for moderate pain, but are limited by concerns over side effects, such as renal impairment, peptic ulceration and inducing acute bronchospasm in asthmatics. They are not adequate as sole analgesic therapy after major surgery.

The report called for further research and, amongst other aims, hoped for the advent of a powerful analgesic on a par with morphine, but without marked respiratory depressant activity. While the development of tailor-made opioid agonists with differential receptor activity has not yet solved this problem, attention turned more to finding alternative pathways at which to attenuate the afferent pain impulses. For example, clonidine has been administered epidurally to stimulate the spinal cord adrenergic inhibitory mechanisms.

Severe acute pain increases morbidity after trauma or surgery.

Appreciation of pain pathways and the three main classes of pain — nociceptive, neuropathic/sympathetic and that of mainly psychological origin — together with enhanced awareness of pain, has led to new and multimodal treatment strategies.

The methods of prevention are:

• adequate analgesia by intravenous narcotic drugs at the time of surgery;

• regional anaesthesia alone or supplementing general anaesthesia during surgery to prevent excitation of central pathways;

• the use of prostaglandin inhibitory drugs during surgery. Diclofenac suppositories are effective in reducing the pain from tissue damage in bone and muscle, and are used at the time of operation.

These three approaches used together are good at preventing the cycle of pain and muscle spasm from becoming established in the recovery period.

The same methods can be used for managing the pain of acute trauma.
Postoperative pain management

Severe pain from a large incision in a frail patient may require high doses of intravenous opiate drugs leading to elective postoperative endotracheal intubation and ventilation until the patient is stable. This approach should be used if the patient is likely to become hypoxic through struggling in pain if other methods of pain relief are not effective. Other methods of pain relief, properly used, can usually prevent the need for mechanical ventilation even in very major thoracic and abdominal surgery. Acute pain relief teams, using continuous methods of pain relief in high dependency areas well equipped with monitoring, are becoming a routine feature of the postoperative care in both the USA and the UK. Regular intramuscular morphine injection, supplemented by anti-inflammatory analgesic drugs and, possibly, a regional anaesthetic block, are effective treatment for the majority of surgical patients. Each patient should have a pain relief measurement chart for regular assessment with other routine nursing observations. Special methods of pain relief used under close supervision are:

- continuous epidural anaesthesia with opiate or local anaesthetic drugs;
- continuous intravenous opiate analgesia;
- patient controlled analgesia by injection intravenously or epidurally of opioid analgesia. The patient is trained to give a bolus dose of drug by pressing a control button on a machine whose functions have been regulated by the medical staff. The strength, frequency and total dose of drug in a given time are all limited by computer.

Effective postoperative pain relief encourages early mobilisation and hospital discharge.

Simple analgesic agents

In minor surgery, and when the patient is able to eat after major surgery, aspirin and paracetamol are often the only drugs necessary to control pain. Fear of metabolic acidosis and Reye’s syndrome of hepatotoxicity in children have made paracetamol a preferable drug to aspirin in the younger age group. Codeine phosphate is the analgesic favoured after intracranial surgery because it does not have a powerful respiratory depressant effect; it may never be given intra-venously as it causes profound hypotension on intravenous injection. Patients with a tendency to peptic ulceration may need cover with omeprazole or misoprostol during analgesic treatment with anti-inflammatory agents.
**Chronic pain relief**

In surgical practice, the patient with chronic pain may present for treatment of the cause (e.g. pancreatitis) or have concomitant pathology. Surgery itself may have been the cause of the now chronic symptom, as acute pain may progress to chronic pain. There is a developing belief that inadequate treatment of acute pain may make this more likely.

Chronic, intractable pain may be of malignant or benign origin and of several types.

- **Nociceptive pain** — pain may result from musculoskeletal disorders or cancer activating cutaneous nociceptors. Pro-longed ischaemic or inflammatory processes result in sensitisation of peripheral nociceptors and altered activity in the central nervous system leading to exaggerated responses in the dorsal horn of the spinal cord. The widened area of hyperalgesia and increased sensitivity (allodynia) has been attributed to increased transmission of afferent pain impulses consequent upon this spinal cord dynamic plasticity.

- **Neuropathic (or neurogenic) pain** — dysfunction in peripher al or central nerves (excluding the physiological pain due to noxious stimulation of the nerve terminals). Neuro-pathic pain is classically ‘burning’, ‘shooting’ or ‘stabbing’, and may be associated with allodynia, numbness and diminished thermal sensation. It is poorly responsive to opioids. Examples include trigeminal neuralgia, metatarsalgia, postherpetic and diabetic neuropathy. Monoaminergic, tricyclic and anticonvulsant drugs are the mainstay of treatment.

- **Psychogenic pain** — psychological factors play a greater or lesser role in many chronic pain syndromes. Whichever the primary cause may have been, depressive illness and chronic pain may exacerbate each other.

The treatment of pain of malignant origin differs from that of pain of a benign cause, and may be the more difficult to overcome. Drugs, preferably, should be taken by mouth, but the patient must be regularly reassessed to ensure that analgesia remains adequate as the disease process changes.

**Malignant disease**

In intractable pain, the underlying principle of treatment is to encourage independence of the patient and an active life in spite of the symptoms. The main guide to the management of cancer pain is the World Health Organisation Booklet (now in its second edition), which portrays three levels of treatment. The ‘pain stepladder’ includes the following treatments:

- **first rung**: simple analgesics — aspirin, paracetamol, NSAIDs, tricyclic drugs or anticonvulsant drugs;
- **second rung**: intermediate strength opioids — codeine, tramadol or dextropropoxyphene;
- **third rung**: strong opioids — morphine. (Pethidine has been withdrawn from the second edition.)

Oral opiate analgesia is necessary when the less powerful analgesic agents no longer control pain on movement, or enable the patient to sleep. Fear that the patient may develop an addiction to opiates is usually not justified in malignant disease.

Oral morphine can be prescribed in shortacting liquid or tablet form and should be administered regularly every 4 hours until an adequate dose of drug has been titrated to control the pain over 24 hours. Once this is established, the daily dose can be divided into two separate administrations of enteric-coated, slow-release morphine tablets (MST morphine) every 12 hours. Additional short-acting morphine can then be used to cover episodes of ‘breakthrough pain’. Nausea is a problem early in the use of morphine treatment and may need control by antiemetic agents, e.g. haloperidol, methotrimeprazine, metoclopramide or ondansetron. Nausea does not usually persist, but constipation is frequently a persistent complication requiring regular prevention by laxatives.

In fusion of subcutaneous, intravenous, intrathecal or epidural opiate drugs

The infusion of opiate is necessary if a patient is unable to take oral drugs. Subcutaneous infusion of diamorphine is simple and effective to administer. Epidural infusions of diamorphine can be used on mobile patients with an external pump. Intrathecal infusions are prone to infection, but implantable reservoirs with pumps programmed by external computer are being used for long-term intrathecal analgesia. Intravenous narcotic agents may then be reserved for acute crises, such as pathological fractures.

**Neurolytic techniques in cancer pain**

These should only be used if the life expectancy is limited and the diagnosis is certain. The useful procedures are:

- subcostal phenol injection for a rib metastasis;
- coeliac plexus neurolytic block with alcohol for pain of pancreatic, gastric or hepatic cancer. Image intensifier control is essential;
- intrathecal neurolytic injection of hyperbaric phenol — this technique is useful only if facilities for percutaneous cordotomy are not available as it can damage motor pathways;
- percutaneous anterolateral cordotomy divides the spino-thalamic ascending pain pathway — this is a highly effective technique in experienced hands, selectively eliminating pain and temperature sensation in a specific limited area.

Alternative strategies include:

- the development of hormone analogues, such as tamoxifen and cyproterone, enables effective pharmacological therapy for the pain of widespread metastases instead of pituitary ablation surgery;
- palliative radiotherapy can be most beneficial for the relief of pain in metastatic disease;
- adjuvant drugs such as corticosteroids to reduce cerebral oedema or inflammation around a tumour may be useful in symptom control. Tricyclic antidepressants, anticonvulsants and, occasionally, flecainide are also used to reduce the pain of nerve injury.

**Pain control in benign disease**

Surgical patients may have persistent pain from a variety of disorders including chronic inflammatory disease, recurrent infection, degenerative
bone or joint disease, nerve injury and sympathetic dystrophy. Chronic pain may result from persistent excitation of the nociceptive pathways in the central nervous system, invoking mechanisms such as spontaneous firing of pain signals at N-methyl-D-aspartate receptors in the ascending pathways. Such activity is poorly responsive to opiates; neuroablative surgery is unlikely to produce prolonged benefit and may make the pain worse.

As is well known, amputation of limbs may result in phantom limb pain, the likelihood being further increased if the limb was painful before surgery. Continuous regional local anaesthetic blockade (epidural or brachial plexus), established before operation and continued postoperatively for a few days, is believed to reduce effectively the establishment of phantom pain.

The following are treatments for chronic pain of benign origin.

- Local anaesthetic and steroid injections — these can be effective around an inflamed nerve and they reduce the cycle of constant pain transmission with consequent muscle spasm. Epidural injections are used for the pain of nerve root irritation associated with minor disc prolapse. This treatment should be in association with active physiotherapy to promote mobility.

- Nerve stimulation procedures — acupuncture, transcutaneous nerve stimulation and the neurosurgical implantation of dorsal column electrodes aim to increase the endorphin production in the central nervous system altering pain transmission.

- Nerve decompression — decompression of the trigeminal nerve at craniotomy is now performed for trigeminal neuralgia, rather than percutaneous coagulation of the trigeminal ganglion, in patients who are fit for craniotomy.

Treatment of pain is dependent on sympathetic nervous system activity. Even minor trauma and surgery (often of a limb) can provoke chronic burning pain, allodynia, trophic changes and resultant disuse. The syndrome has been attributed to excessive sympathetic adrenergic activity inducing vasconstriction and abnormal nociceptive transmission. Management may include:

- test response to systemic alpha-adrenergic blockade using intravenous phentolamine;
- intravenous regional sympathetic blockade using guanethidine, under tourniquet;
- local anaesthetic injection of stellate ganglion or lumbar sympathetic chain.

Percutaneous chemical lumbar sympathectomy with phenol under radiographic control is practised by both surgeons and anaesthetists for relief of rest pain in advanced ischaemic disease of the legs. It can also promote the healing of ischaemic ulcers by improving peripheral blood flow.

**Drugs in chronic benign pain**

Escalating doses of opioid analgesic drugs are to be avoided, and certainly the patient must not become dependent on analgesic injections. However, for debilitating levels of chronic pain, opioid drugs are indicated. Combinations of drugs often prove useful to achieve the optimal combination of efficacy with minimal side-effects.

Paracetamol and NSAIDs are the mainstay of musculoskeletal pain treatment, but NSAIDs are handicapped by gastrointestinal intolerance and peptic ulceration. These carry significant levels of noncompliance, contraindication and morbidity. Specific cyclo-oxygenase 2 inhibition, with preservation of protective cyclo-oxygenase 1 activity, promises to improve tolerability and safety in nonsteroidal anti-inflammatory treatment.

The tricyclic antidepressant drugs and anticonvulsant agents are often useful for diminishing the pain of nerve injury, although side-effects can prove troublesome and reduce compliance.

In the management of chronic pain of benign cause, a multidisciplinary approach by a team using psychologists, physiotherapists and occupational therapists under medical supervision can often achieve much more benefit than the use of powerful drugs. To help the chronic benign pain patients who do not respond to conventional means, ‘pain management programmes’ have been devised, comprising a multidisciplinary approach of pain specialists, psychologists, physiotherapists and occupational therapists. They help a number of the patients to cope with the pain and resume a higher quality life.

Physiology and manifestation

Background. It is clear that the Egyptians knew about infection. They certainly were able to prevent putrefaction which is testified in their skills of mummification. Their medical papyruses also describe the use of salves and antiseptics to prevent wound infections. This had also been known, although less well documented, by the Assyrians and the Greeks, particularly in Hippocratic teachings, which had refined the use of antiseptic antimicrobial practice. The use of wine and vinegar to irrigate open infected wounds before successful secondary closure was practised widely. Common to all these cultures, and the later Roman practitioners, was a dictum that whenever pus developed in an infected wound it needed to be drained.

Galen recognised that localisation of infection (suppuration) in wounds inflicted in the gladiatorial arena often heralded recovery, particularly after drainage of the pus (pus bonum et laudabile). Sadly, this dictum was misinterpreted by many until well into the Renaissance; many practitioners actually promoted suppuration in wounds by application of many noxious substances, including faeces, in the misbelief that healing could not occur without pus formation. There was occasional light in this long, dark tunnel: Theodoric of Cervia, Ambroise Pare and Guy de Chauliac all realised that clean wounds, closed primarily, could heal without infection or suppuration.

The understanding of the causes of infection came in the nineteenth century—Microbes had been seen under the microscope, but Koch laid down the first definition of infective disease (Koch’s postulates). These were basically that a particular microbe could be considered responsible for an infection when it was found in adequate numbers in a septic focus, could be cultured in pure form from specimens taken from the focus and could cause similar lesions when injected into another host.

The Austrian obstetrician, Ignac Semmelwe is, showed that maternal mortality caused by puerperal sepsis could be reduced from over 10 per cent to under 2 per cent by the simple act of hand washing between postmortem examinations and the delivery suite.

Louis Pasteur recognised that microorganisms spoil wine and Joseph Lister applied this knowledge to the reduction of organisms in compound fractures allowing surgery without infection. However, his toxic phenol spray and principles of antisepic surgery soon gave way to aseptic surgery at the turn of the century — a technique still employed in modern operating theatres.

The concept of a ‘magic bullet’ which could kill microbes but not their host led to early sulphonamide chemotherapy.

The antibiotic penicillin, the discovery of which is ascribed to Alexander Fleming, was isolated by Florey and Chain. The first patient to receive penicillin was Police Constable Alexander, who had a severe staphylococcal illness. He made a partial recovery before the penicillin ran out but later relapsed and died. Since then there has been a huge increase in antibiotic groups with improved antibacterial spectra. Few staphylococci are now sensitive to penicillin but streptococcal illnesses respond, although they are seen increasingly rarely in surgical practice. Many bacteria develop resistance through the acquisition of beta-lactamases which can break up the 3-lactam ring, common in the formula of many antibiotics. In general surgery, the synergy of aerobic Gram-negative bacilli with anaerobic Bacteroides spp. presents the most challenging infection. Wide-spectrum antibiotics can be given empirically to treat such infections, or more specific, narrow-range antibiotics given based on culture and sensitivity. The range of surgery now practised owes much to rational antibiotic use — faecal peritonitis may not be considered to be lethal, and wounds made in the presence of such contamination can heal primarily without infection in 80—90 per cent of patients. Patients undergoing prosthetic surgery or who are immuno-suppressed can be spared infection in their wounds by the appropriate use of prophylactic antibiotics.

Physiology

Bacteria are normally prevented from causing infection in tissues by intact epithelial surfaces, but these are broken down by surgery. In addition to this mechanical barrier, there are other protective mechanisms, i.e. chemical (such as the low gastric pH), humoral (antibodies, complement and opsonins) and cellular (phagocytic cells, macrophages, polymorphonuclear cells and killer lymphocytes).

Host response is weakened by malnutrition which may present as obesity as well as recent rapid weight loss (Table 7.1 Metabolic diseases, diabetes mellitus, uraemia and jaundice may weaken defences, and disseminated cancer may also be included together with immunosuppression caused by radiotherapy, chemotherapy, steroids and acquired immunodeficiency syndrome (AIDS) (Fig 7.1 and Fig 7.2).

When enteral feeding is suspended in the perioperative period, the gut rapidly becomes colonised and bacteria, particularly Gram-negative bacilli, translocate to mesenteric nodes. Release of endotoxin may follow, which further increases susceptibility to infection. In these circumstances, nonpathogens become important (opportunism).

The pathogenicity and size of bacterial inoculum also relates to the chance of developing an established wound infection after surgery. Poor surgical technique that leaves devitalised tissue, excessive dead space or haematoma may increase this risk. Foreign materials of any kind, including sutures and drains, promote infection. A logarithm reduction in the number of organisms is needed to cause a wound infection in the presence of a silk suture. These factors need consideration in prosthetic orthopaedic and vascular surgery.

In the first 4 hours after a breach in an epithelial surface and underlying connective tissues made during surgery or trauma, there is a delay before host defences can become mobilised through acute inflammatory, humoral and cellular processes. This period is called the ‘decisive period’ and it is during these first 4 hours after incision that bacterial colonisation and established infection can begin. It is logical that prophylactic antibiotics will be most effective during this time.

Local and systemic manifestation

Infection of a wound can be defined as the invasion of organism(s) through tissues following a breakdown of local and systemic host defences. Sepsis is the systemic manifestation of a documented infection, the signs and symptoms of which may also be caused by multiple trauma, burns or pancreatitis. Bacteraemia should not be confused with this systemic inflammatory response syndrome (SIRS) although the two may coexist (see Table 7.2). Septic manifestations are mediated by release of cytokines [such as interleukins (IL) and tumour necrosis factor (TNF)] and other modules from poly-morphonuclear and phagocytic cells and, in its most severe form, presents as multiple system organ failure (MSOF). Infection may cause SIRS through the release of lipopolysaccharide endotoxin from the walls of dying Gram-negative bacilli (mainly Escherichia coli) and other toxins, which in turn causes release of cytokines (Fig. 7.3). A reduced defence to wound infection follows.

Pathogens resist host defences by release of toxins, particularly in unfavourable anaerobic conditions, which favours their spread in wound infections. Clostridium perfringens, which is responsible for gas gangrene, releases many spreading proteases such as hyaluronidase, lecithinase and haemolysin. Many resistant pathogens can produce beta-lactamases which destroy the beta lactam ring of antibiotics. This resistance can be acquired and passed on through plasmids.

The human body harbours approximately 10^6 organisms. They are released into tissues by surgery, contamination being most severe when a hollow viscus is opened (e.g. colorectal surgery). Any infection which follows may be termed primary, community acquired or endogenous.
Exogenous infections are usually hospital acquired (nosocomial) and are secondary, being introduced into the tissues after surgery not during it, unless introduced via inadequately filtered air in the operating theatre.

A major wound infection is defined as a wound which discharges pus and may need a secondary procedure to be sure of adequate drainage (Fig. 7.4). There may be systemic signs of tachycardia pyrexia and a raised white count (SIRS). The patient may be delayed in returning home beyond the planned day. Minor wound infections may discharge pus or infected serous fluid but should not be associated with excessive discomfort, systemic signs or delay in return home (Fig. 7.5). The differentiation of major and minor wound infection is important in audit trials of antibiotic prophylaxis and is of relevance to ‘league tables’ of hospital infection as major wound infections must be accounted for.
Types of infection

Wound abscesses

A wound abscess presents all the Celsian clinical features of acute inflammation: calor (heat), rubor (redness), dolor (pain) and tumour (swelling), to which can be added functio leea (loss of function). It hurts the infected part is not used. Pyogenic organisms, predominantly Staphylococcus aureus, cause tissue necrosis and suppuration. Pus is also composed of dead and dying white blood cells which release damaging cytokines, oxygen-free radicals and other molecules. An abscess is surrounded by an acute inflammatory response, and a pyogenic membrane composed of fibrinous exudate and oedema, and the cells of acute inflammation. Granula-tion tissue (macrophages, angiogenesis and fibroblasts) forms later around the suppuration and beads to collagen deposition. If excessive or partly stabilised by antibiotics (anti-bioma), a chronic abscess may result. Abscesses usually track along planes of least resistance and point towards the skin. Wound abscesses may spontaneously discharge through a surgical incision but most take 7—9 days to form after surgery. Many infections may present after the patient has left hospital.

Abscesses may need débridement and curettage with an exploration to break down all loculi before resolution can occur. Persistent chronic abscesses may lead to sinus or fistula formation. In a chronic abscess, lymphocytes and plasma cells are seen with sequestration and later calcification. Certain organisms are related to chronicity, sinus and fistula formation, e.g. mycobacteria and actinomycyes, and should not be forgotten.

Perianastomotic abscesses may be the cause or result of anastomotic leakage. Deep cavity abscesses (pleura or peritoneum) may be difficult to diagnose or locate even when there is strong clinical suspicion (Fig. 7.6). Plain or contrast radiographs may not be helpful, whereas ultrasonography, computerised tomography, magnetic resonance imaging and isotope scans are usually accurate and may allow guided aspiration without the need for surgical intervention.

The role of antibiotics in the treatment of wound abscesses is controversial unless there are signs of spreading infection (cellulitis or lymphangitis). Surgical decompression and curettage must be adequate and may allow resuture without antibiotics but this is also controversial. Delayed primary or secondary suture is safer.

Cellulitis and lymphangitis

This is the nonsuppurative invasive infection of tissues. In addition to the cardinal signs of inflammation, there is poor bocabisation. Spreading infection is typical of organisms such as f3-haemolytic streptococci (Fig. 7.7), staphylococci (Fig. 7.8) and C. perfringens. Tissue destruction and ulceration may follow, caused by release of streptokinase, hyaburonidase and other proteases.

Systemic signs (toxaemia) are common: SIROS, chills, fever and rigors. These follow release of exotoxins and cytokines but blood cultures are often negative.

Lymphangitis is caused by similar processes but presents as painful red streaks in affected lymphatics. Cellulitis is usually located at the point of injury and subsequent tissue infection. Lymphangitis is often accompanied by painful lymph node groups in the rebated drainage area.

Bacteraemia and septicaemia

These are unusual in superficial wound infections but common after anastomotic breakdown. They are usually transient and follow procedures undertaken through infected tissues (particularly instrumentation in infected bile or urine). Bacteraemia is important when prosthetics have been implanted, particularly cardiac valves. Septicaemia commonly relates to colonisation and translocation in the gastrointestinal tract and may follow anastomotic breakdown accompanied by MSOF (Fig. 7.3). Aerobic Gram-negative bacilli are mainly responsible but S. aureus and fungi may be involved, particularly after the use of broad-spectrum antibiotics.

Specific wound infections

Gas gangrene is caused by C. perfringens. The Gram-positive, spore-bearing bacilli are widely found in nature, particularly soil and faeces, which is relevant to military and traumatic surgery, and colorectal operations. Patients who are immunocompromised, diabetic or have malignant disease are at risk, particularly when anaerobic wound conditions are present with necrotic or foreign material. Wound infections are associated with severe local wound pain and crepitus (gas in the tissues which may also be noted on plain radiographs). The wound presents a thin, brown, sweet-smelling exudate, from which bacteria can be recognised on Gram staining. Oedema and spreading gangrene follow the release of collagenase, hyaburonidase, other proteases and a-toxin. Systemic complications with circulatory collapse and MSOF supersede without appropriate intervention.

Prophylaxis in patients at risk should always be considered, particularly amputation for peripheral vascular disease. Once established, barge doses of intravenous penicillin and aggressive débridement of affected tissues are required. The use of hyperbaric oxygen is controversial.

Synergistic spreading gangrene (necrotising fasciitis) is not caused by clostridia. A mixed pattern of organisms is respon-sible — cobiforms, staphylococci, Bacteroides spp., anaerobic streptococci and pepto-streptococci have been implicated. Synonyms have been associated with abdominal wall infec-tions (Meloney’s synergistic hospital gangrene) and scrotal infection (Fournier’s gangrene, Fig. 7.9). Patients are almost always immunocompromised (such as diabetes mellitus). The initial wound may have been minor, but severely contaminated wounds are more likely to be the cause. Severe wound pain, signs of spreading inflammation with crepitus and smell lead on to widespread gangrene. The extent of subdermal spread of gangrene is always much more extensive than at first is apparent. Wide-spectrum antibiotic therapy must be combined with aggressive circulatory support and wide excision and laying open of affected tissue. Débrid-ment may need to be extensive. Patients who survive need barge areas of skin grafting.
Treatment

Following the trend to discharge patients earlier, many wound infections may be missed by surgeons unless they undertake a prolonged and carefully audited follow-up with family doctors. Suppurative wound infections take 7—10 days to develop, whereas cellulitis around wounds caused by invasive organisms (such as the beta-haemolytic streptococcus) appears in 3-4 days. Major wound infections with systemic signs (Fig. 7.10) or evidence of cellulitis justify the use of appropriate antibiotics. The choice may be empirical or based on culture and sensitivities of isolates harvested at surgery. Although the identification of organisms in wound infections is necessary for audit and wound surveillance purposes, it is usually 2—3 days before sensitivities are known (Fig 7.11 and Fig 7.12). It is illogical to withhold antibiotics but if clinical response is poor by the time sensitivities are known then antibiotics can be changed. This is unusual if the empirical choice of antibiotics is sensible — change of antibiotics promotes resistance and risks complications, such as Clostridium difficile enteritis. When the wound is under tension or there is clear evidence of suppurative removal of sutures aids evacuation of pus. There is no evidence that subcuticular continuous skin closure enhances or worsens the effect of suppuration. In severely contaminated wounds, e.g. laparotomy for faecal peritonitis, or incisions made for drainage of an abscess, it is logical to leave the skin layer open. Delayed primary or secondary suture is undertaken when the wound is clean and granulating (Fig 7.13 and Fig 7.14). Leaving wounds open after dirty operations is not practised as widely in the UK as in the USA or mainland Europe.

When taking pus from infected wounds, specimens should be sent fresh for microbiological culture. Swabs should be placed in transport medium but as barge a volume of pus as possible is likely to yield more accurate results. Communication with microbiologists is essential for the most meaningful results. If bacteraemia is suspected, repeat specimens may be needed to exclude negative results.

Reports on infective material can be based rapidly on an immediate Gram stain. Aerobic and anaerobic culture on conventional media allows sensitivities to be assessed by disc diffusion. The measurements of minimum inhibitory antibiotic concentrations (MIC in mg/litre), together with measurements of endotoxin and cytokine levels, are usually only used in research.

Many dressings are now available for use in wound care. These are listed in Table 7.3. Polymeric films are used as incise drapes and also to cover sutured wounds but are not indicated for use in wound infections. Agents that can be used to help débride open infected wounds, others to absorb excessive exudate or to encourage epithelialisatation and formation of granulation tissue are also listed (Fig. 7.15).
Prophylaxis

Prophylactic antibiotics. If antibiotics are given empirically they must exert their action when local wound defences are at their best (the decisive period). Ideally, maximal blood and tissue levels should be achieved at incision before contamination occurs. Intravenous administration at induction of anaesthesia is optimal. In long or prosthetic operations, or unexpected contamination, antibiotics may be repeated 8 and 16 hours later. The empiric choice of an antibiotic depends on the expected spectrum of organisms likely to be encountered, the cost and local policies, which are based on experience of local resistance trends. The use of the newer, wide-spectrum antibiotics for prophylaxis should be avoided. Table 7.4 gives some examples of prophylaxis which can be used in elective surgical operations.

Lower limb amputation should be covered against C. perfringens using 1.2 g of benzyl penicillin intravenously at induction or anaesthesia and hourly thereafter for 48 hours.

Patients with known vavvubar disease of the heart (or with any implanted vascular or orthopaedic prosthesis) ought to have prophylaxis during dental, urobogical or open viscus surgery. Single doses of wide-spectrum penicillin, e.g. amoxyciblin, orally or intravenously administered, are sufficient for dental surgery. In urobogical instrumentation a second generation of cephabosporin, such as cefuroxime, is sufficient but, in open viscus surgery, addition of metro-nidazole should be considered.

Preoperative preparation. Short preoperative hospital stay lowers the risk of acquisition of methicibbin-resistant S. aureus(MRSA) and multiply resistant, coagulase-negative staphylococci (MRCNS). The value of personal hygiene is obvious (both patient and surgeon). Open, infected skin lesions should preclude admission to the operating theatres.

The value of antiseptic bathing (usually chborhexidine) is popular in Europe but there is no hard evidence for its efficacy in reducing wound infections. Preoperative shaving should be avoided except for aesthetic reasons or to prevent adherence of dressings. Shaving should be undertaken immediately before surgery but poses a higher infection rate (over 5 per cent) when performed the night before because minor skin injury enhances superficial bacterial colonisation. Cream depilation is messy but clipping is best, with beard infection (reportedly under 2 per cent in clean wounds).

Scrubbing of operators’ hands with aqueous antiseptics should be confined to nails for the first operation of the day (repeated extensive scrubbing releases more organisms), with washing to the elbows, repeated alone for subsequent operations. Skin preparation of the operative site is adequate with one application of an alcoholic antiseptic (over 95 per cent reduction in flora and fauna). Antiseptics in common use are listed in Table 7.5.

Theatre technique and disciplines also contribute. Only careful surveillance can ensure the quality of theatre ventilation, instrument sterilisation and aseptic technique. Operator skill in gentle manipulation and dissection of tissues is much more difficult to measure but avoidance of dead space, excessive use of diathermy and haematomas surely contribute. There is no evidence that drains, incise drapes or wound guards help to reduce wound infection.

Similar wound surveillance is needed in postoperative care. Secondary (exogenous) nosocomial infections are related to poor hospital wound care. Outbreaks of MRSA are rare but serious. This organism also acts as a marker of adequacy of postoperative wound care but can be very difficult and expensive to eradicate.

Careful audit should lead to changes in practice and follow-up should ensure that loops are closed. It is critical that surgeons manage their own audit — league tables kept by nonmedicab or related personnel must be accurate but are to be deprecated. Scoring systems are useful in audit but, in general, have only been used in wound infection research.
Classification of wounds

Potential for infection

The best measure of wound contamination at the end of an operation, and the risk of developing infection, is to sample tissue in the wound edge. Bacteria will already be affected if antibiotic prophylaxis has been given, but the theoretical degree of contamination relates well to infection rates (Table 7.6). When wounds are heavily contaminated or an incision is made into an abscess, continuing prophylaxis as therapy is justified. Infection rates after nonprosthetic clean surgery may be higher if looked for. Antibiotic prophylaxis is controversial.

Bacteria involved in wound infection

Streptococci form chains and are Gram positive on staining (Fig. 7.16). The most important is the 13-haemolytic streptococcus which resides in the pharynx of 5—10 per cent of the population. It is in group A of the Lancefield A—G carbohydrate antigens. The alternative name of Streptococcus pyogenes is deserved because of its tendency to spread (cellulitis) and to cause tissue destruction through release of streptolysin, streptokinase and streptodornase. Streptococcus faecalis is the enterococcus in Lancefield group D (often found in synergy with other organisms) and the y-haemolytic (no haemolysis on blood agar) peptostreptococcus is an anaerobe. Both may be involved in wound infection after large bowel surgery. The ct-haemolytic Streptococcus viridans is not related to wound infections. The streptococci are still sensitive to penicillin; erythromycin and cephabosporins are alternatives in case of allergy.

Staphylococci form clumps and are Gram positive (Fig. 7.17). Staphylococcus aureus is the most important pathogen in this group and resides in the nasopharynx of up to 15 per cent of the population. It can cause exogenous suppuration in wounds (and implanted prosthetics), and MRSA can be involved in epidemics. Doctors and nurses may need to be swabbed and carriers identified and treated in an epidemic. Infections are usually localised (see Wound abscess above). Most hospital S. aureus strains are now f3-lactamase producers and are resistant to penicillin. Sensitivity to flucloxacillin, vancomycin, aminoglycosides, some cephabosporins and fusidic acid (used in osteomyelitis) is still high.

Staphylococcus epidermidis (syn. albus and most conventionally coagulase-negative Staphylococcus) was regarded as a commensal but is now recognised as a major threat in prosthetic (vascular and orthopaedic) surgery. It exists in hospitals as a nosocomially acquired organism and is resistant to many antibiotics.

Clostridial organisms are Gram-positive, obligate anaerobes which produce resistant spores (Fig. 7.18). Clostridium perfringens is the cause of gas gangrene (Specific wound infections above). Clostridium tetani causes tetanus following implantation in the tissues or a wound by release of the exotoxin tetanospasmin. A short prodromal period is related to development of severe spasms including opsithotonus, respiratory arrest and death. A longer prodromal period of 4—5 weeks is associated with a much milder form of the disease. Prophybaxis with toxoid is the best preventative treat-ment but, once established, minor débridement with benzyl penicillin and reoxants (even with ventilation) may be required. The use of antitoxin is controversial.

Clostridium difficile is the cause of pseudomembranous colitis but is not involved in wound infection.

Aerobic Gram-negative bacilli (AGNB) are normal inhabitants of large bowel. Escherichia coli and Klebsiella spp. are lactose fermenting; Proteus is nonlactose fermenting. Most organisms in this group act in synergy with Bacteroides to cause wound infections after bowel operations (in particular appendicitis, diverticulitis and peritonitis). The pseudomonads tend to colonise burns and tracheostomy wounds, as well as the urinary tract (all members of this group are a cause of urinary tract infection). Pseudomonads may be regarded as markers and colonise wards and intensive care units from which they may be difficult to eradicate. Surveillance of cross-infection is important in outbreaks. Hospital strains become resistant to 3-lactamase which can be transferred by pbasmids and individual sensitivity testing may be needed. Wound infections only need antibiotic therapy when there is progressive or spreading infection with systemic signs. The aminoglycosides are effective but some cephalosporins and penicillin may not be. Many of the new quinolones, e.g. ciprofloxacin, or carba-penems, e.g. meropenem, are useful in severe infections.

Bacteroides are nonspore-bearing, strict anaerobes which colonise the large bowel, vagina and oropharynx. Bacteroides fragilis is the principal organism which acts in synergy with AGNB to cause wound infection after colorectal or gynae-cological surgery. They are sensitive to the imidazobes, e.g. metronidazole, and some cephalosporins, e.g. cefotaxime.
Principles of antimicrobial treatment

Antimicrobials may be used to prevent (Prophylaxis above) or treat established wound infection. The use of antibiotics for established infection in wounds ideally requires the isolation of the bacterium and a determination of its sensitivity; this is the overriding first requirement, for after antibiotics are administered, the clinical picture may be confused, the patient no better, and the opportunity to make a precise diagnosis has been lost. However, it is unusual to have to treat wound infections with antibiotics. Only spreading infection or signs of systemic sepsis really justify them. Appropriate treatment must include drainage of pus and débridement if necessary. Presented with pus, or other material draining from a wound, the microbiologist can isolate the causative organisms and this may guide therapy. There are two approaches to treatment:

- the use of a narrow-spectrum antibiotic to treat a known sensitive infection, e.g. an MRSA sensitive to flucloxacillin (or if not, vancomycin), isolated from pus;
- the use of broad-spectrum antibiotic combinations where the organism is not known or where it is suspected that there may be one, two or more, usually gut-derived bacteria responsible for the infection acting in synergy. Thus, during and following emergency surgery within the abdomen, or requiring the opening of bowel where any of the gut organisms may be responsible for subsequent peritoneal or bacteraemic infection, a combination of broad-spectrum penicillins, such as ampicillin or mezlocillin with an amino-glycoside, e.g. gentamicin, and metronidazole may be used postoperatively to support the patient’s own body defences.

Alternatives are a cephalosporin, e.g. cefturoxime, with metronidazole (increasingly popular as gentamicin toxicity and monitoring of bevels are avoided), or monotherapy using a carbapenem or quinolone.

In surgical units with multiple resistant Pseudomonas or other Gram-negative species (such as Klebsiella) which have become ‘resident opportunists’, there may become a necessity for antibiotics and anti-Gram-negative chemotherapy between the broad-spectrum penicillins, e.g. azlocillin 2 g i.v. 8-hourly and cephaporosins, e.g. cef-tazidime 50—100 mg/kg per day, or ceftoxime 2 g 8-hourly.

The use of these routines, the monitoring of subsequent wound infection and the alternation of combinations of chemotherapy should be monitored by the infection control team. It should not be forgotten, in treating postoperative pyrexial infection, that a failure to respond to a very broad spectrum of these combined antibiotics requires a critical bedside review to exclude collections of pus and other causes of a raised temperature.

New antibiotics should be used with caution and, whereever possible, sensitivities should have been obtained. There are certain general rules from which the choice of antibiotics may be based originally; thus it is unusual for Pseudomonas aeruginosa to be found as a primary infecting organism unless the patient has had surgical or hospital treatment. Local antibiotic sensitivity patterns vary from centre to centre and from country to country, and the sensitivity patterns of common pathogens will be known to the hospital microbiologist.

Antibiotics used in treatment and prophylaxis of wound infection

Antimicrobials may be produced by living organisms (antibiotics) or by synthetic methods. Some are bactericidal, e.g. penicillins and aminoglycosides, and others bacteriostatic, e.g. tetracycline and erythromycin. In general, penicillins act upon the cell wall and are most effective against bacteria that are multiplying and synthesising new cell wall materials. The aminoglycosides act at ribosomal bevel, preventing or distorting the production of proteins required to maintain the integrity of the enzymes in the bacterial cell.

Penicillin. Florey and Chain produced the first therapeutic preparation in 1941, benzylpenicillin, which has proved most effective against Gram-positive pathogens including most streptococci, the coxstidia and some of the staphylococci which do not produce β-lactamase. It is still effective against actinomycosis, which rarely is a cause of wound infection, and may be used to treat spreading streptococcal infections specifically, even if other antibiotics are required as part of therapy of a mixed infection. All serious infections, e.g. gas gangrene, require high-dose intra-venous benzylpenicillin, e.g. 1.2 g 4-hourly.

Flucloxacillin and methicillin. These are beta-lactamase-resistant penicillins and are therefore of use in treating staphylococcal 3-beta-lactamase-producing organisms. This is the only reason for using them; and flucloxacillin has poor activity against other pathogens.

Ampicillin and amoxycillin. These 3-bactam penicillins are absorbed orally or may be given parenterally. Pharmaco-dynamically, amoxycillin is superior. Both are effective against enterobacteriaeae, against E. faecalis and the majority of group D streptococci, but not species of Klebsiella or Pseudomonas.

Mezlocillin and azlocillin. These are ureidopenicillins with good activity against species of Enterobacter and Klebsiella. Azlocillin is particularly effective against Pseudomonas. Each has some activity against Bacteroides and enterococci, but each is susceptible to 13-lactamase. Combined with an amino-glycoside, mezlocillin is a valuable treatment for severe mixed infections, particularly Gram-negative organisms in the immunocompromised patient. Klebsiella strains are best treated with mezlocillin, Pseudomonas strains with azlocillin.

Clavulanic acid is available combined with amoxycillin for oral treatment. This anti beta lactamase protects the amoxycillin from inactivation by beta-lactamase-producing bacteria. It is of considerable value for treating Klebsiellastrains and beta-lactamase-producing E. coli infections, but of no value against Pseudomonas strains. Sometimes it is used for localised ecbobullos or superficial staphylococcal infection and should be used for infected human and animal biles. It is available for oral or intravenous therapy.

Cephalosporins. There are many beta-lactamase-susceptible (not further considered here) and beta lactamase-stabbe cephalosporins available. There are three that find a place in surgical practice: cefuroxime, cefotaxime and ceftazidime. The first two are most effective in intra-abdominal skin and soft tissue infections, being active against S. aureus, and most entero-bacteria. As a group, the enterococci (S. faecalis) are not sensitive to any of the cephalosporins. Ceftazidime, although being active against the Gram-negative organisms and, to a lesser extent, S. aureus, is most effective against P aeruginosa. These cephalosporins may be combined with an amino-glycoside, such as gentamicin, or an imidazole, such as metronidazole, if guaranteed anaerobic cover is needed.

Aminoglycosides. Gentamicin and tobramycin have similar activity and are particularly effective against the Gram-negative enterobacteriaeae. Gentamicin is effective against many strains of Pseudomonas, although resistance develops rapidly, but all aminoglycosides are inactive against anaerobes and streptococci. Serum levels immediately before and 1 hour after intramuscular injection must be taken 48 hours after the start of therapy, and dosage should be modified such that the trough level remains at or below 2.5 mg/litre and the peak level should not rise above 10 mg/litre. Ototoxicity and nephrotoxicity may follow sustained high toxic levels. They have a marked postantibiotic effect and single large doses are effective and may be safer.

Vancomycin is most active against Gram-positive bacteria. It is ototoxic and nephrotoxic. Serum bevels should be moni-tored but this...
antibiotic has proved most effective against multiresistant staphylococcal infection and, when given oral-by, it is effective against C. difficile in cases of pseudomembranous colitis.

Metronidazole is the most widely used member of the imidazob group and is active against all anaerobic bacteria. It is particularly safe and may be administered orally (up to 600 mg 8-hourly), rectally (up to 1 g suppository 8-hourly) or intravenously (500 mg 8-hourly). Infections with anaerobic cocci and strains of Bacteroides and Clostridia are effectively treated — or prevented — by its use. Metronidazole is responsible for the reduction of anaerobic infections after abdominal, coborectab and pelvic surgery.

Mention has been made of meropenem which, together with imipenem, is a member of the carbopenems, which are stable to beta-lactamase. They have useful broad-spectrum anaerobic as well as Gram-positive activity but are expensive.

The quinolones are potent microbicidab agents with action against Pseudomonas spp., e.g. ciprofloxacin. Their clinical robe in managing wound infection has not been defined.

Clostridia

Tetanus

It has been estimated that, every year, between 300 000 and 500 000 cases of tetanus occur world-wide with an overall mortality of 40—45 per cent. In the UK, 200 cases occur annually, and the condition is also relatively uncommon elsewhere in Europe, in the former Soviet Union and in North America. The burden of this agonising infection falls on those in the other countries of the world, particularly on the children, the neonates (tetanus neonatorum) and the elderly. An education programme to have universal active immunisation can and will lead to a reduction in the number of cases and, significantly, the mortality. Tetanus toxoid (now known as tetanus vaccine) practically eliminated tetanus in the armies during World War II. Today, if active immunity is properly initiated and maintained in an individual, death is unlikely even in the presence of clinical tetanus.

_Clostridium tetani_, the causal organism, is a Gram-positive anaerobic rod with terminal spores (drumstick appearance, Fig. 7.18). Found in manure and soil (notably in market garden areas), it will invade any wound. It multiplies and produces a powerful toxin in any deep, contused wound in the presence of dead tissue, foreign bodies and other bacteria. Penetrating injury from the hoof of an animal can be associated with this infection, while the prick from a rose thorn in a well-manured rose garden can be the sting of death to an elderly assiduous horticulturalist. The exotoxin produced in the inoculation site inhibits the cholinesterase at the motor endplates, resulting in an excess of acetylcholine locally and, therefore, a sustained state of tonic muscle spasm. The exotoxin also travels along the nerves to the central nervous system and causes extreme hyperexcitability of motor neurons in the anterior horn cells, thereby evoking explosive and widespread reflex spasms of muscle in response to sensory stimuli. Once fixed in the nerve anterior, the toxin can no longer be neutralised by antitoxin.

**Period of onset**

The shorter the interval between the first symptom and the first reflex spasm the poorer is the prognosis. (Hippocrates, _circa_ 46—77 BC, is believed to have been the first to recognise this fact.) If the interval is less than 48 hours, death is likely. It should be remembered that wounds containing tetanus organisms may have healed and been forgotten for months or years before some (unknown) change produces the right conditions for the organism to multiply and produce toxin (latent tetanus).

**Symptoms and signs**

Dysphagia, jaw stiffness and severe pains in the neck, back and abdomen precede the tonic muscle spasms. The sardonic smile of tetanus (_risus sardonicus_) is evidence of the onset of tonic muscle spasm. Respiration and swallowing become progressively more difficult, and reflex convulsions occur affecting all muscles and causing great pain, opisthotonus (spasm of the extensors of the neck, back and legs to form a backward curvature) and even muscle rupture. The spasms are spontaneous, but can be induced by trivial stimuli such as noise or movement and, when severe, will prevent respiration and produce cyanosis. Between the reflex convulsions, the tonic muscular spasm remains, thus distinguishing strychnine poisoning. The temperature is elevated, the pulse is rapid, and respiratory failure and death during a cyanotic attack will usually follow if treatment is not initiated.

At an early stage, the symptoms and signs of tetanus might be mistaken for tonsillitis, flu, backstrain or an acute upper abdominal condition. Therefore, careful examination of the patient for a wound is of paramount importance.

**Treatment**

Isolation, quietness and comfort, drainage of pus and wound toilet will be needed. Human anti-tetanus globulin (e.g. Humotet) is given intramuscularly (i.m.) to limit the effects of free toxins and should be used in doses of 25—500 units to give cover throughout the period of establishing active immunity by giving toxoid (tetanus vaccine, adsorbed) i.m. Equine tetanus antiserum has been used but about 20 per cent of patients develop serum sickness and occasional anaphylactic reactions occur. Antibiotics, including penicillin and metronidazole, are indicated along with measures to protect the lungs.

**Stage 1.** A mild case, where there is tonic rigidity alone, will require initial sedation, relaxation by drugs such as promazine up to 200 mg i.m. and a barbiturate or diazepam [—50 mg intravenously (i.v.)]. These drugs will be needed approximately four times during any 24-hour period.

**Stage 2.** A seriously ill patient, with dysphagia and reflex spasm, will need to have a nasogastric tube passed and sedation continued. The diet, the need for intravenous nutrition, the maintenance of balanced protein intake, and of renal function and cardiac function will be priorities. A tracheostomy should be considered if the patient has any difficulty in breathing. The meticulous care of the tracheostomy tube includes suction and humidification (Chapter 43).

**Stage 3.** In dangerously ill patients, a major cyanotic convulsion will require curarisation, e.g. up to 40 mg tubocurarine i.v. initially and afterwards i.m. to maintain relaxation. It should be remembered that the curarised patient, although unresponsive, is conscious and sensitive and can hear every-thing that is being said. Intermittent positive-pressure respiration should be provided, and intensive nursing care with increasing sedation would be needed because it has been estimated that a patient at this stage will require at least 350 individual acts of nursing each day. The objective is to reduce the risk of death from spasms or pneumonia wherever pos-sible, while realising that a lethal amount of toxin has already caused severe damage to the motor neurons and the brain with concomitant myocarditis and vascular failure. If recovery takes place, the patient can be weaned from the ventilator (after about 14 days as long as convulsions do not recur when the effects of the relaxants wear off).

Results. With the proper attention to nursing care, prophylactic antibiotic therapy, active and passive suction against tetanus and, where indicated, tracheostomy, curarisation and assisted respiration, the death rate can be reduced to approximately 15 per cent. The results in the very young and very old nevertheless are still poor. The tetano-spasmin produced by the infection is insufficient to generate an immune response so a course of immunisation is recommended on recovery.

**Gas gangrene**

Wounds allowing the patient's own faecal flora, or clostridial spores in the soil, to enter the tissues can give rise to anaerobic gas-producing infections. Surgery around the hip joint and leg amputations are at high risk from this post-operative complication, as are the wounds of warfare (Chapter 19). _Clostridium perfringens_ (welchii) is usually the cause in about 80 per cent, but other clostridia, including _Clostridium novyi_ (Clostridium oedematium), _Clostridium histolyticum, Clostridium bifermentans_ tans and _Clostridium septicum_ may be causal. _Clostridium welchii_ is found in the stools and therefore is also found on the perineum and, occa-sionally, as normal flora in the vagina. The clostridia produce...
numerous toxins, including an α-toxin believed to be important in the pathogenesis of gas gangrene.

Clostridial invasion of a traumatised muscle affects the whole of that muscle from origin to insertion, producing a foul-smelling necrosis of the bundles which lose contractibility and become dull red, green or black in appearance. If septicaemia occurs, gas is produced in many organs, notably the liver (which at necropsy drips with frothy blood — the ‘foaming liver’).

Subcutaneous tissues alone can be infected; the foul-smelling necrosis, often spreading extensively, can begin in the margin of an abdominal or a thoracic wound.

**Clinical features**

The wound is under tension and between the sutures the pouting edges exude a brownish and foul-smelling fluid. The skin becomes discoloured — a khaki colour — owing to associated haemolysis. Crepitus can usually be detected. (Crepitus, to the examining hand, feels like an old hair mattress.) A radiograph will show the gas in the muscles or under the skin. The patient, although toxic and pale, with raised pulse, misleadingly appears mentally clear.

**Treatment**

Treatment, to be effective, requires immediate action:

1. maximum doses of penicillin (up to 2.4 g 4-hourly) — traditionally the treatment of choice, although recent work suggests a better outcome with clindamycin and metronidazole;
2. blood transfusion;
3. either exposure of all the affected muscle groups by long incisions or, in the subcutaneous infections, multiple subcutaneous drainage and slough extraction by incisions into the subcutaneous tissue;
4. hyperbaric oxygen where this is available. It is said to be helpful in the postoperative period.

The use of antiserum used to be recommended, but clinical experience was variable, stocks are now depleted and there has been little interest in resuming production.

**Clostridial pseudomembranous colitis**

This is an acute, profuse, antibiotic-associated diarrhoea which produces characteristic changes of the colon, recognisable sigmoidoscopically by a pseudomembrane and subsequently by sloughing of the colonic mucosa. The organism responsible, *C. difficile*, produces a toxin which cross-reacts with *Clostridium sordellii* antitoxin to produce a serious, sometimes fatal, colitis. The toxin can be demonstrated by its cytopathic effect in cell culture as well as by a number of commercial enzyme-linked immunosorbent assay (ELISA) kits. The organism can be cultured from stool but this does not necessarily indicate a pathogenic role. A spectrum of disease is recognised, ranging from antibiotic-associated diarrhoea (AAD) to antibiotic-associated colitis (AAC) to pseudomembranous colitis (PMC). The incidence is high among older patients, especially where broad-spectrum antibiotics (penicillins and cephalosporins) or clindamycin have been used, although almost every antibiotic has been implicated.

Treatment involves stopping antibiotic therapy where possible, general supportive measures and oral metronidazole or vancomycin. Relapse is well documented and further courses of therapy may be required. Being a sporing organism, it survives well in the hospital environment and in some centres is a considerable problem. It is readily transmitted by hand contact.

**The salmonellas**

*Salmonella typhi, paratyphi.* These are enteric pathogens which cause enteric fevers with bacteraemia, osteomyelitis and sometimes perforation of ileal ulcers. Persistence of the bacteria in the gallbladder may lead to the carrier state and subsequently person-to-person spread in the community (see Chapter 54). The use of ciprofloxacin 500 mg twice daily for 10 days is recommended for *S. typhi* infections although resistance has now been demonstrated in the Indian subcontinent. It is useful as it prevents or cures long-term carriage, and resistance to the more commonly used drugs (ampicillin, chloramphenicol) has reached very high levels in some parts of the world. The other salmonellas are associated with food poisoning, diarrhoea and, therefore, dehydration. Control of the symptoms only is usually required, and the use of antimicrobials is not usually helpful for thereby resistant strains are encouraged, excretion can be prolonged, and in any case the intestinal symptoms are self-limiting. In the unusual event of systemic spread and bacteraemia, it will be necessary to use the antibiotics to which the isolate is sensitive. If treatment is started before the organism is isolated, a broad-spectrum penicillin combined with an aminoglycoside may then be required. The commonest nontyphoid salmonellas are *S. typhimurium, S. enteritidis* and *S. virchow*. They are found in cattle, calves, poultry, turkeys and domestic animals, and infection in humans is by direct spread from contaminated food. These organisms can spread within a hospital if patients (or staff) with diarrhoea are not recognised as a risk; close contacts of excreta must be properly protected by apron and gloves to reduce the likelihood of the infection being spread by unwashed hands which have become conta-minated with faeces.
Mycobacteria

Tuberculosis

*Mycobacterium tuberculosis* was discovered by Robert Koch in 1882, while he was working in the Imperial Health Office, Berlin, Germany. This acid-fast bacillus is spread by airborne infection (or from infected cows in the case of bovine tuberculosis). There are three routes of primary infection:

- direct spread to lungs;
- from tonsils to the lymph nodes of the neck where an abscess may form and track round the edge of the sternomastoid muscle, producing a collar-stud abscess;
- from lower ileal infection to the lymph nodes of the ileocaecal angle.

The bacterium, which produces no pigment, grows well at 37°C and may be seen, if there are very many organisms, in the Ziehl—Neelsen stained smear. Growth of the bacteria takes 6 weeks; thus sensitivities to the antituberculous drugs will be delayed. Recently, new techniques — including the polymerase chain reaction (PCR) — have given hope that more rapid diagnosis will soon be possible.

For the accounts of the manifestations of this disease in various organs as applied to the practice of surgery, the reader is referred to the appropriate chapters of this book.

**Guidelines for treatment**

Nutrition and hygienic living conditions are still crucially important in preventing the spread of this infection.

Treatment with triple therapy consisting of rifampicin 600 mg, isoniazid 300 mg and pyrazinamide 1500—2000 mg per day given orally for at least 2—3 months is the standard chemotherapy at present, followed by 6 months of double therapy (rifampicin plus isoniazid). Sensitivity testing is usually available at the end of the first period of triple therapy and, if the source of the infection is with an organism that is resistant to one of these drugs, appropriate changes can then be made. Ethambutol may be of use in resistant cases. In cases of pulmonary tuberculosis, the sputum should be examined to assess progress every month until the smears are negative, but should the number of acid-fast bacilli increase or the cultures remain positive, the development of resistance or non-compliance of the patient with treatment should be considered.

Genitourinary and orthopaedic tuberculosis is usually effectively treated by the standard 9-month course but the use of pyrazinamide with rifampicin and isoniazid may be required. All of these antituberculous drugs have side effects which may require repeated careful assessment and control; isoniazid causes a peripheral neuritis, ethambutol produces visual impairment and rifampicin is hepatotoxic. Pyrazinamide should be avoided in patients with gout.

It should be remembered that it is nigh impossible to eradicate every tubercle bacillus from the body. Lying dormant and enveloped in fibrous tissue, any remaining bacilli are still able to cause a flare-up of the disease, particularly after trauma, after gastrointestinal operations resulting in nutritional deficiency, and in old age, immune deficiency or long-term use of steroids. Of great concern recently is the appearance of multidrug-resistant tuberculosis (MDRTB). This has arisen as a result of poor compliance with treatment. Although there are some drugs available to treat these strains, patients with underlying immunosuppression often fail to respond and this means that the disease is now a serious threat among patients with human immunodeficiency virus (HIV) infection. Several outbreaks have been described among acquired immunodeficiency syndrome (AIDS) sufferers and a number of healthcare workers has also been infected. Drugs that may be useful in the treatment of MDRTB include ethionamide, ofloxacin, capreomycin and cycloserine.

Opportunist mycobacteria

'Slow-growing' opportunistic mycobacteria may be found producing lesions similar to *M. tuberculosis* in susceptible patients. Thus, *M. kansasii* is a slow-growing opportunist mycobacterium which may cause pulmonary lesions. *Mycobacterium chelonae* and *M. fortuitum* occasionally cause subcutaneous abscesses following skin trauma. This group should always be remembered in the differential diagnosis of subcutaneous abscesses associated with skin traumas or injections (e.g. tetanus immunisation). Skin granulomas in swimmers may be caused by *M. marinum*, while the surgically important Buruli ulcer occurring in East Africa, which affects the exposed surface of the limbs, is caused by *M. ulcerans*, and presents as a spreading granulomatous nodule which subsequently breaks down and forms an ulcer. Incision of the nodule at an early stage and treatment with rifampicin may prevent an ulcer forming, but secondary infection of a Buruli ulcer may result in fibrosis and considerable deformities of a limb as a result. *Mycobacterium avium-intracellulare* is becoming increasingly recognised as a pathogen in patients with AIDS. All of the opportunistic mycobacteria should be cultured to assess their sensitivity to the antituberculous drugs.

Leprosy (Hansen’s disease)

Gerhard Hansen first showed that leprosy was a bacterial infection caused by *M. leprae*. Because of the stigma attached to leprosy, Dr R.G. Cochrane and others recommended that it should be referred to as Hansen’s disease. There are probably from 10 to 15 million leprosy sufferers in the world today.

Leprosy is an infectious disease widely spread throughout the tropical and subtropical areas of the world. It is caused by *M. leprae*, an acid-fast bacillus morphologically like the tubercle bacillus. It is mainly, but not entirely, contracted in childhood and late adolescence. While the mode of trans-mission regarding the portal of entry of *M. leprae* is not known, the source of infection is mainly from the nasal secretions of patients with lepromatous leprosy and not from their skin. Leprosy is no longer endemic in northern Europe, as it was in the Middle Ages, and in Norway until the late nineteenth century; neither is it now spread by immigrants in Europe. These facts suggest that leprosy requires for its transmission some factors associated with poverty or lack of hygiene that are common in the areas where it is still endemic. A vast change in the outlook for this disease has occurred in the last 30 years. The condition was formerly regarded as hopeless, but in spite of the fact that it is no’ y curable, only 25 per cent of the cases of this widely spread disease are under treatment. It is probably true to say that leprosy causes more paralysis, deformity and misery than any other disease, but that, in many cases, these could now be prevented by modern therapy, given an adequate service for early diagnosis.

Although leprosy is a systemic infection, it presents predominantly as an infection of the skin, upper respiratory tract and dermal and
peri-pher al nerves. Leprosy must always be considered in a patient presenting with a combination of skin and neural disorder, particularly because of the variation in the preponderance of these two manifestations and the tremendous variation in the appearance and histopathology of the dermal lesions among individual patients with leprosy. These diverse manifestations led to a plethora of classification systems until Ridley and Jopling found that there was a spectrum of disease in leprosy determined by the resistance of the host (Fig. 8.1). The spectrum ranges from polar lepromatous (LL) to polar tuberculoid (TT) leprosy, denoting patients with minimal and maximal irreversible capacities to mount an immunological response against *M. leprae*. The majority of patients is more labile in having some residual immunological capacity against *M. leprae*, and thus are represented as borderline (BB), or borderline lepromatous (BL) or borderline tuberculoid (BT), if they veer more towards lepromatous or tuberculoid leprosy. If left untreated, patients anywhere within the borderline spectrum can deteriorate towards lepromatous leprosy, whereas under treatment they will shift towards polar tuberculoid leprosy.

Lepromatous leprosy

There is little or no resistance, the bacilli multiply with little cellular response, until the subcutaneous tissues may be loaded with masses of bacilli, many of them distending macrophages as large ‘globi’. The cellular infiltrate is mainly of macrophages with a few lymphocytes.

Tuberculoid leprosy

There is a strong tissue response, the bacilli are not numerous and are seldom seen except by special concentration methods. The histology consists of an epitheloid granuloma, many lymphocytes and a few giant cells.

Characteristically, *tuberculoid* leprosy causes sharply localised lesions often affecting only one part of the body, while *lepromatous* leprosy is symmetrical and extensive. Since the damage in leprosy is mainly due to the response of the host cells, tuberculoid leprosy causes early, severe but localised deformity, while lepromatous leprosy causes deformity late, and more mildly and widely spread. The most severely deformed patients are those affected by some of the borderline forms where the disease may be both widespread through the body and also rather violent in its reactions.

A unique feature of the disease is its predilection not only for the surface of the body, but also for the cool part of the surface. Warm areas such as the axilla and gluteal cleft are spared, while the parts of the upper respiratory tract, such as the lining of the nose, are severely involved. The testis is affected, while the ovary, and other deeply placed glands and organs, are unaffected. Since leprosy does not affect the vital organs of the body, it rarely causes death, and patients do not even feel ill for most of the time they have the disease.

During treatment, many patients manifest acute episodes, which are referred to as ‘reactions’, of which there are two distinct types.

1. The ‘lepra or type I reaction’ occurs in the borderline form of leprosy (BT, BB and BL), in which the skin lesions become erythematous, warm to touch and may break down, and the nerves swell and become painful and tender to touch. It is usually caused by a rapid increase in cell-mediated immunity by the host with an outpouring of lymphocytes into the lesions giving rise to acute inflammation with associated oedema. For this reason, the lesions have been referred to as ‘reversal reactions’, advantageous by resulting in destruction of *M. leprae*, but causing irreversible destruction of axons when the inflammation and oedema occur in nerves.

2. The other type of reaction is referred to as erythema nodosum lepro-sum (ENL or type 2 reaction), usually occurring during treatment, but confined to patients with lepromatous type leprosy (BL, LL). Here there are no changes in the established leprosy lesions, but new crops of very small erythematous lesions in the skin appear associated with systemic symptoms such as malaise, fever and nerve and joint pain. Occasionally, rhinitis, acute iridocyclitis, swollen and tender lymph glands, acute epididymo-orchitis and proteinuria occur. This is an Arthus-type reaction, due to the deposition of immune complexes in and around blood vessels, locally or generalised throughout the body, and more akin to chronic serum sickness. This reaction may come and go or be persistent, and can in its most severe form be fatal.

One of the most characteristic features of leprosy is its effect on nerves (Fig. 8.2). Histologically, the cellular infiltrate may be seen localised around nerve fibres in and under the skin and, on clinical examination, superficial nerves such as the ulnar and posterior auricular may be observed to be swollen and tender. The anaesthesia that results from nerve involvement is an important point in diagnosis, and is also a cause of secondary damage and deformity. Much of the loss and disfigurement of hands and feet which has always been associated with leprosy is now known to be due not to leprosy itself, but to the damage and misuse which follow loss of pain sensation.

Medical treatment

Until 1980, dapsone (diaminodiphenyl sulphone, DDS) was the standard treatment for leprosy. The problems of DDS resistance and the inordinately long duration of therapy have led to today’s standard treatment — multidrug therapy (MDT). For multicellular cases (which include LL, BL, BB and some BT cases), the treatment duration is 2 years or until negativity is achieved, whereas for paucibacillary leprosy (which includes all tuberculoid cases and many BT cases) the treatment duration is 6 months or until the lesions become inactive. Rifampicin, the first bactericidal drug against *M. leprae*, is given in a dose of 600 mg a day for 2 days at the beginning of each month, while DDS is given in a dose of 100 mg daily. This two-drug regimen is adequate for paucibacillary cases. For multicellular leprosy clofazimine at 50 mg daily is added as the third drug. Recently, clarithromycin, ofloxacin and minocycline have been shown to be effective.

For reactions, symptomatic treatment, including analgesics, is given for milder cases. Evidence of nerve damage indicates a necessity to start steroid therapy. For the more severe reactions, reversal and ENL, it is absolutely essential to treat with steroids to protect the nerves and to keep the patient going. In ENL reactions, but only in LL cases, thalidomide has proved to be very beneficial and is also useful in the treatment of steroid dependency. Thalidomide, if available, is used to treat only male patients, or females outside the childbearing years,because of its known teratogenic effects. Psychotropic drugs, e.g. chlorpromazine and amitriptyline, are often needed in cases of severe reaction to treat associated psychological disturbances.

Decompression of nerves

The relief of compression caused by the thickened nerve sheath and by the fibrous roofs of tunnels at entrapment sites (cubital, carpal and tarsal tunnels) is an important supplementary procedure to prevent further damage to the involved peripheral nerve trunks. Intractable pain is a
definite indication, while increasing paralysis, in spite of treatment with steroids, is a further indication for nerve decompression.

**Surgery**

The deformities of leprosy are divided into *primary* — those which are caused directly by leprosy and its reactions and *secondary* — those which result from anaesthesia and consequent misuse. The stigma of leprosy is the stigma of deformity, and a wide-open field awaits the plastic surgeon in this disease.

The face. **Primary deformity.** The skin of the face becomes thickened and sometimes nodular in lepromatous leprosy (Fig. 8.3); the forehead, cheeks, nose and ears are especially affected. The result in the acute phase is referred to as leonine facies’. This infiltration subsides under medical treatment, but may leave the skin wrinkled and without its normal support, producing, in a younger person, a caricature of old age. The hair of the eyebrows falls out and the lateral cartilages and septum of the nose may be destroyed, leaving collapse of the centre of the nose and lifting of the tip towards the bridge (Fig. 8.4). The upper branches of the facial nerve may be paralysed, giving rise to lagophthalmos; the lower branches are sometimes partially paralysed.

Patients with the above deformities usually find it quite impossible to return to normal social relationships even though their leprosy may be cured. Plastic surgery can completely transform such faces using a postnasal inlay to the nose (Fig. 8.4) and an ‘island flap’ for the eyebrows. A temporalis muscle segment reactivates the eyelids and a facelift may restore more normal contours to the skin.

Eyes. Some of the blindness of leprosy is simply due to exposure following paralysis of the eyelids. This is correctable by plastic surgery. Other causes of loss of vision are lepromatous infiltration of the anterior segment of the eye and acute allergic changes of the tissues associated with reaction. Acute iridocyclitis is one of the commonest manifestations of this allergic reaction. Any redness of the eye or loss of visual acuity in leprosy demands full examination and prompt treatment if the sight is to be saved. Treatment should include atropine and hydrocortisone eyedrops as well as oral steroids.

Hands (Fig. 8.5). The work on reconstruction of the hand in Hansen’s disease was started by Professor Paul Brand.

**Primary deformity.** In the upper limbs, leprosy causes paralysis, frequently in the ulnar nerve at the elbow and in the median nerve at the wrist (Fig. 8.2) but rarely in the motor part of the radial nerve (1 per cent).

**Treatment.** The extensor carpi radialis brevis muscle is extended into the hand with free grafts which run along the lines of the lumbrical tendons to correct the clawing of the fingers. The flexor sublimis tendon to the ring finger is withdrawn in the forearm and rerouted to oppose the thumb along the line of the abductor brevis. In this way the fingers and thumb may be balanced and function almost normally. Before attempting operation it is important to make sure that the fingers are made mobile by massage and exercise.

**Secondary deformity.** Since the hand is often totally anaesthetic, patients frequently burn or damage themselves by the uninhibited strength which they use through their fingertips. Their hands become scarred and progressively absorbed until only stumps remain. It takes patience and perseverance to teach patients that their hands can be preserved only by constant alertness to foresee possible dangers, and constant gentleness to their own tissues which are not protected by pain. Once they are convinced that it is not leprosy that is destroying their fingers, they may be willing to accept the discipline of caring for themselves.

Feet. **Primary deformity.** In the lower limbs, the posterior tibial nerve is often involved at the ankle, giving rise to ‘clawing’ of the toes and anaesthesia of the sole of the foot. The lateral popliteal nerve may also be destroyed, giving rise to footdrop. The medial popliteal nerve is never involved, so the tibialis posterior muscle can be safely used to correct footdrop.

**Secondary deformity.** The anaesthesia of the sole of the foot is very serious because almost every patient with insensitive feet sooner or later develops trophic ulceration. If patients then continue to walk on their ulcers, the condition progresses and the infection spreads until, after a few years, the foot is contracted and distorted, and destroyed to the point where amputation must be advised.

It is important for patients to understand the pathology of their ulcers and to realise that they are not due directly to leprosy. These ulcers heal readily with rest in a plaster cast and their recurrence can be prevented by the regular use of special footwear designed to spread the weight evenly over the whole foot.
Acquired syphilis

Acquired syphilis is an STD infection caused by Treponema pallidum, a delicate spiral organism (spirochaete), 6—15 m in length. A dramatic decline in incidence after the introduction of penicillin has been followed by a gradual but significant increase throughout the world.

Transmission is by direct contact with a surface lesion containing treponemes, which penetrate the skin or mucosa at the point of contact. Since treponemes are present only in the surface lesions of early syphilis, i.e., primary, secondary and the first 2 years of latency, syphilis is only infective during that period. After 2 years, acquired syphilis is rarely com-municable and the ulcerative cutaneous lesions of tertiary syphilis are not infective as they contain few, if any, tre-ponemes. The organism dies rapidly on drying, hence infec-tive early lesions are predominantly sited on moist areas, e.g., genitals, mouth and anus, so that infection almost always occurs during intercourse including orogenital contact and—of great importance now—homosexual practices involving the anus and rectum.

Clinical features

The disease is divided into four stages: primary, secondary, latent and late.

Primary syphilis. A primary sore or chancre (Fig 8.6 and Fig 8.7) develops at the site of entry of the treponemes in about 3—4 weeks. It may resolve at any stage of its development and thus be quite atypical. It may simulate other penile or vulval lesions, traumatic lesions such as splits or tears chancroid, herpes genitalis, burns, furunculosis and carcinoma, as well as balanoposthitis and lymphogranuloma venereum (Chapter 67).

Starting as an indurated papule, it becomes eroded and when fully developed will present the following signs of a classic Hunterian chancre: a shallow, indurated, painless, nonbleeding ulcer, usually single, oval or round, with a raised hyperaemic margin, often extending into a dusky red oede-ma. A painless, discrete and ‘shorty’ enlargement of the asso-ciated lymph nodes occurs which has a rubbery consistency. The prepuce of the penis must always be fully retracted as otherwise tiny sores in the coronal sulcus may be missed. As there are no constitutional symptoms, a female patient will be unaware of the presence of a cervical chancre, a lesion which accounts for about 45 per cent of all sores in that sex. Extragential chancres of the lip, tongue, nipple, etc., are now rare, but rectal and perianal primaries are common in homosexuals and are usually atypical, frequently resembling painful anal fissures which occasionally get excised in error. Spasm of the anal sphincter is usually less with true sores and a typical (lateral) inguinal lymphadenitis may be present.

Diagnosis is by finding T pallidum in the clear exudate from the lesion by dark-field microscopy. The serum tests do not become positive for 10—90 days (usually 3—5 weeks) after the appearance of the chancre, hence initial negative results must never be interpreted as excluding primary syphilis. This is because the tests identify a gradually developing antibody response. The tests should be repeated for up to 3 months where doubt persists.

Secondary syphilis. Signs usually appear in 6—12 weeks, extremes being 3 weeks to 6 months. The commonest sign is a dull red or coppery rash, which is generalised, symmetrical, indolent and nonirritant. Often inconspicuous, sometimes absent (in 25 per cent of cases), the rash is characteristically pleomorphic, being roseolar or macular at first, with papular, papulovesicular or other elements appearing later. Papules on contiguous moist sites, e.g. vulva and perineum, may enlarge to form condylomata lata, fleshy, wart-like growths teeming with treponemes. Small, round, superficial erosions may occur in the mouth where they may coalesce to form the so-called snail-track ulcers. The rash can characteristically pleomorphic, being roseolar or macular at first, with papular, papulovesicular or other elements appearing later. Papules on contiguous moist sites, e.g. vulva and perineum, may enlarge to form condylomata lata, fleshy, wart-like growths teeming with treponemes. Small, round, superficial erosions may occur in the mouth where they may coalesce to form the so-called snail-track ulcers. The rash can

Late syphilis (syn. tertiary syphilis). Syphilis in all its stages is essentially a vascular disease. In each stage, treponemes cause inflammatory reactions in the perivascular lymphatics with plasma cell cuffing of terminal vessels. In the tertiary stage only there is subsequent obliterative endarteritis, tissue necro-sis and fibrosis. Since almost any structure may be involved, the signs can be extraordinarily variable, and will be referable to the site or system involved. Only about 35 per cent of untreated syphilitics will develop tertiary syphilis. About 5—15 years after infection, 10 per cent will develop neurosyphilis, 10—12 per cent cardiovascular syphilis and after 6 months up to many years later, 10—15 per cent will develop late benign syphilis involving less vital structures. The three types are not mutually exclusive. The typical lesion of late benign syphilis is the localised gumma (Fig 8.8) or diffuse gummatous infiltratio. The gumma is a syphilitic hypersensitivity reaction con-sisting of granulation tissue with central necrosis. Sloughing of a subcutaneous gumma may produce the typical, painless, punched-out gummatous ulcer with a ‘wash-leather’ base (Fig 8.9). On healing, it leaves a silvery ‘tissue-paper’ scar. Alternatively, the gummatous process may be nodular or infiltrative without ulceration, and slow peripheral spread occurs with central healing. The individual lesions are round and indurat-ed, and grouped lesions are circinate in outline with sharply defined, hyperpigmented margins.

Diagnosis. Dark-field microscopy. This is performed on aspirates from skin or mucous membrane lesions and is the quickest method of diagnosis in early acquired syphilis.

Serological tests for treponemal diseases are of two types.
1. **Nonspecific (syn. reagin, nontreponemal, lipoidal antigen tests).** Examples are the cardiolipin Wasserman (WR), Kahn, Meinicke, and Venereal Disease Research Laboratory (VDRL) slide test. The last is the best. These test the presence of any antibody reagin in the serum of patients with treponemal infections, but biological false positives (BFP) arise from reagin present in nontreponemal conditions, e.g. malaria, vaccinia, glandular fever, and also after any kind of vaccination. Stronger and persistent reactions may occur in leprosy, sarcoidosis, collagen diseases and chronic liver disorders. A diagnosis of syphilis requires confirmation from one or more of the specific tests.

2. **Group-specific tests (treponemal antigen tests).** Examples are: Reiter’s protein complement fixation test (RPCF), Treponema pallidum haemagglutination assay (TPHA), absorbed fluorescent antibody test (FTA Abs) and Treponema pallidum immobilisation test (TPI).

The first is obsolete (in the UK) and the last rarely required. The routine practice is to perform the VDRL and TPHA adding the FTA if either is positive or the clinical findings justify it. In primary syphilis, the usual order of conversion is ETA, VDRL with rising titre and TPHA, although this sequence is not invariably. After treatment, the VDRL usually reverts to negative in up to 6 months, the FTA in 70 per cent, but the TPHA hardly ever, of which facts the patients must be told — ‘a little scar in the blood’ is usually adequate. Persistence of treponemal antibodies, if it is known that adequate treatment has been given, is not a cause for concern but if there is any doubt, confirmed reactions on repetition should be treated as for latent infection.

**Treatment**

No local treatment except isotonic saline should be applied to a suspected chancre until dark-field examinations have proved negative on 3 successive days. No treponemalicidal antibiotics should be prescribed until syphilis is confirmed or excluded, but if there is secondary infection a course of sulphonamides may help. Penicillin has supplanted all other forms of treat-ment. A high cure rate is achieved in early syphilis with intramuscular procaine penicillin G 1.2 g daily for 15 days. This dosage is prolonged to 21—30 days for late syphilis. Clinical and serological observation should be continued for 2 years after treatment. In penicillin-allergic patients, tetracycline and erythromycin are alternatives. The best treatment is doxy-cycline 100 mg twice daily for the equivalent period.

Janisch—Herrheimer reaction. About 6 hours after the first injection, 60 per cent of early syphilitics will develop pyrexia, malaise and possible rigor lasting for a few hours only. Patients must be warned about this. The reaction is infrequent in late syphilis, but may be more serious. In late cases only, prednisone 10 mg four times daily for 3 days before the main treatment should prevent it.

Prognosis is excellent after standard treatment for early syphilis. In late syphilis, particularly of the cardiovascular system, cure of the underlying disease may not significantly improve the condition of the patient.

**Congenital syphilis**

Transmission. Infection occurs when treponemes from an infected expectant mother cross the placental barrier to the foetal circulation. The more recent the mother’s infection, the more likely is this to occur and the more serious the effects on the child. The results of foetal infection vary from death in late foetal life or early infancy, or the birth and normal development of an apparently healthy child who, nevertheless, has latent congenital syphilis.

Early congenital syphilis. Signs in the newborn, which may be delayed for a few weeks, include a generalised rash, mucous erosions as in secondary syphilis and the ‘souffles’, a syphilitic rhinitis with nasal discharge which interferes with sucking causing loss of weight, epiphysitis, periostitis, osteochondritis, hepatosplenomegaly and basal meningitis. Signs may be so slight as to escape notice or so severe as to cause death in early infancy, usually due to syphilitic ‘pneumonia alba’.

Late congenital syphilis. The extraordinary variety of clinical manifestations which can occur in acquired tertiary syphilis can also occur in childhood or puberty in late congenital syphilis, e.g. congenital neurosyphilis, cutaneous, visceral or skeletal gummata, but congenital cardiovascular syphilis is practically unknown. In addition, some manifestations, the stigmata, occur in congenital, but never in acquired, syphilis.

The stigmata of late congenital syphilis (Hutchinson’s classic triad) consist of the following:

1. **interstitial keratitis:** the most frequent of the stigmata is a syphilitic hypersensitivity reaction with onset between 5 and 15 years. The cornea becomes inflamed causing pain, lacrimation and photophobia. It tends to be bilateral and recurrent. Prolonged severe recurrent attacks result in a hazy ‘ground glass’ appearance of the cornea, with yellowish-red corneal patches in severe cases (salmon patches, not to be confused with the salmon-patch birthmark). It is uninfluenced by antisyphilitic treatment but can be controlled by local cortisone treatment; and
2. **eighth nerve deafness:** a progressive, bilateral, perceptive deafness, onset about puberty, but occasionally delayed until later and uninfluenced by treatment;
3. **Hutchinson’s teeth:** a peg or band-shaped deformity of the upper central incisors, second dentition. Moon’s molars (mulberry molars):

   the 6-year molars erupt with dwarfed cusps. Other classic signs include nasal deformities, e.g. saddle nose (Fig. 8.10), collapsed nasal septum (Fig. 8.11), perforation of the palate (Fig. 8.12), sabre tibia, Glutton’s joints (painless effusions, commonly in the knee joint) and parietal bossing

   prevention and treatment. A dosage of 1.2 million units of procaine penicillin G given to the mother for 15 days as early as possible in pregnancy not only will protect her from the ravages of late syphilis, but will prevent infection of the foetus, or may even cure it if in utero, if already infected. An infected neonate, whose mother received no treatment during pregnancy, should be treated as for late acquired syphilis with the dosage adjusted to weight.

**Neonatal serology.** An expectant mother who has received no treatment during pregnancy, or who is an untreated latent syphilitic, may produce a child free from syphilis but seropositive owing to passive transfer of maternal antibodies. This serological problem can be solved by performing tests on the immunoglobulin G (IgG) and 1gM fractions of the infant’s serum but not on the cord blood. In the case of passive transfer, the IgG tests will be positive and the 1gM tests negative. Positive 1gM tests indicate active disease in the child since the 1gM fraction of the maternal serum proteins does not cross the barrier of the normal placenta. Exceptions occur if the placenta has been damaged from...
other causes. In all cases, careful clinical and serological follow-up of mother and child is essential. The virtual disappearance of congenital syphilis from the UK and similar countries is one of the great triumphs of modern medicine.

Syphilis contacts. At all stages of the disease, the known contacts must be followed up. This applies to late and congenital cases when other members of the patient’s family are often found to have untreated latent syphilis.

Yaws\(^2\) (framboesia\(^3\))

Yaws is an endemic disease of rural areas in tropical countries of high humidity. The causative organism, *Treponema pertenue*, appears indistinguishable from *T pallidum* and produces identical serological reactions. Direct contact with an early lesion is the usual mode of transmission. It is not sexually transmitted. The primary lesion is most frequently seen on the legs of children. About a month after infection, a papule appears at the site of entry of the treponeme; this ulcerates giving the lesion a pink, raised, raspberry-like (framboesia\(^2\)) appearance. Secondary lesions, usually papillomatous, appear some weeks later. After 5 or more years of latency, a minority of patients develops late gummatous-like lesions of soft tissue or bone similar to those of tertiary syphilis. The cardiovascular and nervous systems are not involved and congenital yaws does not occur. Treat as for syphilis.
Other infections (nonviral)

Candidiasis

*Candida albicans* (formerly called *Monilia*) is a yeast, frequently present in small numbers in the healthy bowel and mouth. It may cause primary infection in the newborn or superinfection when flora are disturbed by antibiotic treatment. In thrush (candidial stomatitis) white patches are seen in the mouth; it may occur in infants, in postoperative patients, and with ill-fitting dental plates. Vaginitis is common in pregnancy and diabetes. *Candida* may infect moist skin under breasts and the nailfolds, and cause severe intertrigo. Administration of broad-spectrum antibiotics often results in proliferation of *Candida* in the respiratory tract and bowel, and may be responsible for digestive upsets. Systemic candidiasis with invasion of lung and bloodstream is a complication of immunosuppression in transplantation surgery, and in the chemotherapy of malignant disease. Oral thrush also occurs in AIDS.

Candida infections are treated by the topical antibiotic nystatin or by gentian violet. Treatments for vaginal candidiasis include pessary treatment with clotrimazole (Canesten), miconazole nitrate (Gynodaktanin), econazole (Ecostatin) or tsoconazole nitrate (Travogyn) from 1 to 6 days or nystatin for 14 days. Ketoconazole 200 mg twice daily for 5 days and fluconazole 150 mg (single dose) are more recent oral treatments. In all cases of treatment failure, the male partner should be investigated for balanoposthitis, easily cured with clotrimazole or nystatin ointments locally.

**Aspergillus**

*Aspergillus* species can cause a variety of clinical syndromes.

*Asthma*

A type I hypersensitivity reaction.

**Allergic bronchopulmonary aspergillosis**

May be due to a type I and type III hypersensitivity reaction. Asthma and a chronic cough with sputum production occur and bronchiectasis may result.

**Aspergilloma**

A chronic infection in a previously damaged area of lung, e.g. an old tuberculcous cavity, producing a characteristic radio-graphic appearance. Haemoptysis may result and surgical removal may be necessary.

**Disseminated aspergillosis**

Usually found in immunocompromised patients such as those undergoing chemotherapy for leukaemia. Treatment involves the use of amphotericin B.

**Chancroid (soft sore)**

This infection is rare in Western countries. It is caused by the Gram-negative bacillus Ducrey (*I-Iaemophilus ducreyi*). Two to 5 days after infection, sores, often multiple, appear on the genitals. They become pustular and ulcerate, forming rounded, painful, soft, readily bleeding ulcers with undermined edges. Inguinal adenitis follows, the swollen nodes being hard and tender causing a feeling of stiffness in the groin. Resolution may occur at this stage, but suppuration may follow, the nodes becoming matted together forming a fluctuant unilocular abscess (hobo) with red overlying skin, in one or both groins. The bubo should never be incised since healing is very slow. Aspiration is correct. Phagedaena (a rapidly destructive ulceration) sometimes occurs.

Treatment. Any antibiotic which may prevent the identification of *T pallidum* in a case of concomitant syphilitic infection, or when the aetiology of the lesion is in doubt, is contraindicated. The mainstay of treatment has been co-trimoxazole 960 mg twice daily or erythromycin 500 mg four times daily for 1 week. However, resistance to co-trimoxazole is now appearing. Ciprofloxacin 500 mg twice daily for 3 days is an alternative. Regular daily cleaning of ulcers with isotonic saline is recommended.

**Gonorrhoea**

This venereal disease is discussed in relation to the genito-urinary system in Chapters 67 and 68.

**Lymphogranuloma venereum**

This is described in Chapter 67.

Granuloma inguinale

This is described in Chapter 67.

**Erysipelas**

Erysipelas is a spreading inflammation of the skin and subcutaneous tissues due to an infection by *Streptococcus pyogenes* (β-haemolytic streptococcus Lancefield group A). Poor hygienic living conditions, recurrent upper respiratory tract infections, debilitating illness and extremes of life are predisposing causes, and the lesion develops around a scratch or abrasion which is the site of inoculation of the streptococcus. A rapid toxaemia associated with the local infection and a rose-pink rash extending over the adjacent skin rapidly develops. The rash has a very clear edge and considerable oedema occurs (Fig. 8.13) over some tissues when infected, e.g. orbit or scrotum. Following the fading of the rash, a brown discoloration of the skin remains. The *S. pyogenes* remains fully sensitive to penicillin (see also ‘Antimicrobial chemotherapy’)

**Anthrax**

*Bacillus anthracis* is a large, Gram-positive, aerobic, spore-forming rod. It is very resistant to heat and antiseptics. The disease is found in cattle
and is likely to appear in people who handle carcasses, wool, hides, hair and bone meal.

The cutaneous type is the commonest human variety; the incubation period is from 3 to 4 days. The lesion usually commences on an exposed portion of the body, such as the hands, forearms or face. An itching papule (Fig. 8.14) occurs, around which a patch of induration soon becomes evident. The papule suppurates and is replaced by a black slough, and a ring of vesicles appears on the surrounding indurated area. This stage comprises the typical ‘malignant pustule’. A brawny, congested area of induration develops around the site of infection. The regional lymph nodes are involved. Toxaemia is always in evidence. A smear of vesicle fluid is used to confirm the diagnosis by culture and animal inoculation.

Treatment. Penicillin is the treatment of choice.

Prevention. This must include precautions to sterilise potentially infected animal products and wool from countries where the disease is endemic. A vaccine is available for those at special risk of exposure.

Differential diagnosis. The condition is easily mistaken for a severe furuncle (Chapter 37).

Other forms of anthrax are rarely, if ever, now seen, e.g. wool-sorter’s disease, a pneumonia due to inhalation of spores, and an alimentary type, following ingestion of spores.

**Actinomycosis**

This disease is caused by *Actinomyces israelii*, an anaerobic, Gram-positive, branching, filamentous organism which sometimes lives as a harmless parasite in the tonsillar crypts and dental cavities of the otherwise normal mouth. It is popularly supposed that it occurs in corn and grasses, but the pathogenic bacillus does not. If the organism invades tissue, it causes a subacute pyogenic inflammation with considerable induration and sinus formation. Trauma and the presence of carious teeth are important predisposing factors in the development of lesions in the mouth.

Diagnosis depends on finding the organism in pus or in tissue section. Pus should be collected in a sterile tube (a swab is usually insufficient) and inspected in a good light for the presence of pinhead-sized ‘sulphur granules’. On microscopy, the granules are seen to consist of Gram-positive branching bacilli. The peripheral filaments radiate from the central part of the granule and may be surrounded by Gram-negative tissue clubs.

Culture. The presence of secondary organisms often makes this difficult.

The lesions are characterised by the formation of a firm, indurated mass, the edges of which are indefinite. Lymph nodes are not affected, but if a vein is invaded, pyaemia is likely.

There are four main clinical forms of actinomycosis.

- **Faciocervical** is the commonest. The lower jaw is more frequently affected, often adjacent to a carious tooth. The gum becomes so indurated that it simulates a bony swelling. Nodules appear, which soften and burst; the overlying skin of the face and neck becomes indurated and bluish in colour, softening occurs in patches. Abscesses burst through the skin and sinuses follow.

- **Thorax.** The lungs and pleura are infected, either by aspiration of the bacillus or by direct spread from the pharynx or neck, or even upwards through the diaphragm. The chest wall, in the late stages, becomes riddled with sinuses. An empyema is not uncommon, and the infection can easily spread through the diaphragm to the liver and the subphrenic spaces.

- **Right iliac fossa** (see Chapter 5).

- **Liver** (see Chapter 52).

Treatment. *Actinomyces* is usually sensitive to penicillin, ret racycline and some other antibiotics, e.g. lincomycin, but the sensitivity should be checked in the laboratory. A prolonged intensive course of penicillin (10 megaunits reducing to 4 megaunits daily) is usually the best treatment until all signs of the disease have disappeared.

Madura foot (and hand). See (Fig. 8.15) and Chapters 30 and 31.

**Parasitic diseases**

- **Filariasis.** See Chapter 17.

- **Hydatid disease.** See Chapter 52.

- **Bilharziasis.** See Chapter 65.

- **Amoebiasis.** See Chapter 57.

- **Dracunculus medinensis.** See Chapter 12.
Viruses

Hepatitis A virus (HAV)

This is described in Chapter 52.

Hepatitis B virus (HBV)

This may follow blood transfusion, plasma infusion and, rarely, the administration of sera, infection resembling infective hepatitis except that the incubation period is about 12 weeks. Transmission by plasma has been reduced by avoiding the pooling of plasma from a large number of donors. Transmission by syringes is prevented if all syringes are disposable. It occurs amongst those who are drug addicts and possibly after tattooing or ear piercing. There is an extremely high rate among certain homosexual communities. In certain centres more than 50 per cent of male homosexual patients have antibody indicating exposure and about 5 per cent have active disease. In Athens, a group of prostitutes was found to have a rate 20 times that of married pregnant women, possibly due to more frequent coitus near the period or to other sexually transmitted diseases, producing bleeding that transmits the infection.

Infection with hepatitis B virus is associated with the appearance in the blood of one or more antigens, viz, hepatitis B surface antigen (HBsAg), hepatitis Be antigen (HBeAg), the Dane particle (probably the complete virus) and DNA polymerase activity. Under electron microscopy, particles can be seen in the sera of these patients and are associated with the virus. These particles are antigenic. Such patients usually suffer the severest form of hepatitis. The antigen is the scourge of renal dialysis and transplantation units, and hospital staff must avoid contact with blood from such patients.

A genetically engineered vaccine is now available (EngenixB). Three doses produce a good antibody response in most recipients, although poor responders may need a booster.

Good antibody levels usually persist for about 5 years and a booster is recommended at this time. It is important that the injection is given intramuscularly in the deltoid as this produces a higher response rate than the buttock. All surgeons are strenuously recommended to have a course of this vaccine.

Hepatitis nonA nonB is a variant, with an incubation period similar to HBV but with milder clinical features. Several causative agents have been described, one of which is hepatitis C. Detection of antibodies to hepatitis C indicates exposure to the disease and the presence of viral ribonucleic acid (RNA) in the blood indicates chronic infection. There is a number of serotypes with varying responses to therapy with a combination of interferon and ribavirin. Sadly, a large number of patients relapses after treatment and the development of new and more effective antiviral agents is awaited.

Natural history of HIV disease

Following infection by the HIV-1 virus into the blood, there is a brief seroconversion illness which is characterised by flu-like symptoms and lymphadenopathy. There then follows a latent period when the infected subject remains well but which is associated with a progressive fall in CD4+ lymphocyte count (Fig. 9.2). The progress of the disease has been classified by the US Centers for Disease Control (Table 9.1). It is expected that 25—35 per cent of those infected will develop acquired immunodeficiency syndrome (AIDS) within 2 years of infection if left untreated. The mortality from AIDS is thought to be 100 per cent. HIV-1 viral titres are at their highest during the initial ‘seroconversion’ and the late-AIDS phases of the illness (Fig. 9.2).

The likely period of survival of an HIV-seropositive patient is important in assessment for both emergency and elective surgery. There are three important factors: CD4 (T-helper cell) count, HIV plasma load, and the ability of the patient to receive antiretroviral therapy (HAART).

HIV-seropositive patients die as a result of a wide variety of opportunistic infections caused by the CD4 count falling below a critical level. A low CD4 count is often the best guide to likely clinical events or death within the near future, whereas the plasma viral load (a surrogate for extent of viral production) is the best long-term guide to prognosis — in part because it predicts the rate at which the CD4 count is likely to fall.

Effect of immune adsfunction

The extent of depletion in immune function correlates with the loss of CD4+ helper T-cells. However, there is also destruction of dendritic cells, damage to the thymus and immune dysregulation associated with production of autoantibodies and of immune complexes with persistent complement activation. Functional impairment of CD4+ lymphocytes results in disorders of antibody production, delayed hypersensitivity and macrophage function. In addition, secretory immune deficiency occurs in the gut with depletion of immunoglobulin A (IgA)-containing jejunal and rectal plasma cells. This results in a vulnerability to many opportunistic infections, an increased risk of cancer development, and malnutrition due to a reduction in nutrient absorption and metabolism.

Introduction

The human immunodeficiency virus type 1 (HIV-1) is a mem-bcr of the slow virus (lentivirus) family of retroviruses. It is a distant relative of the human T-cell lymphocytotropic virus (HTLV)-1 and HTLV-2 viruses which produce some human leukaemia, but is more closely related to nonhuman retroviruses which produce degenerative disease in animals, such as the simian immune deficiency syndrome which occurs in monkeys.

Retroviruses are ribonucleic acid (RNA)-coded viruses that contain reverse transcriptase which transcribes viral RNA into deoxyribonucleic acid (DNA) within the host genome (Fig. 9.1). Viral infection of the host cell may be either latent, where the DNA is integrated but viral replication does not occur, or productive, where RNA and virus assembly occurs. One reason that the host immune system is ineffective at clearing HIV-infected cells is that the proportion of latently infected cells is high in relation to productively infected cells.

HIV-1 has a cell-surface protein (gp 120) which recognises and binds to receptors on several types of human cells. In particular, HIV binds to the CD4 receptor which is carried in high density on the surface of the CD4+ lymphocyte (helper T-lymphocyte). Other reservoirs of HIV infection are macrophages, neural, renal and perhaps epithelial cells.
surgeon may become involved are:

• the management of colorectal and anal disorders including infections and cancer;
• lymph node excision biopsy where there is diagnostic uncertainty;
• the provision of chronic venous access to facilitate chemo-therapy for infections (particularly cytomegalovirus retinitis) or neoplasms.
Anal diseases

Warts

These are usually sexually transmitted, although anoreceptive intercourse is probably not necessary for the development of anal canal warts (Fig. 9.3). The treatment of these warts requires local scissor excision or destruction by some other local method, for example diathermy or laser. Less extensive wart infection can be controlled by application of podophyllin. The wart virus (human papilloma virus) is able to incorporate in the human genome and some types predispose to cancer development. In the presence of reduced immune surveillance, this can result in early neoplastic change within the anal epithelium which is termed anal intraepithelial neoplasia (AIN). The risk of progression of this intraepithelial neoplasia to invasive anal malignancy is small, although a precise figure is unknown. The finding of AIN in HIV disease is probably of little clinical significance since progression to invasive malignancy is unlikely within the prognosis of the HIV disease. The objective of anal wart treatment in these patients should be to control the local discomfort or leakage associated with the warts. AIN may also occur in the absence of warts (Fig. 9.4), although these patients are probably infected with human papilloma virus.

Perianal sepsis

The usual varieties of anal fistula can develop in HIV-positive patients. The combination of local anal trauma resulting from anoreceptive sex with reduced immunity probably results in an increased risk of perianal sepsis. Perineal healing is reduced in patients with advanced HIV disease associated with a low CD4+ lymphocyte count. In those patients who do not have a CD4+ count of less than 100, conventional management of perianal sepsis is appropriate.

For patients with severe reduction in CD4+ count who are likely to have AIDS, a more conservative approach to control sepsis, for example, with the use of a seton, is probably more appropriate. It was initially believed that perianal sepsis was more complex in the HIV than in the non-HIV patient population. However, subsequent experience does not suggest that HIV-positive patients are more likely to have difficult or complicated high fistulas.

Anorectal ulceration

Ulcers may occur in any part of the anal canal (Fig. 9.5) or lower rectum, and are usually associated with AIDS. In some cases they can be shown to be due to herpes simplex virus infection, but in other cases no organism has been demonstrated, although infection remains the most likely cause. Treatment for herpes simplex virus with acyclovir should be tried first. Occasionally, excision of the ulcerated area with a gentle anal stretch can be helpful. In some cases it is not possible to achieve healing of the ulcer.

Anal neoplasia

The probability of an HIV-positive patient with anorectal ulcers having anal neoplasia is much higher than in the non-HIV population. The commonest anal neoplasms are squamous carcinoma of the anal canal (Fig. 9.6), Kaposi’s sarcoma involving the anal canal, and perirectal or perianal non-Hodgkin’s lymphoma. Lymphoma can produce a tense painful swelling in the ischiorectal fossa which is easily mistaken for perianal sepsis. Thus needle aspiration is helpful before incision and drainage of suspected ischiorectal abscesses in the HIV-positive patient since this may avoid a breach in the skin overlying the lymphoma with subsequent risk of ulceration. The majority of patients with anal neoplasia has advanced HIV disease.

Faecal incontinence

Homosexuals who undergo repeated anorectal intercourse weaken the internal anal sphincter. The association of a weakened internal anal sphincter with some degree of infective proctitis (see below) can produce minor faecal incontinence.
The acute abdomen in AIDS

Abdominal pain occurs in over 10 per cent of all AIDS patients. However, only 5 per cent of AIDS patients with abdominal pain require surgery, and this includes a small group of patients who develop acute abdominal symptoms where emergency laparotomy is necessary. The principal indications for emergency laparotomy in the AIDS patient are as follows.

Appendicitis

This presents as in the normal population. Where the signs and symptoms suggest a diagnosis of appendicitis in an HIV-positive patient, then appendicectomy should be carried out and the postoperative course is similar to the non-HIV patient.

Infective colitis

This arises from infection with cytomegalovirus and a variety of other organisms, and can result in severe bloody colitis (Fig. 9.7), toxic megacolon or colonic perforation which may be life threatening.

*Mycobacterium avium* intracellulare infection

This produces an illness in which generalised symptoms are more prominent with vague abdominal pain associated with fever and marrow suppression. Laparotomy is better avoided in these patients if possible. The diagnosis can be made by marrow aspirate or needle biopsy of enlarged lymph nodes.

Non-Hodgkin’s lymphoma (Fig. 9.8)

Diagnostic laparotomy to obtain lymph node tissue for histological examination should be avoided where possible. Occasionally, patients undergoing chemotherapy treatment for non-Hodgkin’s lymphoma develop acute abdominal symptoms, for example, due to small bowel perforation at the site of tumour necrosis. The general experience with emergency laparotomy in the HIV-positive individual in this situation has been disappointing, and it is probably better avoided.

Overall, where conventional clinical criteria indicate the need for emergency laparotomy, the results in the HIV-positive patient suggest a 10 per cent perioperative mortality with a median survival of about 6 months following emergency surgery. Thus, this policy does seem to offer some additional life to these unfortunate patients.
Cholangitis

Some patients with advanced HIV disease develop liver function test abnormalities consistent with cholangitis. Endoscopic retrograde cholangiopancreatography in these patients reveals changes which are similar to sclerosing cholangitis (Fig. 9.9). The aetiology of this condition is not clearly established but it is thought that the inflammation has an infective basis, perhaps cytomegalovirus. Surgical treatment is not required.
Lymphoma

In addition to abdominal non-Hodgkin’s lymphoma (see above) lymphomatous swellings can occur in other areas of the body, particularly the parotid and in the mediastinum. Tissue biopsy is occasionally helpful where there is uncertainty about whether the lymph node enlargement is due to lymphoma or to infection. However, major surgical excision biopsy is unhelpful.
Splenectomy

Splenectomy is occasionally indicated to correct an HIV-related form of autoimmune thrombocytopenia.
Risk of transmission of HIV disease from patient to surgeon

The surgeon is regularly exposed to blood, which is the most infective medium for HIV transmission. The risk must be greater where there are more HIV particles in the blood and this occurs during the earliest and later stages of the disease (Fig. 9.2). Thus, patients undergoing surgery who have had a recent seroconversion illness and who may be unaware that they are HIV positive are infectious, as well as patients who are known to be HIV positive. The extent of risk to the surgeon depends on the prevalence of HIV in the patient population, the number of procedures carried out by the surgeon, and the length of the period of risk. It is estimated that the risk to a surgeon working in a high-prevalence American or European inner city area over a 30-year career is roughly a one in 800 chance of acquiring HIV infection. In Africa, where the prevalence of HIV disease is thought to be much higher and the risk of HIV infection in blood products is also higher, a similar career risk has been estimated to be as high as one in four.

Sources of infection

The principal route of occupationally acquired HIV infection in healthcare workers is by skin perforation with a hollow needle containing HIV-infected blood. Although infection has been reported after solid needle skin perforation, the risk seems to be about 10-fold less than with hollow needle perforation where more blood may be injected. Extensive splashing of mucous membranes and skin, as occurred with spillage of a pack of blood over a nurse, has also been reported to produce HIV infection.

Precautions

Although screening of all patients for HIV infection before routine surgery would identify a substantial proportion of patients who might infect the surgeon, this has not, been accepted because of political and social constraints in most countries. The risk of contamination to the surgical team can be reduced by the use of ‘universal precautions’ involving wearing either safety spectacles or a face mask (Fig. 9.10), and a gown which provides waterproof protection to the sur-geon’s anterior trunk and arms. In addition, boots rather than open-toed shoes should be worn to improve protection to the feet should something sharp be dropped. Needle-stick injuries to the hands most frequently occur on the index finger and palm adjacent to the thumb of the nondominant hand. This is presumably a result of passing the needle through tissue with a needle holder held by the dominant hand and attempting to locate the tip of the needle with the nondominant hand which is also used to retract tissue. Skin contamination from glove perforation can be reduced approximately fivefold by wearing two pairs of gloves. It is usually more comfortable if the larger-sized glove is worn on the inside next to the skin and a half-size, smaller glove is worn as the outer second layer.

The most important operative precaution is to carry out the procedure in an orderly manner. Surgical assistants should be kept to a minimum and should be instructed not to move while the operation is proceeding. If the assistants’ position is to be adjusted then the operating surgeon should stop operating while changes are being made. This should avoid the risk of the operating surgeon injuring an assistant’s hand while it is being moved across the operative field. The operation should proceed in a slow and methodical manner with meticulous attention to haemostasis, taking care to avoid unexpected rapid bleeding which changes the tempo of the procedure and increases the risk of inadvertent injury to the operators. No sharp instruments or scalpsels should be passed across the operative field from hand to hand. All instruments are passed from the scrub nurse to the surgeon and back to the scrub nurse in a dish (Fig. 9.11), thereby reducing the risk of injury while passing instruments. It is not practicable to adopt universal precautions in all patients, although the precautions related to operative technique should be carried out with all cases regardless of HIV status. It may be helpful to screen patients for factors in the history which are known to predict a higher risk of HIV positivity. These factors are:

- homosexual lifestyle;
- a history of intravenous drug abuse;
- a history of haemophilia treated with factor VIII;
- residents of sub-Saharan Africa;
- the partners of the above, higher risk groups.

Procedure in the event of contamination with infected blood

A surgeon who has been contaminated with HIV-infected blood should immediately clean the contaminated area by washing under running water. Where the source patient comes from a high-risk group and the HIV status is unknown, it is important that postexposure prophylaxis to HIV should be offered. This should be started within 1 hour of the injury where possible, so it is inappropriate to await the result of an HIV antibody test in a high-risk patient before commencing the prophylaxis. The prophylaxis con-sists of: zidovudine 250 mg twice daily, lamivudine 150 mg twice daily and indinavir 800 mg three times daily for 1 month. The surgeon should then be given hepatitis prophylaxis (Fig. 9.11), thereby reducing the risk of injury while passing instruments. It is not practicable to adopt universal precautions in all patients, although the precautions related to operative technique should be carried out with all cases regardless of HIV status. It may be helpful to screen patients for factors in the history which are known to predict a higher risk of HIV positivity. These factors are:

Where a medical practitioner discovers that he or she is HIV positive, the requirement of the UK General Medical Council is that ‘if their duties involve performing or assisting in surgical or invasive procedures, they must seek and act upon occupational advice on any modifications or limitations to their duties which may be necessary for the protection of patients’.
Infection of the patient by the surgeon

Patient infection from an HIV-positive dentist while undergoing a dental procedure has occurred. Patient cross infection may also have occurred from an HIV-positive to an HIV-negative patient undergoing a minor surgical procedure on the same operating list. There is no reported case of a patient undergoing a general surgical procedure acquiring HIV infection from the surgeon.
Further reading

**Introduction**

Surgical infection still causes considerable morbidity and high costs to the health-care systems, and is becoming increasingly important in medicolegal aspects. Although antibiotic pro-phylaxis, utilising single high-dose broad-spectrum antibiotics, is important, it has unfortunately tended to lull surgeons into a state of unjustified security where too little attention to sterile precautions, and particularly surgical technique, is paid.

Wound infection results from bacterial contamination of the wound. Infection rate is proportionate to:

- number of bacteria;
- type of bacteria;
- incisions involving mucus surfaces;
- sites of existing infection in the body;
- the use of prosthetic implants.

An appreciation of the sources of bacteria is important and in abdominal surgery these may be summarised as:

1. endogenous from the patient’s visera (98 per cent);
2. endogenous from the patient’s skin;
3. contamination from the air in the operating theatre — rare (by comparison, in 98 per cent of orthopaedic infections the contaminating organisms are ultimately derived from the air with 30 per cent of these sedimenting directly into the wound and the remainder on to drapes and then become dislodged into the wound);
4. direct contamination, such as punctured gloves — very uncommon.
The theatre

The siting of the theatre, by contrast to its design, is not of major importance from a bacteriological point of view, although obviously it should not be adjacent to an incinerator or refuse. Clean and dirty areas should be separated and well demarcated with trafficking of personnel kept to a minimum through the sterile area. The dirty corridor should have an independent exit for contaminated materials.

The scrub room

Design of the scrub room should incorporate:

- two doors leading to the corridor and into the theatre;
- sinks with taps that can be manipulated with the elbows and soap holders that can be manipulated by foot pedals or the elbows. Good drainage and suitable panels incorpo-rated in the sink to prevent splashing of clothes;
- anti-slip floors;
- easily cleaned shelves for gownpacks and gloves;
- adequate facilities for separate disposal of linen and paper;
- brushes for cleaning finger nails.

The operating room

The operating room should have a double-door entrance from the anaesthetic room and a double-door exit into the clean corridor. There will also be two small door entrances from the clean store room where sutures, dressings and needles are kept (this is a subsidiary of the main store in the theatre area) and an opening from the scrub room. There is also a single exit door to the dirty corridor for removal of drapes, instruments and waste products at the end of the procedure. All the doors should be well sealed in order to comply with the air ventilation system.

The operating table should be adjustable with all working parts sealed. The cushions should be easy to clean and in good repair. The lights should be adjustable, sealed and easily cleaned with facilities for attachment of light handles so that the surgeon and scrub team can adjust them. The plaster work and floor should be well sealed and any defects must be repaired as a matter of urgency as disturbance of plaster or the soaking through of leaking water will cause an increase in the bacterial content in the theatre environment.

- Fixed surfaces in the operating theatre should be avoided and reliance placed on steel trolleys. X-ray viewers should be inset into the wall and kept in good repair, as should electric sockets.

Control of air quality

Because the nonvisceral bacteriological contamination of wounds is predominantly from the air in theatre, it is essen-tial that modern theatres are fitted with controlled ventila-tion and filters. For a general surgical theatre the maximum benefits can be obtained from 20 air changes per hour using a 5-mm pore size filter. In an unventilated operating theatre the bacteria present in air can be as high as 3000 colony forming units (CFU) per m$^3$. With appropriate ventilation and air changes this can be reduced to 200 CFU/m$^3$.

In general surgery there is conflicting evidence as to whether improvement in ventilation has reduced postopera-tive infection, but in orthopaedic surgery there is no such ambiguity as air is a significant factor in the development of postoperative infection and modern orthopaedic operating theatres utilise ultra-clean air where the bacterial count is kept below 10 CFU/m$^3$. The principle includes the provision of a rapid high-volume flow of air over the operating theatre with high-efficiency particulate filters. Essential measures, in addition to efficient air ventilation and filtration, include:

- reduction in the number of individuals in the theatre;
- avoidance of excess movement of individuals in the theatre;
- ensuring that the air vents are not obstructed and that the doors are closed.

Instruments

- Cleaning is a process which removes contamination but does not necessarily destroy microorganisms. It is an essential prerequisite of decontaminating equipment before sterilisation or disinfection is undertaken.
- Sterilisation results in the complete destruction or removal of all viable microorganisms including spores and viruses. In practice it may be difficult to establish. The term is usually applied to solid objects, such as instruments and equipment, but not to skin.
- Disinfection reduces the number of viable microorganisms but will not necessarily inactivate viruses and bacterial spores. It may be classified into:
  - high level — which is cidal to spores, bacteria and viruses;
  - medium — which is cidal to bacteria and viruses;
  - low — which is cidal to only bacteria and viruses of low resistance.

It is applicable to delicate instruments that will be damaged by sterilisation.
Sterilisation

Sterilisation by steam

Instruments can be sterilised by steam under pressure using autoclaves. Vegetative bacteria, including tuberculosis, and viruses such as hepatitis B, hepatitis C and human immunodeficiency virus (HIV) and heat-resistant spores, including Clostridium tetani and Clostridium perfringens, are killed. The combination of pressure, temperature and time with the moist heat is important:

- $134^\circ C$ (30 lb/in.$^2$) for a hold time of 3 minutes;
- $121^\circ C$ (15 lb/in.$^2$) for a hold time of 15 minutes;

- prepacked materials and instruments are processed through a porous load autoclave which incorporates a prevacuum cycle necessary to extract air. If this is not achieved then the dried saturated steam cannot penetrate efficiently. Unwrapped instruments can be sterilised in a small autoclave within the theatre precinct, which is convenient when instruments are dropped.

Monitoring

All autoclaves must be regularly maintained according to the manufacturer’s instructions, and a record should be kept of the cycle time, the prevacuum phase, the pressure and temperature. In addition, the steam penetration test (Bowie—Dick test) and chemical indicators, for example Brownes tubes or impregnated tapes, are used to ensure that such errors as poor packing do not prejudice the efficiency of the process. Biological indicators are not appropriate.

Sterilisation by ethylene oxide

Ethylene oxide is a highly penetrative noncorrosive gas which has a broad-spectrum cidal action. It is utilised for heat-sensitive materials including electrical equipment. It is not recommended for ventilator respiratory equipment or soiled instruments because organic debris, including serum, has a marked adverse effect.

Sterilisation by hot air

This is inefficient compared with moist steam sterilisation, but it has the advantage in the ability to treat solid nonaqueous liquids grease/ointments and to process closed (airtight) containers. Lack of corrosion may be important, particularly with instruments with fine cutting edges such as ophthalmic instruments. It cannot be used for substances such as rubber, plastics and intravenous fluids which are denatured.

Sterilisation by low-temperature steam and formaldehyde

This uses a combination of dried saturated steam and formaldehyde, with the main advantage being that sterilisation is achieved at a low temperature ($73^\circ C$) and the method is therefore suitable for heat-sensitive materials and items of equipment with integral plastic components. It is not recommended for sealed, oily items or those with retained air. Some plastics and fabrics absorb formaldehyde, releasing this in a delayed manner which may cause hypersensitivity to the users.

Sterilisation by irradiation

This technique employs gamma rays or accelerated electrons. It is an industrial process and is particularly appropriate to the sterilisation of large batches of similar products, such as syringes, catheters and intravenous cannulas. The delivery of an irradiation dose in excess of 25 kGy is accepted as providing adequate sterility assurance.
Disinfection

Cleaning of items is essential before disinfection is undertaken and the efficiency also depends on:

1. the nature of microorganisms;
2. the load of microorganisms;
3. the duration of exposure to the agent;
4. the temperature.

Disinfection with low-temperature steam

Typical conditions include exposure to dry saturated steam at a temperature of 73°C for a period of 20 minutes at a pressure below atmospheric. This is a useful process for dealing with dirty returns from the operating theatre or clinics which may be contaminated with protein from bodily secretions and microorganisms. Following this method of disinfection the instruments must be cleaned.

Disinfection with boiling water

This utilises soft water at 100°C at normal pressure for 5 minutes. Instruments must be thoroughly cleaned before being utilised.

Disinfection with formaldehyde

Formaldehyde gas is a broad-spectrum antimicrobial agent. This process utilises a cabinet which is airtight and circulates gaseous formaldehyde up to 50°C.

Disinfection with glutaraldehyde

A 2 per cent solution of glutaraldehyde is effective against most bacterial viruses, including hepatitis B and C and HIV, and is particularly useful for the decontamination of flexible endoscopes.

- Thorough cleansing is essential.
- The degree of decontamination is proportional to the time of immersion.
- It is a toxic substance and causes irritant, allergic reactions to the staff, particularly skin reactions, which limits its use.

Safeguards for equipment during sterilisation

Safeguards during sterilisation must include:

- thorough cleaning;
- appropriate packing for the sterilisation process in order to avoid reduced penetration of the active agent. This is particularly important in the packing in the autoclave;
- arrangements of articles so that all surfaces are directly exposed to the agent. This includes opening or unlocking jointed instruments and disassembling instruments;
- the use of chemical indicators routinely;
- the interval monitoring of sterilisation process with chemical, thermal and, sometimes, biological indicators;
- the utilisation of flash sterilisation, where a temperature of 147°C is used at a pressure of 40 lb/in.², is now rare and should only be considered in an emergency situation;
- a careful maintenance plan for all sterilisation processes.
Theatre staff

Bacterial infection

The presence of an infected skin lesion, such as a boil, paronychia or carbuncle, known carrier state, particularly in the nares and the presence of an acute bacterial infection, particularly an upper respiratory tract infection, must lead to the exclusion of such a person from the team. There is good microbiological evidence to show that failure to do so will lead to an increasing number of infections.

Showering

Showering is preferable to bathing and the utilisation of a 4 per cent chlorhexidine gluconate soap by the surgical team is of benefit before the start of an operating list, and has been recommended for the operating surgeon between cases when the procedure is long.

Clothing and gowning

Desquamation principally occurs from the lower half of the body and the changing from normal clothes to clean linen reduces the bacterial count; cotton pores are 100 μm in size whereas skin scales are 5—60 μm, and thus cotton clothing will not serve as a barrier. Cotton suits worn below cotton gowns results in a decrease in bacterial count in air by 30 per cent. The newer bacterial impermeable fabrics further reduce the count but are of no value when worn over cotton pajamas because the desquamation process continues and bacteria still escape, particularly at the ankles but also at the neck. The wearing of elastic anklets on trousers will reduce bacterial counts by 47 per cent. The most effective reduction of airborne bacteria is obtained by using the Charnley exhaust gowns — this is particularly important in orthopaedic procedures, but probably not significant in general surgery.

Caps are usually worn, although the amount of pathogenic bacteria dispersed is unlikely to be of any significance in general surgery, but may again be significant in implant surgery.

• Pajamas with elasticated ankles and wraparound breath-able membrane fabrics will reduce the bacterial count.

• In orthopaedic surgery, use of the Charnley exhaust gown is optimal.

Masks

The oropharynx is a low-level source of bacteria (36 bacteria per 100 words spoken are generated), the number of bacteria that settle on culture plates is not affected by wearing a mask and several studies exist to show that the wearing of masks in general surgery does not affect the wound infection rate, although the wearing of masks in implant surgery is appropriate as their use has been shown to decrease the number of bacteria detected at the operating site.

• Their use is indicated in implant and orthopaedic surgery.

• They offer protection to the wearer.

• Reduction of speech at the operating table is important.

Gloving

Although gloving or double gloving is widely practised there is little evidence that wound infection is related to glove puncture. This would suggest that disinfection of the hands is important in keeping the incidences of wound infection low.

Scrubbing up

Brushes should only be used for cleaning finger nails. A scrub-up time of 3—5 minutes with chlorhexidine soap or povidone iodine soap is utilised; the former is a broad-spectrum rapidly active agent with persistent activity, whereas the latter has a relatively short duration. The technique should include thorough washing of the hands to the elbows, with removal of the soap in the direction hand to elbow.

Excess soap is not required but a steady and methodical method of massage is important, and adequate drying is again essential, the preferred technique using paper towels in the direction hand to elbow. Jewellery should be removed
The operation

Preoperative preparation of patient

Factors to be taken into account include the following.

- Preoperative showering with hexachlorophane is widely used in Sweden but not elsewhere; subjects shower twice on the day before and once on the day of surgery. This has been shown to reduce the incidence of wound infection. The former practice of wrapping limbs, before vascular surgery, in povidone—iodine dressings has not been shown to reduce infection rates.

- A short preoperative hospital stay is important; this reduces both the presence of pathogenic bacteria on the skin and the incidence of nasal carrier state (Staphylococcus aureus) among patients on the ward.

- Preoperative screening with swabbing of the skin and nose is expensive, and has not been shown to have been of value in altering outcome in terms of infection.

- Shaving — the trauma of shaving undoubtedly results in lacerations to the skin, which can increase infection rate; it is preferable to use either clippers or, ideally, depilation cream but the latter is expensive.

- Transport — the value of trolleys as opposed to transportation in the bed has not been shown to alter infection rates; similarly, the value of transfer trolleys, i.e. keeping one trolley for outside theatre use and one for inside theatre use, and the use of a sticky mat at the theatre entrance have been shown to be ineffective measures.

Skin preparation

Before arrival in theatres the skin of the operation site should be washed with detergent-impregnated soap. This both cleans and degreases the skin. In the operating theatre antisectic solutions, usually of an alcohol-based detergent such as chlorhexidine or povidone—iodine, give optimal disinfection. The solution should be allowed to dry to maximise the reduction of bacteria, and pools of residual alcoholic solution, such as occur at the umbilicus or in the perineum, must be dried off completely, otherwise there is a danger of burning with the use of diathermy. The vagina and perineum should be cleaned with aqueous chlorhexidine and cetrimide solution. Adhesive plastic drapes are widely used and have the advantage of keeping either cotton or fabric drapes in place, but there is no evidence that they reduce the incidence of wound infection.

The procedure

High standards of asepsis in the operating theatre demand clear protocols or guidelines with regard to the conduct of surgery, and must be monitored by the theatre manager. The proper performance of surgery ensures safety for the patient, surgeon and staff.

Instruments must be handled in such a way as to avoid injury to the patient and staff.

- Sharps should be kept in receivers and disposed of safely using sealed containers.

- Instruments should not be left on drapes where they can directly injure the patient or damage the drapes, breaching asepsis.

- Disposable instruments, particularly those with contaminated blood, should be discarded securely in labelled containers.

- Instruments should be well maintained so that no body fluid remains on the instruments after washing.

- When the preliminary count is done at the start of an operation, instruments should be checked so that all joints, nuts, screws and surfaces that slide over each other are clean with no detritus present, and move freely.

- Swabs should be counted carefully and stored in the special plastic racks containing individual ‘swab pockets’.

High-risk infection procedures

Again, there should be careful protocols for the handling of blood and body fluids in order to reduce the risk of auto-infection and cross-infection, for hepatitis B and C viruses, HIV and cytomegalovirus; such precautions are of particular importance in patients who have pre-existing infection or who are immunosuppressed.

General measures include:

- education of staff so that they are fully aware that there is a full vaccination programme for hepatitis B;

- the availability of advice for staff in the event of injury.

practical measures include:

- identifying high-risk patients on the operating list;

- reduction of the number of staff in the theatres to cover essential roles only;

- removal of all extraneous equipment from the theatre;

- Staff should avoid contact with contaminated body fluids, especially blood, and in this respect abrasions should be covered. If the member suffers from eczema, he or she should be excluded from the theatres and if contamination does occur rapid washing should be undertaken.

- When handling potentially contaminated blood or body fluids, scrub staff should use nonpermeable gowns and masks with eye protection and should double glove.

Circulating personnel should use plastic aprons and wear gloves.

- Spills should be dealt with by staff wearing gloves and using absorbent disposable clothes; hypochlorite 1 per cent solution may be applied to
• Particular care should be taken with the handling of sharps, which should always be kept in receivers.

• Swabs should be counted but not left exposed, as for routine operations on a spike rack, they should be placed in deep ‘swab pockets’ on plastic racks.

• Disposable equipment should be placed in yellow bags at the earliest possible time, then sealed and double bagged with a hazard label attached.

• Soiled linen should be placed in special alginate bags and sent to the laundry clearly marked. At the end of the case all surfaces should be cleaned with detergents and the Domestic Officer informed.
Conclusion

Antibiotics, both prophylactic and therapeutic, have not reduced the essential role of asepsis and sterile precautions. Protocols with regard to instrument sterilisation, equipment maintenance, air filtration and ventilation, and staff behavior are essential. Regular staff education is imperative.

Historical perspective

Since early times the idea of tissue and organ transplantation has captured the imagination of successive generations, and over the centuries numerous fanciful descriptions of successful transplants have been recorded. One of the most widely cited early examples is that of the Christian Arab saints Cosmas and Damien. They were reputed, around 300 AD, to have successfully replaced the diseased leg of a patient with that from a black man who had died several days earlier (Fig. 11.1). The modern era of transplantation began in the 1950s and relied on surgical techniques for anastomosing blood vessels which had been developed at the beginning of the twentieth century by Mathieu Jaboulay and Alexis Carrel. The first successful kidney transplant was a living donor transplant performed between identical twins in 1954 at the Brigham Hospital in Boston by Joseph Murray and colleagues. This and other kidney transplants between identical twins demonstrated the technical feasibility of kidney transplantation, but attempts to perform renal transplantation when the donor and recipient were not genetically identical failed because no effective immunosuppressive therapy was available (Fig. 11.2). Then, in 1959, Schwartz and Dameshek discovered that 6-mercaptopurine had immunosuppressive properties, and Roy Caine showed that azathioprine, a derivative of 6-mercaptopurine, prevented rejection of canine kidney transplants. From the early 1960s, a combination of azathioprine and corticosteroids was used with success in the clinic to prevent graft rejection after kidney transplantation. These chemical agents were sometimes supplemented with a polyclonal antilymphocyte antibody given at the time of transplantation as immunoprophylaxis or used to treat an episode of graft rejection. The cyclosporin era began in the late 1970s following the discovery of the new agent by Borel at the Sandoz laboratories in Basle and the demonstration, by Caine, of its potent immunosuppressive properties in clinical studies. The introduction of cyclosporin was a major advance and cyclosporin (usually given together with azathioprine and steroids) not only improved the results of renal transplantation but also allowed transplantation of the heart and liver to be undertaken with acceptable results. Organ transplantation is now well established as an effective treatment for selected patients with end-stage organ failure. Transplantation of the kidney, liver, pancreas, heart and lungs are all routine procedures, and transplantation of the small intestine is becoming more widely practised. Today, transplant activity is limited only by the shortage of cadaveric organs.
Definitions

- Allograft (synonymous with the old term homograft) — an organ or tissue transplanted from one individual to another.
- Syngeneic graft (isograft) — a transplant between identical twins.
- Orthotopic graft — a transplant placed in its normal anatomical site.
- Heterotopic graft — a transplant placed in a site different to that where the organ is normally located.
- Xenograft — a graft performed between different species.
Graft rejection

Allografts provoke a powerful immune response that results in rapid graft rejection unless immunosuppressive therapy is given. The pioneering studies of Medawar in the 1940s and 1950s firmly established that allograft rejection was due to an immune response and not a nonspecific inflammatory response. Later studies demonstrated that T-lymphocytes play an essential role in orchestrating the graft rejection response. The immunological effector mechanisms responsible for graft rejection are those that have evolved to provide protection from pathogens — in other words there are no unique immunological mechanisms causing graft rejection. Cytotoxic T-cells, delayed-type hypersensitivity and antibody-dependent effector mechanisms all play a role.

The allograft rejection response is directed against a group of cell-surface molecules called the ‘human leucocyte antigens’ (HLAs) which were first described by Dausset in 1958. HLAs are highly polymorphic (i.e. the amino acid sequence is very variable between individuals) and play a special role in immune recognition. Their normal physiological function is to display antigenic peptides derived from foreign pathogens so that they can be recognised by T-lymphocytes.

There are two types of HLA molecule — HLA class I and HLA class II. HLA class I molecules comprise a polymorphic alpha-chain which is associated with a smaller nonpolymorphic chain known as a betat-2-microglobulin. HLA class II molecules comprise two polymorphic polypeptide chains designated alpha and beta. The tertiary structure of HLA class I and HLA class II is similar. In both classes of HLA molecule, the extracellular domains form a cleft, the purpose of which is to bind and display foreign peptides for surveillance by T-lymphocytes (Fig. 11.3). Each individual HLA molecule only binds one peptide at a time but can bind a wide range of different peptides. The two classes of HLA molecule differ with respect to the source of the peptides they bind. HLA class I molecules present antigenic peptides derived from within the cell, for example antigenic peptides derived from intra-cellular viruses. HLA class II molecules, in contrast, present peptides derived from the extracellular environment. In the context of organ transplantation it is important to note that the peptide-binding grooves of HLA molecules never lie empty. When they are not occupied by an antigenic peptide derived from an invading microorganism they are occupied by nonantigenic peptides derived from intracellular proteins, including peptides derived from HLA molecules themselves.

HLA class I antigens are present on all nucleated cells, while HLA class II antigens have a more restricted distribution and are expressed strongly on antigen-presenting cells such as dendritic cells, macrophages and B-lymphocytes. However, HLA class II expression is readily inducible on all cell types by cytokines such as interferon-gamma. HLA molecules expressed on donor tissues trigger a strong graft rejection response in the recipient by virtue of their special role in T-cell recognition and the fact that they are so polymorphic. It is rare for two unrelated individuals to have a completely identical set of HLA molecules. The high degree of HLA polymorphism between individuals is clearly unfortunate from the viewpoint of organ transplantation because it ensures immunological incompatibility between unrelated individuals. However, transplantation of organs is nonphysiological and it is reassuring to remember that the existence of extensive HLA polymorphism provides a survival advantage for the human species by maximising the chance that a given population will be able to recognise and mount an effective immune response to new pathogens.

T-lymphocytes recognise peptide antigens bound to HLA molecules through their T-cell receptor (TCR), and each T-cell expresses a unique TCR that binds to a particular HLA—peptide complex. During their development, T-cells that recognise self-derived peptides displayed by self-HLA are normally deleted as they mature in the thymus gland, thereby eliminating self-reactive T-cells and avoiding autoimmunity.

The TCR is a heterodimer comprising an alpha- and beta-chain. It associates at the surface of the T-cell with the CD3 complex, which is involved in intracellular signalling after the TCR is activated by engaging antigen. Mature T-cells bear either CD4 or CD8 coreceptors and these bind to nonpolymorphic regions of class II and class I HLA, respectively, on antigen-presenting cells. Activation of a T-cell by an antigen-presenting cell requires the delivery of two distinct signals (Fig. 11.4). The first signal (signal 1) is delivered after ligation of the T-cell receptor with an HLA—antigen complex. The second signal (signal 2) is delivered following the interaction of additional nonpolymorphic ligand—receptor molecules or co stimulatory molecules on the surface of the antigen-presenting cell and T-cell.

In the context of organ transplantation, allogeneic HLA molecules are exceptionally strong antigens because they are able to stimulate T-cells directly without the need to be broken down into short peptides and presented in the cleft of an HLA molecule. This pathway of antigen recognition is unique to transplantation and is called direct allorecognition. All of the commonly transplanted organs have large numbers of dendritic cells distributed throughout their parenchyma. These professional antigen-presenting cells are richly endowed with class I and class II antigens and possess all of the necessary costimulatory molecules to trigger activation of recipient T-cells. Allogeneic molecules can also be processed like other types of antigen and displayed as antigenic peptides associated with HLA molecules on recipient antigen-presenting cells — this is termed indirect allorecognition and makes an important contribution to graft rejection.

After encountering alloantigens, activated T-cells undergo a period of clonal expansion which is dependent on IL-2 and other T-cell growth factors. CD4 T-cells, through release of cytokines, play a central role in orchestrating various effector mechanisms which are responsible for graft rejection (Fig. 11.5). The cellular effectors of graft rejection include cytotoxic CD8 T-cells that recognise donor HLA class I antigens expressed by the graft and cause target cell death by releasing lytic molecules such as perforin and granzyme. Graft-infiltrating CD4 T-cells that recognise donor HLA class II mediate direct target cell damage and are also able, by releasing cytokines such as interferon-gamma, to recruit and activate macrophages which act as nonspecific effector cells. Finally, CD4 T-cells provide essential T-cell help for B-lymphocytes that produce alloantibodies which bind to graft antigen and induce target-cell injury directly or through antibody-dependent cell-mediated cytotoxicity.

Types of allograft rejection

Allograft rejection can be divided into three distinct types on the basis of timescale and underlying pathophysiology:

- **Hyper acute rejection** (occurs immediately);
- **Acute rejection** (occurs in the first 6 months);
- **Chronic rejection** (occurs months and years after transplantation).

Hyper acute rejection is avoidable and acute rejection, although common, can usually be reversed by immunosuppressive therapy. Chronic rejection occurs after all types of organ transplantation and, because it is largely resistant to currently available immunosuppressive therapy, is a major cause of graft failure. Allograft rejection manifests itself as functional failure of the transplant and is confirmed by histo-logical examination. Biopsy material is obtained from renal and pancreas grafts by needle biopsy, and from hepatic grafts by percutaneous or transjugular liver biopsy. Cardiac grafts are biopsied by transjugular endomyocardial biopsy, and lung grafts by transbronchial biopsy. After small intestinal transplantation, mucosal biopsies are obtained from the graft stoma or more proximally by endoscopy. A standardised histological grading system, termed the Banff classification (named after the Canadian town where the initial scientific workshop was held) defines the presence and severity of allograft rejection after solid organ transplantation.
Hyperacute rejection is due to the presence in the recipient of preformed cytotoxic antibodies against HLA class I antigens expressed by the donor. These may arise from blood transfusion, a failed transplant or previous pregnancy. This type of rejection also occurs if an ABO blood group-incompatible organ graft is performed. After revascularisation of the graft, antibodies bind immediately to the vasculature, activate the complement system, and cause extensive intravascular thrombosis and graft destruction within minutes and hours. Kidney transplants are particularly vulnerable to hyperacute graft rejection, whereas heart and liver transplants are relatively resistant to this type of rejection. In clinical practice, hyperacute rejection can be avoided by performing a cross-match test on recipient serum to ensure that it does not contain antibodies directed against HLAs expressed by a prospective kidney donor. Even in the presence of a strongly positive cytotoxic cross-match test, liver transplants rarely undergo hyperacute rejection, although their long-term survival is inferior. It is not clear why the liver is so resistant to hyperacute rejection, but one factor may be that it is less susceptible to ischaemia than the kidney by virtue of its dual blood supply: 60 per cent of the hepatic blood supply derives from the portal vein and 40 per cent from the hepatic artery.

Acute allograft rejection usually occurs during the first 6 months of transplantation but may occur later. It is mediated predominantly by T-lymphocytes, but alloantibody may also play an important role. Acute rejection is characterised by mononuclear cell infiltration of the graft (Fig. 11.6). The mononuclear cell infiltrate is heterogeneous and includes cytotoxic T-cells, B-cells, natural killer (NK) cells and activated macrophages. Antibody deposition may also be present. All types of organ allograft are susceptible to this form of rejection and it occurs in 25—50 per cent of cases. Fortunately, the majority of acute rejection episodes can be reversed by appropriate immunosuppressive therapy.

Chronic allograft rejection occurs after the first 6 months, and is due to antibody- and cell-mediated effector mechanisms. All types of transplant are susceptible to chronic rejection and it is the major cause of allograft failure. Interestingly, however, the liver appears more resistant than other solid organs to the destructive effects of chronic rejection. The pathophysiology of chronic allograft rejection is not completely understood. The underlying mechanisms are immunological, and both allo-antibodies and cellular effector mechanisms appear to contribute. However, it is now clear that alloantigen-independent factors also play a role in the pathogenesis. A number of risk factors for chronic rejection has been identified in the context of renal allograft rejection. These are:

- previous episodes of acute rejection;
- degree of HLA mismatch;
- long cold ischaemia time;
- cytomegalovirus (CMV) infection;
- raised blood lipids;
- inadequate immunosuppression (poor compliance).

The single most important risk factor for chronic rejection is acute rejection. After kidney transplantation, acute rejection with vascular inflammation and recurrent episodes of acute rejection are strongly predictive of subsequent graft failure from chronic rejection.

The histological picture of chronic rejection is dominated by vascular changes with arterial myointimal proliferation which results in ischaemia and fibrosis (Fig. 11.7). In addition to vasculopathy, there are organ-specific features of chronic graft rejection. These are:

- kidney — glomerular sclerosis and tubular atrophy;
- pancreas — acinar loss and islet destruction;
- heart — accelerated coronary artery disease (cardiac allograft vasculopathy);
- liver — vanishing bile duct syndrome;
- lungs — obliterative bronchiolitis.

Chronic rejection causes functional deterioration in the graft resulting after months or years in graft failure. Unfortunately, currently available immunosuppressive therapy has had little effect in preventing chronic rejection.
**Histocompatibility testing and screening for presensitisation**

HLA molecules are encoded by the major histocompatibility complex (MHC), a cluster of genes situated on the short arm of chromosome 6 (Fig. 11.8). The HLA class I antigens comprise HLA-A, -B and -C, and the HLA class II antigens comprise HLA-DR, -DP, and -DQ. Expression of MHC genes is codominant, i.e., the genes on both the maternally derived and the paternally derived chromosomes are expressed. Consequently, an individual may express between six and 12 different HLAAs, depending on the degree of homozygosity (shared genes) at individual loci. Determination of the HLA or tissue type of an individual was traditionally performed on I- and B-lymphocytes by serological methods using a panel of antisera directed against the different HLA specificities in a microcytotoxicity assay, as described by Terasaki in 1965. However, increasing reliance is now placed on DNA-typing techniques to determine tissue type. These include techniques such as polymerase chain reaction (PCR) analysis using HLA sequence-specific primers.

In renal transplantation, attempts are made to match the donor and recipient histocompatibility antigens for as many of the relevant HLAAs as possible. In addition to reducing the risk of graft loss from rejection, a well-matched kidney allo-graft that subsequently fails is less likely to cause sensitisation to the HLAAs that it expresses. It is particularly important in children and young adults to avoid, where possible, grafts that are mismatched for common HLAAs because, if retransplantation is required subsequently, it may be difficult to find an organ donor that does not express the antigens to which the recipient has become sensitised. In terms of organ transplantation, HLA-A, -B and -DR are the most important anti-gens to take into account when attempting to match donor and recipient in an attempt to reduce the risk of graft rejection (Fig. 11.9). HLA matching has a relatively small but definite beneficial effect on renal allograft survival (HLA-DR > HLA-B > HLA-A). Recipients who receive well-matched renal allografts may require less intensive immunosuppression and also have less trouble from rejection episodes. It is common practice to express the degree of HLA matching between the donor and recipient in terms of whether or not there are mismatches at each locus for HLA-A, -B and -DR. A '000 mismatch' is a full-match or complete match, whereas a '012 mismatch' is matched at the HLA-A locus, has one mismatched HLA-B antigen and is mismatched for both DR antigens. Cadaveric kidneys are allocated in some countries, including the UK, by a points system which optimises HLA matching but also takes into account other factors, such as time on the waiting list and the relationship between the donor and recipient age. Allocation of organs for transplant-tion must also take into account the relative size of donor and recipient. This is not an issue in renal transplantation as adult kidneys can be readily used for paediatric recipients (and vice versa). However, for heart, lung, liver and small bowel transplantation, it is important to consider size compatibility between the donor and recipient.

HLA matching does not appear to confer an advantage for liver transplants and, although it is beneficial in cardiac trans-plantation, it is not practicable because of the relatively small size of the recipient pool and the short permissible cold ischaemic time.

As already noted, however, it is essential for all types of organ graft to ensure blood group compatibility. Permissible transplants are:

- group 0 donor to group 0, A, B or AB recipient;
- group A donor to group A or AB recipient;
- group B donor to group B or AB recipient;
- group AB donor to group AB recipient.

There is no need to take account of rhesus (Rh) antigen compatibility in organ transplantation. Interestingly, after an ABO mismatched but permissible liver transplant (0 donor into non-O recipient and A or B liver into an AB recipient) about 50 per cent of recipients develop an early and transient episode of haemolysis due to antibodies produced by donor lymphocytes in the transplanted liver.

In contrast to HLA matching, which is very desirable but not vital to success, the detection of sensitisation to HLA antigens in prospective renal allograft recipients is absolutely essential in order to avoid hyperacute rejection. Immediately before renal transplantation, a cross-match is performed by testing recipient sera against donor I-cells (which express HLA class I but not class II). When the cross-match test is positive transplantation should not proceed as anti-HLA class I antibodies cause hyperacute rejection. An additional cross-match test using donor B cells (which express both HLA class I and class II antigens) is also performed to detect antibodies directed against HLA class II antigens. A negative I-cell but positive B-cell cross-match may indicate the presence of HLA-specific anti-class II antibodies, and these are associated with an increased likelihood of acute rejection and a poor clinical outcome. Patients on the renal transplant waiting list should be screened for the development of HLA antibodies on a regular basis and especially after potential priming to HLAAs by blood transfusion. Sensitisation is particularly common after blood transfusion in women who have been previously primed to paternal HLAAs during pregnancy. Recipient sera are screened against an HLA-typed panel representing a broad range of HLAAs found within the general population so that the specificity of recipient HLA antibodies can be determined. Highly sensitised recipients are arbitrarily defined as those whose sera contain immunoglobulin G (IgG) HLA-specific antibodies reacting with > 85 per cent of the donor cell panel. Traditionally, cross-matching is performed by complement-dependent lymphocytotoxicity, but flow cyto-metric cross-matching is becoming more widespread. Flow cytometric cross-matching is more sensitive than cytotoxicity, and is particularly valuable for screening highly sensitised recipients and patients undergoing retransplantation.

Patients awaiting heart transplantation are also screened for the presence of panel-reactive antibodies. Relatively few patients are highly sensitised (< 10 per cent) but in those who are, a prospective cross-match using donor lymphocytes should be performed. Although heart allografts rarely undergo hyperacute rejection, cardiac transplantation in the presence of a positive cross-match is associated with a high incidence of graft loss from accelerated acute rejection. In practice, highly sensitised heart transplant recipients are difficult to transplant because prospective cross-matching is problematic owing to the time constraints imposed by the short donor cold ischaemia time.
Immunosuppressive therapy

Evolution of immunosuppressive therapy

In tracing the development of clinical immunosuppression, three different eras can be identified:

- the early or precyclosporin era (from the early 1960s to the late 1970s);
- the cyclosporin era (from the early 1980s);
- the modern era (the 1990s).

Until the discovery of cyclosporin in the late 1970s, steroids and azathioprine were used for immunoprophylaxis. During the cyclosporin era the monoclonal antibody OKT3, directed against the CD3 molecule expressed on T-lymphocytes, also became available and was sometimes used along with cyclosporin based regimens as immunoprophylaxis (especially in North American centres) or to treat steroid resistant graft rejection. The 1990s can be regarded as the modern era of immunosuppression. Although cyclosporin is still the mainstay of many immunosuppressive regimens, several new agents have now been introduced. The place of cyclosporin has been challenged by tacrolimus and other important immunosuppressive agents have recently become available, including mycophenolate mofetil, rapamycin and monoclonal antibodies directed against the interleukin-2 (IL-2) receptor (CD25). When considering immunosuppressive therapy for organ transplantation, the transplant surgeon is now faced with an increasing range of different agents from which to choose (Table 11.1).

Calcineurin blockers

Cyclosporin and tacrolimus, although structurally distinct, exert their principal immunosuppressive effect through the same pathway. Each of the two agents binds within the T-cell to a particular cytoplasmic protein or immunophilin (cyclosporin binds to cyclophilin and tacrolimus to FK binding protein). The resulting immunophilin—drug complex then blocks the activity of calcineurin (a phosphatase) within the cytoplasm of the T-cell. Calcineurin plays a critical role in facilitating the transcription of IL-2, the main T-cell growth factor, and other cytokines after T-cell activation. By blocking cytokine synthesis, cyclosporin and tacrolimus exert a potent immunosuppressive effect. The agents therefore share a number of side effects, the most notable of which is nephrotoxicity (Table 11.2). Cosmetic side effects may be particularly distressing for the patient (Fig. 11.10). The calcineurin blockers have a relatively small therapeutic window, and monitoring of whole blood drug levels is an important guide to optimal therapy. If, after renal transplantation, the graft fails to function immediately because of acute tubular necrosis, calcineurin blockers may be withheld temporarily to avoid the risk of drug-induced nephrotoxicity. The relative efficacy of cyclosporin and tacrolimus in pre-venting graft rejection is broadly comparable, and the choice between the two agents is dependent on the preference of the transplant unit and on individual patient tolerance to the different side effects of the two agents.

Antiproliferative agents

Lymphocytes are among the most rapidly proliferating cells in the body, and lymphocyte proliferation and clonal expansion is an integral part of the immune response to an allograft. The antiproliferative agents available for immunoprophylaxis are azathioprine and mycophenolate. Azathioprine is converted in the liver to its active metabolite 6-mercaptopurine which blocks purine metabolism and thereby inhibits cellular proliferation. Mycophenolate is a recently introduced antiprolifera-tive agent that, after ingestion, is converted to its active metabolite, mycophenolic acid. It inhibits the enzyme inosine monophosphate dehydrogenase that is the rate limiting enzyme in the de novo pathway of purine nucleotide synthesis. Because lymphocytes do not have a salvage pathway for purine synthesis, their ability to proliferate is selectively impaired.

Steroids

Steroids have always been an important component of immunoprophylactic regimens. Glucocorticoids are potent anti-inflammatory agents and have wide-ranging effects on the immune response. Because of their numerous and well-known side effects, many centres attempt to withdraw gradually steroids from patients who have stable graft function at around 1 year after transplantation, but this sometimes precipitates a rejection episode and necessitates continued treatment with steroids.

Antibody therapies

Many North American transplant units also include antilym-phocyte antibody preparations as part of their immunopro-phylaxis — so-called ‘triple therapy’. A polyclonal antilymphocyte preparation (ALG or ALS) may be used or, alternatively, a monoclonal antibody directed against CD3 or CD25 (IL-2 receptor) on T-cells may be given. In Europe, the use of antibody preparations is more common after heart transplantation, where irreversible rejection is usually synonymous with death of the patient. Antibody therapy is often used in renal transplantation for patients who are thought to be at particular risk from graft rejection, for example highly sensitised and second- or third-time graft recipients.

Rapamycin

Rapamycin is a newly discovered immunosuppressive agent that was isolated from a fungus found on Easter Island. Like tacrolimus, it is a macrolide which binds within the I-cell to FK binding protein. However, the mode of action of rapa-mycin is completely different to that of both cyclosporin and tacrolimus. It acts by interfering with intracellular signalling from the IL-2 receptor and arrests I-cell division in the G1 phase. Rapamycin and cyclosporin therefore act at different stages in I-cell activation and their immunosuppressive effects are synergistic.

Immunosuppressive regimens

When selecting an immunosuppressive regimen some of the important points to bear in mind are as follows.

- The challenge is to provide levels of immunosuppression that are sufficient to protect the graft from rejection with-out exposing the recipient to excessive risk from infection and malignancy as a result of nonspecific immunosuppression.
- Immunosuprophylaxis is started at the time of transplantation and continued indefinitely (as maintenance therapy), although the requirement for immunosuppression is highest in the first few weeks after transplantation when the risk of acute rejection is greatest.
- Individual immunosuppressive protocols vary somewhat but almost all use a combination of immunosuppressive agents. All include a calcineurin blocker (cyclosporin or tacrolimus) as the main agent and this is most often given along with an antiproliferative agent (azathioprine or myco-phenolate mofetil) and steroids — so-called ‘triple therapy’. Less often, a calcineurin blocker is used with an
antiproliferative agent alone or with steroids alone (dual therapy).

- A few renal transplant units use monotherapy with a calcineurin blocker and then add other agents only if needed to treat rejection. At the other end of the spectrum, some units, particularly those in North America, advocate the use of antibody induction therapy (monoclonal or polyclonal preparations) followed by a calcineurin blocker, an anti-proliferative agent and steroids (quadruple therapy).

- Many renal transplant units reserve the more intensive antibody induction protocols for recipients judged to be at increased risk of graft rejection (e.g. highly sensitised recipients and grafts with a poor HLA match).

- The principles of immunoprophylaxis are similar for all types of organ transplantation. However, after thoracic organ transplantation there is a tendency to use more intensive immunosuppression than for kidney transplantation, in part because loss of a heart or lung graft from rejection almost inevitably culminates in death. Interestingly, liver grafts seem less susceptible to graft rejection, for reasons that are still unclear.

- The place of the newer immunosuppressive agents, such as rapamycin and anti-CD25 monoclonal antibodies, still remains to be established but recent trials have shown promising results.

Acute rejection during the first 6 months of transplantation occurs in around 20—40 per cent of transplant recipients. Fortunately, the majority of acute rejection episodes responds to a short course of high-dose steroid therapy. This can be given as three daily intravenous doses of methylprednisolone (0.5—1 g/dose) or a several-day course of oral prednisolone (e.g. 200 mg tapering to 20 mg). If the response to treatment is inadequate or if acute rejection recurs it can often be treated successfully by recourse to anti-thymocyte antibody therapy and/or switching from cyclosporin to tacrolimus (or vice versa).
Complications of immunosuppression

All immunosuppressive regimens used in organ transplantation increase the risk of infection and malignancy.

Infection

Transplant recipients receiving immunosuppressive therapy are at high risk from opportunistic infection, especially by viruses. Opportunistic infection is a potential problem in all transplant recipients, but those receiving aggressive immunosuppressive therapy after liver, heart, lung and small bowel transplantation are most at risk. Chemoprophylaxis is important in high-risk recipients.

Bacterial infection

The risk of bacterial infection is highest during the first month after transplantation. Transplant recipients are, like all patients undergoing major surgery, at risk of bacterial infections in the wound, respiratory tract and urinary tract. It is standard practice to give a broad-spectrum antibiotic to cover the perioperative period as prophylaxis against wound infection and possible bacterial contamination of the donor organ. The risk of bacterial infection is greatest in transplant recipients who are critically ill before or after surgery and are in the intensive care unit with indwelling catheters and lines. After recovery from surgery, the risk of bacterial infection is much reduced. Tuberculosis is a concern in patients who have previously had mycobacterial infection and in patients from the Indian subcontinent, and it is usual to give immunocompromised prophylaxis to these individuals for a period of 6—12 months after transplantation.

Viral infection

The risk of viral infection is highest during the first 6 months after transplantation and the most common problem is CMV infection. Most adults (> 80 per cent) develop CMV infection when they are children and have acquired immunity, as evidenced by the presence of IgG antibodies to CMV. Following organ transplantation, CMV disease may arise because of reactivation of latent infection or because of primary infection that can be transmitted by an organ from a CMV-positive donor. The recipients at most risk from CMV infection are those who are CMV seronegative and receive an organ from a CMV-seropositive donor. Matching seronegative donors with seronegative recipients is an effective strategy for reducing the risk of CMV infection but is not very practicable. CMV disease typically presents with a high swinging fever, lethargy and leucopenia. The severity of the disease is variable and the clinical picture depends on the organ system most affected. It may present as:

- pneumonia;
- gastrointestinal disease;
- hepatitis;
- retinitis;
- encephalitis.

Severe CMV disease is potentially fatal. Prophylaxis for CMV consists of passive immunisation using hyperimmune immunoglobulin or, more commonly now, administration of antiviral agents in the form of aciclovir or ganciclovir. A diagnosis of active CMV infection can be confirmed by serology, detection of CMV antigenaemia, CMV culture, PCR to detect viral DNA and histological examination of biopsy material. Treatment is with ganciclovir and is more effective when given pre-emptively on the basis of increased viral load as judged, for example, by quantitative PCR analysis for CMV.

Herpes simplex virus (HSV) infection is common after transplantation and is usually due to reactivation of latent infection. It causes mucocutaneous lesions around the mouth and sometimes the genitalia. These usually respond to topical treatment with acyclovir, but in severe cases systemic antiviral therapy is needed. Disseminated HSV infection is rare. Varicella zoster infection occurs more frequently in transplant patients and should be treated with systemic antiviral therapy.

Protozoal infection

Pneumocystis carinii is the most important protozoal infec-tion after transplantation. It occurs during the first few weeks and presents with respiratory symptoms. The diagnosis is made by examination of bronchoalveolar lavage fluid or lung biopsy material for evidence of parasite infection. Prophylaxis with co-trimoxazole is highly effective and is usually continued for 6 months after transplantation.

Fun gal infection

Invasive fungal infections are uncommon in renal transplant recipients but infection with Candida or Aspergillus is more common after other types of solid organ transplantation. Fungal infection usually occurs in the first 3 months after transplantation, and early diagnosis and aggressive treatment are essential to avoid fatal infection.

Malignancy

After transplantation there is an increased risk of developing certain types of malignant disease, especially those tumours where viral infection plays an aetiological role. The increased risk of malignancy is particularly high for skin cancer and non-Hodgkin’s lymphoma. Most of the skin cancers seen are squamous cell carcinomas, but basal cell carcinoma and malignant melanoma are also more common (Fig. 11.11). The risk of skin cancer after transplantation rises with age and with exposure to sunlight, and it has been predicted that 50 per cent of transplant patients will develop a skin malignancy by 20 years. Patients must be warned of this risk before they undergo transplantation and advised to use an effective sun-screen. They should undergo regular review of their skin to detect malignancy and when such lesions occur they must be treated promptly and aggressively.

The risk of developing non-Hodgkin’s lymphoma is significantly increased after transplantation. This type of malignan-cy is classified as post-transplant lymphoproliferative disease (PTLD). Most of them are Epstein—Barr virus-induced B-cell tumours. The overall risk of PTLD is around 1 per cent per annum and is highest in patients who have received aggressive immunosuppression. PTLD may occur in lymph nodes or at extranodal sites such as the gastrointestinal tract, lung, liver or in the transplanted organ (Fig. 11.12). If PTLD is identified at an early stage reduction or cessation of immuno-suppressive therapy may cause disease regression and result in a cure. When advanced it is usually fatal. Both disseminated disease and central nervous system (CNS) involvement have a very poor prognosis.

Transplant patients also have a 300-fold increased risk of developing Kaposi’s sarcoma, although this malignancy is still very uncommon after transplantation.
Organ donation

Most of the organs used for transplantation are obtained from brainstem-dead, heart-beating cadaveric donors and in the majority of cases multiple organs are procured. However, the number of organs required to satisfy the needs of transplant patients far exceeds the number of cadaveric organs available. This has prompted a relaxation in the organ-specific donor selection criteria and the use of organs from so-called ‘marginal donors’. In the case of kidney transplantation there is a trend towards increased living donor transplantation and the use of kidneys from non-heart-beating cadaver donors.

Determination of brainstem death

Brain death occurs when severe brain injury causes irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity for breathing. In most countries, it is accepted that the condition of brain death equates in medical, legal and religious terms with death of the patient. The concept of brain death arose through necessity in the management of patients with irreversible brain damage on life support where there was no prospect for recovery. It was not in the interest of such patients, their relatives or the hospital in which they were being treated to delay their inevitable demise by continuing with futile life support. Acceptance of the concept of brain-death had major implications for organ transplantation as it allowed the possibility for removal of viable organs from brain-dead patients before their circulation failed.

In the UK, and many other countries, brain death is defined in terms of permanent functional death of the brain-stem as neither consciousness nor spontaneous respiration is possible in the absence of a functional brainstem. A diagnosis of brainstem death should only be considered when certain preconditions have been met. The patient must have suffered major brain damage of known aetiology, be deeply unconscious and require artificial ventilation. Traumatic head injury and sudden intracranial haemorrhage are the most common causes of brainstem death. Particular care must be taken to ensure that muscle-relaxant agents and drugs with known CNS-depressant effects are not contributing to the clinical picture. Hypothermia, profound hypotension and metabolic or hormonal conditions that may contribute to CNS depression and confound the diagnosis of brainstem death must also be excluded. When the necessary preconditions have been satisfied formal clinical assessment of the brainstem reflexes can be undertaken (Table 11.3). The UK guidelines state that the tests should be performed on two separate occasions by two clinicians experienced in this area. At least one of the two clinicians should be a consultant and neither should be connected with the transplant team. The time that must elapse between the two sets of brainstem tests is not specified in the guidelines and is determined on the basis of clinical judgement. In the UK there is no requirement to perform electrophysiological or brain perfusion studies to aid the diagnosis of brainstem death. Particular care is required in the diagnosis of brainstem death in neonates and infants.

Evaluation of the cadaveric donor

After a brainstem-dead donor has been referred to the transplant team with a view to organ donation the general suitability of the potential organ donor must be carefully assessed. Particular care must be taken to assess the donor from the point of view of transmissible infectious agents and malignancy. The medical history should be carefully scrutinized and evidence of risk factors for human immunodeficiency virus (HIV), such as intravenous drug abuse, sought. The presence of HIV infection is an absolute contraindication to organ donation, as is hepatitis B infection (in most countries) and active systemic sepsis, for example major abdominal infection. The presence of malignancy within the past 5 years is also an absolute contraindication to organ donation, with the exceptions of low-grade primary tumouts of the CNS, nonmelanotic turnouts of the skin and carcinoma in situ of the uterine cervix. If there are no general contraindications to organ donation consideration is then given to organ-specific selection criteria.

The demand for cadaveric organs for transplantation far exceeds the supply and, consequently, there has been a progressive relaxation in the organ-specific selection criteria. The chronological age of the donor is less important than the physiological function of the organs under consideration for transplantation. As a rough guide acceptable donor age ranges for each of the commonly transplanted organs are as follows:

- kidney — 2—74 years;
- liver — 0—75 years;
- heart — 0—65 years;
- lung — 0—60 years;
- pancreas — 10—50 years.

The organs to be donated should generally be free from primary disease. Kidney donors should not have evidence of primary renal disease. They should have a reasonable urine output and normal serum urea and creatinine, although acute terminal elevations are acceptable. Liver donors should not have hepatic disease, although impaired liver function tests are common in cadaver donors and do not necessarily preclude donation. Heart donors should not have a history of pre-existing heart disease. They should have a normal electrocardiogram (ECG); in doubtful cases an echocardiogram may also be necessary. Lung donors should have no history of primary lung disease. The chest X-ray and gas exchange should be satisfactory, and bronchial aspirates should be free from fungal and bacterial infection. Pancreas donors should not have a history of diabetes mellitus, but elevations of blood glucose and serum amylase are not uncommon in cadaveric donors and do not preclude transplantation.

Organ procurement

When brainstem death has been confirmed, management of the donor is aimed at preserving the functional integrity of the organs to be procured. Brainstem death produces profound metabolic and neuroendocrine disturbances leading to cardiovascular instability. Careful monitoring and management of fluid balance is essential. Inotropic support is given and there may be a role for the use of tri-iodothyronine (13) and argipressin.

Procurement of multiple organs from a cadaveric donor requires co-operation between the thoracic and abdominal surgical teams. A midline abdominal incision and median sternotomy are used to obtain access. After dissection of the organs to be procured, they are perfused in situ. The heart is perfused with cold cardioplegic solution via a cannula in the ascending aorta, and the lungs are perfused via a cannula in the pulmonary artery. The abdominal organs are perfused with chilled organ preservation solution via an aortic and portal cannula. Blood and perfusate are vented from the left atrial appendage and the inferior vena cava. This produces rapid cooling of the organs, reduces their metabolic activity and preserves their viability. Additional surface cooling of the abdominal organs may be achieved by application of saline ice slush. The heart and lungs are excised followed by the liver and pancreas and then the kidneys, either in bloc or separately. The extent to which the abdominal organs are dissected prior to cold flush depends on the preference of the surgical team. Some surgeons perform minimal dissection prior to cold perfusion and complete the dissection of the abdominal organs in situ or on the back table after the organs have been
removed en bloc. During procurement of the liver care is taken to ensure that, if there is an aberrant hepatic artery arising from the superior mesenteric artery, it is included in the aortic patch. Similarly, care is taken to ensure that any polar renal arteries are included on an arterial patch with the renal artery. A length of the donor iliac artery is excised for use in reconstructing the arterial supply of the pancreas.

After removal from the donor the organs may undergo a further flush with chilled preservation solution and are then each placed in two sterile plastic bags and stored at 0—4°C by immersion in ice while they are transported to the recipient centre to await implantation. After the donor organs have been excised, samples of donor spleen and mesenteric lymph nodes are obtained for determination of tissue type and for the cross-match test.

Various organ-preservation solutions are available for flushing organs before simple cold storage. They all contain impermeants to limit cell swelling, buffers to counter acidosis and electrolytes, the composition of which reflects that of intracellular rather than extracellular fluid. Commonly used preservation solutions include University of Wisconsin (UW) solution and Eurocollins solution, but there are many others.

The use of UW solution (Table 11.4) (developed by Belzer and colleagues) is particularly effective for liver grafts and, after perfusion with UW, the liver can be stored safely for up to 24 hours. The length of time for which an organ can be stored before transplantation varies depending on the type of organ (Table 11.5). After arriving at the recipient transplant centre any necessary bench surgery is undertaken prior to implantation.

**Nonheart-beating (asystolic) donors**

There is renewed interest in the use of kidneys from nonheart-beating or asystolic donors in an attempt to address the shortage of organs for transplantation. Kidneys may be procured from patients who are dead on arrival at the hospital or who have died in hospital after withdrawal of support or following unsuccessful resuscitation. In order to minimise the warm ischaemic time, a double-balloon catheter is introduced into the aorta via a femoral cutdown and used to cool the kidneys in situ by chilled perfusate, preferably within 30 minutes of circulatory arrest. Kidneys obtained from nonheart-beating donors invariably suffer from delayed function and this approach is not suitable for organs other than the kidney.

**Living kidney donors**

Currently, living donor renal transplants account for around 20 per cent of the total renal transplant activity. The justification for living donor renal transplantation is based on the shortage of cadaveric transplants and the superior results obtained. Most living donor transplants are between genetically related individuals. However, living donor kidney transplants performed between genetically unrelated individuals also fare better than even well-matched cadaveric grafts, and this observation has given rise to an increase in living unrelated kidney transplantation activity, usually between spouses or partners. It is essential to ensure in all cases of living donation that the prospective donor is fully informed and is free from coercion to donate and that the risk to the donor is small. Live donation should proceed only after the prospective donor has undergone rigorous assessment to ensure that they are suitable. Before the donation it is essential to perform renal imaging (commonly a selective renal angiogram) to delineate the anatomy of the arterial supply to the kidneys. If the left kidney has a single renal artery it is usually chosen for transplantation because it has a longer renal vein which simplifies the transplant operation. Donor nephrectomy is undertaken either through a loin incision and retroperitoneal approach or through a midline abdominal incision and transperitoneal approach. Laparoscopic donor nephrectomy has recently attracted interest but its role in living donation is not established (Fig. 11.13). The mortality rate for live donation is less than 0.05 per cent and the major complication rate is around 5 per cent. In the long term, a slight elevation in proteinuria and a small rise in blood pressure accompany unilateral nephrectomy.

**Living donors: extrarenal organs**

Living donors have occasionally been used to provide segments of liver, pancreas, small bowel and lung for transplantation but this is more controversial. Several hundred living related liver transplants have been performed world-wide, predominantly in countries where cadaveric donation is not practised. The left lateral segment or left lobe from an adult is transplanted into a paediatric recipient. In countries where heart-beating cadaver donation is undertaken, live donor liver transplantation has been superseded by the techniques of liver reduction or liver splitting. The latter approach allows the liver from a cadaver donor to be split in two, so that the right lobe can go to an adult and the left lobe to a paediatric recipient (Fig. 11.14). In North America, living donor combined kidney and segmental pancreas transplantation has been undertaken to treat insulin-dependent diabetics with end-stage renal disease. In occasional patients living donor small bowel transplantation has been performed using a small bowel graft which comprises a length of around 1.5 m of ileum. Finally, a small number of living donor segmental lung transplants has been performed. To provide sufficient pulmonary tissue without compromising the donor it is necessary to use segments from two different donors for each recipient. The ethical issues raised by living donation for extrarenal organs are understandably complex.

**Resumption of function following organ transplantation**

It is crucial that following heart, lung or liver transplantation, the transplanted organ resumes satisfactory function immediately. If primary nonfunction occurs the only option is rapid re-transplantation. After kidney, pancreas or small bowel transplantation immediate graft function is desirable but not vital. The factors that influence the functional integrity of a transplanted organ are shown in Table 11.6.
Kidney transplantation

Patient selection

Renal transplantation is the preferred treatment for many patients with end-stage renal disease because it provides a better quality of life for them than dialysis. Transplantation releases patients from the dietary and fluid restrictions of dialysis and the physical constraints imposed by the need to dialyse. It is also more cost-effective than dialysis.

In the UK, around 80—100 people per million population develop end-stage renal disease and the incidence increases with age. The causes of end-stage renal disease are numerous and include the following:

- glomerulonephritis;
- diabetic nephropathy;
- hypertensive nephrosclerosis;
- renal vascular disease;
- polycystic disease;
- pyelonephritis;
- obstructive uropathy;
- systemic lupus erythematosus;
- analgesic nephropathy;
- metabolic diseases (oxalosis, amyloid).

Frequently, the primary cause of end-stage renal disease remains uncertain. For renal transplantation, as for other types of organ transplantation, careful patient selection is essential. Before acceptance as suitable candidates on the transplant waiting list, a transplant surgeon and nephrologist should formally assess all patients. A significant number of patients is likely to be considered unsuitable for renal transplantation because of major comorbid disease, especially cardiovascular disease. In the UK around half of the dialysis population are currently on the waiting list for renal transplantation.

The nature of the primary renal disease does not generally affect the decision to proceed to transplantation. Some of the glomerulonephritides (notably focal segmental glomerulosclerosis) may subsequently affect a transplanted kidney but this only occasionally results in failure of the graft in the first 5 years. In the case of primary oxalosis, combined kidney and hepatic transplantation is usually undertaken to eliminate the metabolic defect and thereby prevent early graft failure from the formation of further oxalate stones.

The age of patients with end-stage renal failure accepted for dialysis has gradually risen over the last two decades and in the UK the mean age of patients starting dialysis is around 70 years. There is no absolute upper age limit to renal transplantation but inevitably older patients (over the age of 65 years) are less likely to be considered suitable candidates because of major cardiovascular and other comorbid disease.

A careful assessment of comorbid disease that might significantly reduce the chances of successful outcome after transplantation is essential. Rigorous evaluation of the cardiovascular system is particularly important. Cardiovascular disease is very common in the dialysis population, especially those with diabetes, and is the major cause of death after transplantation. Before listing patients for transplantation it is important to ensure that their urinary tract is functional and that there is no need for corrective urological surgery. Only when there is long-standing renal sepsis, or in the case of very large polycystic kidneys which intrude into both iliac fossae, is native nephrectomy required before transplantation can be undertaken. Finally, the prospective transplant recipient must be judged likely to comply with immunosuppressive therapy.

Immunosuppressive therapy increases the risk of infection and malignancy. Consequently, pre-existing malignancy is an absolute contraindication, and even after curative treatment transplantation should not be considered for at least 3 years. Similarly, the presence of active infection is an absolute contraindication to transplantation.

Technique of renal transplantation

The transplant kidney is placed in the iliac fossa, in the retroperitoneal position, leaving the native kidneys in situ. After induction of general anaesthesia a central venous line and a urinary catheter are inserted. It is helpful to distend the bladder with saline containing methylene blue to allow it to be identified with certainty prior to ureteric implantation. A curved incision is made in the lower abdomen and after dividing the muscles of the abdominal wall, the peritoneum is swept upwards to expose the iliac vessels. These are dissected free so that they can be controlled with vascular clamps. The kidney is then removed from ice and the donor renal vein is anastomosed end-to-side to the external iliac vein. The donor renal artery on a Carrel patch of donor aorta is then anastomosed end-to-side to the external iliac artery (Fig. 11.15a). If the donor renal artery lacks an aortic patch, as in the case of a living donor transplant, it is usually pre-ferable to anastomose the donor artery end-to-end to the recipient internal iliac artery (Fig. 11.15b). While the vascular anastomoses are being undertaken the kidney is kept cold by application of ice. Following completion of the venous and arterial anastomoses the vascular clamps are removed and the kidney is allowed to reperfuse with blood.

The ureter, which is kept reasonably short to avoid the risk of distal ischaemia, is then anastomosed to the bladder (Fig. 11.16). This is most often achieved by direct implantation of the ureter into the dome of the bladder with a mucosa to mucosal anastomosis followed by closure of the muscular wall of the bladder over the ureter to create a short tunnel—the Lich—Gregoire technique. A double-I ureteric stent is often left in situ, especially if there are technical difficulties, and removed after several weeks during cystoscopy. Alteratively, the ureter may be implanted by the Lead-better—Politano technique where the bladder is opened to allow the creation of a submucosal antireflux tunnel. Before closing the transplant wound it is important to ensure that the kidney is lying in a satisfactory position without kinking or torsion of the vessels. In small children receiving an adult donor kidney the abdomen is opened through a midline incision and the graft is placed intra-abdominally with anastomosis of the renal vessels to the aorta and vena cava.
Technical complications

Vascular complications

The incidence of vascular complications after renal transplantation is quite low. Renal artery thrombosis occurs in approximately 1 per cent of cases. Renal vein thrombosis is more common (up to 5 per cent of cases), and although sometimes owing to technical error, the aetiology is uncertain. It presents as sudden pain and swelling at the site of the transplant and the diagnosis is confirmed by Doppler ultrasound. Urgent surgical exploration is indicated and it most cases transplant nephrectomy is required. The incidence of renal vein thrombosis can be minimized by giving low dose heparin or aspirin prophylaxis. Renal artery stenosis presents late (often years) after transplantation with increasing hypertension and decreasing renal function. It may occur in up to 10 per cent of grafts, is diagnosed by angiography and is best treated by angioplasty rather than open surgery.

Urological complications

Urological complications occur in up to 10 per cent of patients in the early post-transplant period, but their incidence can be reduced by leaving a temporary ureteric stent in situ. Urinary leaks result from technical errors at the ureteric anastomosis or because of ureteric ischaemia. They present with discomfort and leakage of urine from the wound and are usually require surgical intervention and reimplantation of the ureter into the bladder or anastomosis of the transplant ureter to the native ureter. Obstruction of the transplant ureter may occur early or late. Causes of obstruction include:

- technical error, external pressure from a haematoma or lymphocele and ischaemic stricture.
- presents with painless deterioration in transplant function and is confirmed by demonstrating hydronephrosis and ureteric dilatation on ultrasound examination. Initial treatment is by percutaneous antegrade nephrostomy and insertion of a stent. Surgical intervention may be needed to treat strictures that are not amenable to correction by balloon dilatation.

Lymphocele

Peritransplant lymphoceles are usually asymptomatic, but occasionally they become large enough to cause ureteric obstruction or oedema of the leg. If they persist, surgical intervention may be needed to drain them into the peritoneal cavity. This can often be achieved by an ultrasound-guided laparoscopic approach.

Investigation of graft dysfunction

Graft dysfunction during the early postoperative period is a common problem. Possible causes are:

- acute tubular necrosis;
- arterial/venous thrombosis;
- urinary leak/obstruction;
- calcineurin blocker toxicity;
- hyperacute/accelerated acute rejection.

Delayed graft function as a result of acute tubular necrosis occurs in up to 50 per cent of cadaveric kidney transplants but is uncommon following living donor transplantation. Often the recipient produces significant volumes of urine from their native kidneys, making the diagnosis of delayed function more difficult. The incidence of delayed function can be minimised by optimising donor management before kidney procurement and by reducing the cold ischaemia time by avoiding unnecessary delay before implantation. As a first step in the management of early graft dysfunction, the uro-nary catheter should be irrigated in case it is occluded by a blood clot. Hypovolaemia, if present, should be corrected with the aid of central venous pressure (CVP) monitoring. A Doppler ultrasound examination of the graft is the single most important investigation as it allows exclusion of vascular thrombosis and urinary obstruction as causes of graft dysfunction. In addition, a renal radionuclide scan is often performed and provides information on renal perfusion and excretion. If graft dysfunction is still present after several days it is usual to perform an ultrasound-guided needle biopsy of the kidney to ensure that graft rejection is not present. To avoid the risk of nephrotoxicity, calcineurin blockers are often withheld or given in reduced doses until graft function is established. If calcineurin blockers are not withheld, it is important to monitor their blood levels carefully to avoid nephrotoxicity. Acute tubular necrosis usually resolves within the first 4 weeks of transplantation but a small number of grafts suffers primary nonfunction.

Allograft dysfunction developing late (> 1 month after transplant) may be due to:

- acute/chronic rejection;
- drug toxicity;
- ureteric obstruction (lymphocele/ureteric stricture);
- recurrent disease;
- infection.

Blood levels of cyclosporine or tacrolimus are assessed to ensure that they are not unduly elevated, and ultrasound examination of the graft is performed to determine whether ureteric obstruction is present. If obstruction is detected, it is further investigated by percutaneous antegrade pyelography. Ureteric stenosis may be amenable to balloon dilatation but a long stricture may require reimplantation of the transplant ureter (or renal pelvis) into the bladder or into the native ureter. If there is uncertainty about the cause of graft dysfunction, transplant biopsy should be performed to establish whether allograft rejection is present.

Outcome after transplantation

The results of organ transplantation are generally defined in terms of patient and graft survival. Patient survival after cadaveric renal transplantation is > 90 per cent at 1 year and > 80 per cent at 5 years. Graft survival is around 85 per cent at 1 year and 65 per cent at 5 years. Graft survival after a second transplant is only marginally worse than after a first graft. After living related kidney transplantation, overall graft
survival is > 90 per cent at 1 year and > 80 per cent at 5 years. Graft survival after transplantation can also be expressed in terms of the half-life of the graft. The half-life for grafts obtained from living donors is substantially longer than for cadaveric grafts:

- cadaveric grafts — 7 years;
- living unrelated — 9 years;
- living haploidentical — 12 years;
- living identical — 24 years.

If a kidney transplant fails late after transplantation, transplant nephrectomy may be indicated, especially if the graft is causing symptoms. The operation is undertaken via the original wound but the kidney is dissected free from the renal capsule and delivered into the wound. The renal vessels are then ligated and divided, leaving behind the original vascular anastomosis.

In addition to graft survival, it is important to consider the extent to which transplantation improves the physical and mental well-being of the patient, and allows them to lead a satisfactory social life. As other types of solid organ transplant, successful kidney transplantation undoubtedly leads to a substantial improvement in quality of life. However, whereas some recipients return to a normal or near-normal life, others fare much less well, and for the group overall the quality of life after transplantation falls short of that seen in normal healthy individuals. Organ transplantation is best regarded, therefore, as an effective form of therapy rather than a complete cure.
**Pancreas transplantation**

Successful pancreas transplantation restores normal control of glucose metabolism and obviates the need for insulin therapy in patients with diabetes mellitus. Improved control of blood glucose levels in diabetes undoubtedly reduces the risk of secondary complications such as retinopathy, peripheral vascular disease and nephropathy. However, in considering the indications for pancreas transplantation, these advantages have to be weighed carefully against the risks posed both by the transplant procedure itself and by the immunosuppressive therapy required to prevent graft rejection. For most patients with diabetes, the additional risks associated with pancreas transplantation and immunosuppression are such that the operation can only be justified when kidney transplantation for diabetic nephropathy is also being undertaken. The only additional risks of pancreas transplantation in such patients relate to the transplant operation itself. In the USA, around half of all diabetic patients undergoing kidney transplantation also receive a pancreas transplant. In most cases, the kidney and pancreas are obtained from the same donor, so-called ‘simultaneous pancreas and kidney transplantation’ (SPKT). Sometimes pancreas transplantation is performed in patients who have already undergone successful kidney transplantation — ‘pancreas after kidney transplantation’ (PAKT). Occasionally, pancreas transplantation alone (PTA) can be justified, for example to treat labile diabetes or hypoglycaemic unawareness.

Careful patient selection is essential to avoid excessive mortality and morbidity. The procedure is usually reserved for those patients with type I diabetes who are relatively young (under the age of 50 years) and do not have advanced coronary artery disease or peripheral vascular disease. Echo-cardiography and coronary angiography are mandatory during assessment of recipient suitability for transplantation.

**Surgical technique**

Most centres now perform transplantation of the whole pancreas together with a segment of duodenum, essentially as pioneered by Lillehei in 1966. Segmental pancreas transplantation is still performed occasionally, especially in France. SPKT is usually performed through a midline incision (Fig. 11.17). The pancreas graft is placed intraperitoneally in the pelvis, usually on the right, and the kidney graft is placed either intraperitoneally or extraperitoneally on the left side. The donor vessels of the pancreas graft are anastomosed to the recipient iliac vessels and the exocrine secretions are dealt with by anastomosing the graft duodenum to either the bladder (urinary drainage) or the small bowel (enteric drainage). The pancreas graft functions immediately after revascularisation, although supplementary insulin may be required for a few days. Technical complications usually occur early and include vascular thrombosis of the graft (5—10 per cent) and anastomotic leaks. Wound infection occurs in around 10 per cent of patients and intra-abdominal infection is relatively common. The specific complications of enteric drainage include intra-abdominal sepsis and gastrointestinal haemorrhage (anastomotic). Bladder drainage of the exocrine pancreas may result in the following complications:

- bladder/duodenal anastomotic leaks;
- cystitis (due to effect of pancreatic enzymes);
- urethritis/urethral stricture;
- reflux pancreatitis;
- urinary tract infection;
- haematuria;
- metabolic acidosis (due to loss of bicarbonate in the urine).

Urinary drainage of the pancreas has the advantage that urinary amylase levels can be used to monitor for graft rejection. However, after bladder drainage, urinary complications are common and, in around 20 per cent of cases, are severe enough to require conversion to enteric drainage. Many centres now prefer primary enteric drainage after SPKT. Acute rejection after SPKT usually involves both the kidney and pancreas graft and serum creatinine can be used, therefore, as a surrogate marker for pancreas graft rejection. Urinary drainage is still preferable after PTA and PAKT because it allows pancreas graft rejection to be monitored by serial measurement of urinary amylase. A fall in urinary amylase is indicative of acute rejection. Measurement of blood glucose levels are less useful as an early indicator of rejection. Acute graft rejection is common but usually responds to treatment with steroids.

**Results of pancreas transplantation**

The results of pancreas transplantation have improved significantly over the last decade. After SKPT, the 1-year patient survival rate is greater than 90 per cent, and the 1-year graft survival rate for pancreas and kidney grafts, respectively, is 80 and 90 per cent. Most deaths are due to cardiovascular complications or overwhelming infection. Patient and kidney graft survival after SKPT in patients with diabetic nephropathy are at least as good as after kidney transplant alone in this group. The results of PTA are not as good as after SKPT (1-year pancreas graft survival 70 per cent) because acute rejection is more difficult to monitor in the absence of a kidney allograft. The aim of pancreas transplantation is to provide freedom from insulin treatment and to improve the quality of life. The extent to which pancreas transplantation halts the progression of the secondary complications of diabetes is still unclear.

**Transplantation of isolated pancreatic islets**

Treatment of diabetes by transplantation of isolated islets of Langerhans is a more attractive concept than vascularised pancreas transplantation because major surgery and the potential complications of transplanting exocrine pancreas are avoided. Pancreatic islets for transplantation are obtained by mechanically disrupting the pancreas after injection of collagenase into the pancreatic duct. The islets are then purified from the dispersed tissue by density gradient centrifugation and can be delivered into the recipient liver (the optimal site for transplantation) by injection into the portal vein. Islet transplantation has been performed in diabetics receiving immunosuppression because of a kidney transplant. Although some degree of islet cell function occurs initially this is not sustained. Obtaining a critical mass of islet tissue for transplantation is problematic and isolated pancreatic islets are particularly susceptible to graft rejection. Attempts have been made to protect isolated islet cells from rejection by encapsulating them inside semipermeable membranes. The protective membranes are designed with a pore size that allows insulin to pass through but prevents antibodies and leucocytes from reaching the islets, thereby avoiding the need for immunosuppressive therapy. A major attraction of this approach is that islets isolated from animals can be used, and bioartificial pancreas grafts containing xenogeneic islets are currently under evaluation.
Liver transplantation

Starzl first attempted liver transplantation in 1963, and by 1967 had obtained prolonged survival. The first liver transplant performed outside the USA was undertaken in Cambridge by Caine in 1968. Throughout the 1970s liver transplantation remained a hazardous procedure that frequently failed, but the introduction of a number of changes led to improved results. These included improved immunosuppression, in the form of cyclosporin, together with improved patient selection and refinements in organ preservation and attention to technical aspects of the transplant operation. Liver transplantation is now a routine operation in specialist centres.

Indications and patient selection

The indications for liver transplantation fall into four groups:

- chronic cirrhosis;
- acute fulminant liver failure;
- metabolic liver disease;
- primary hepatic malignancy.

The most common indication for transplantation is chronic liver failure. In adults the causes include primary biliary cirrhosis, viral liver disease, alcoholic liver disease and sclerosing cholangitis. In children, who account for around 10—15 per cent of all liver transplants, biliary atresia is the most common indication for transplantation. Acute fulminant liver failure requiring transplantation on an urgent basis accounts for approximately 10 per cent of liver transplant activity and is viral or drug (e.g. paracetamol) induced. There is a variety of metabolic diseases for which transplantation offers the prospect of cure. These include Wilson’s disease, oxalosis and a γ-antitrypsin deficiency. Hepatic malignancy is only occa-sionally treated by liver transplantation because of the high risk of tumour recurrence. Hepatomas, when they occur in a cirrhotic liver, may be best treated by transplantation and some centres consider transplantation for cholangiocarcinoma, although there is a high risk of recurrent disease.

Technique of liver transplantation

A transverse abdominal incision with a midline extension is made and the diseased liver mobilised (Fig. 11.18). Because of portal hypertension the recipient hepatectomy is often the most difficult part of the operation, especially if there has been previous surgery in the region. The common bile duct is divided, as are the right and left hepatic arteries. The inferior vena cava is clamped and divided above and below the liver, and the portal vein is clamped and divided allowing the recipient liver to be removed. Occlusion of the vena cava and portal vein results in a reduction in cardiac output and may necessitate the use of vena-venous bypass. The bypass circuit delivers blood from the portal vein and inferior vena cava back to the heart via a cannula inserted into the axillary vein or the internal jugular veins. After placing the donor liver in position, the supra- and infrahepatic caval anasto-moses are performed The portal vein and the hepatic arterial anastomosis are then completed and the graft is reperfused. Finally, biliary drainage is re-established, usually by a duct-to-duct anastomosis (without the use of a T-tube). It may be necessary, for example in recipients with biliary atresia or sclerosing cholangitis, to reconstruct the biliary drainage by a bile duct to Roux loop anastomosis. An alternative ‘piggy-back’ technique of liver transplantation is sometimes pre-ferred in which the diseased native liver is dissected from the intact inferior vena cava and the suprahepatic vena cava of the donor is Anastomosed end-to-side to the anterior wall of the recipient cava.

Many patients undergoing liver transplantation are extremely ill and the surgery involved can be very technically demanding. Optimal perioperative management is crucial to a successful outcome and presents a major challenge. Blood loss during and after the transplant procedure can be very considerable and management of coagulopathy is particularly important. Coagulation is assessed repeatedly throughout the peritransplant period. Many centres use a thromboelastogram to supplement the information from standard coagulation screening (Fig. 11.19). The thromboelastogram comprises an oscillating cuvette into which a small blood sample is placed and into which a piston suspended by a torsion wire is then lowered. As the sample clots, fibrin strands transmit elastic forces to the piston and are recorded to provide an index of coagulation.

Technical complications

Haemorrhage

Meticulous homeostasis during the transplant operation is important in order to minimise the risk of early haemorrhage. It may occasionally be necessary to pack the peritransplant area for 2—3 days to achieve adequate haemostasis when there is diffuse oozing despite correction of coagulopathy. Evacuation of extensive perihepatic haematoma may be required to avoid secondary infection.

Vascular complications

Hepatic artery thrombosis may occur spontaneously or as a result of acute rejection, and is more common in paediatric recipients. It may present as a rise in serum transaminase levels, unexplained fever or bile leak. Doppler ultrasound or angiography are used to confirm the diagnosis and urgent re-transplantation is usually required. Portal vein thrombosis presents more insidiously and does not usually require re-transplantation.

Biliary complications

Biliary leaks are now relatively uncommon and biliary steno-sis is a more common problem. It usually occurs late after transplantation and is managed by endoscopic dilatation and stenting, and less often by surgical correction.

Paediatric liver transplantation

Until recently, the major factor limiting paediatric liver transplantation was the lack of suitably sized donor livers. However, as noted earlier, the development of techniques for using adult livers that have been reduced in size by cut-down techniques has greatly alleviated the problem. For small children, the lateral segment of the left lobe is often used but the entire left lobe or the right lobe may also be used in this way.

Outcome after liver transplantation

The outcome after liver transplantation depends on the under-lying liver disease and the best results are seen in patients with chronic liver disease (Fig. 11.20). Patients undergoing trans-plantation as a result of acute liver failure have a higher mortality in the early post-transplant
period because of multiorgan failure, but those who make a satisfactory recovery have very good long-term liver allograft survival. Conversely, patients transplanted for tumour have a very good early outcome but ultimately fare much less well because of recurrent malignancy. Patients receiving a liver transplant following hepatitis B or hepatitis C infection often develop graft failure as a result of recurrent viral disease.
Small bowel transplantation

Progress in small bowel transplantation has lagged well behind that of other types of solid organ transplantation. Intestinal transplants stimulate a particularly strong graft rejection response, probably because the small intestine contains very large amounts of lymphoid tissue. Moreover, ischaemia and rejection increase intestinal permeability and allow translocation of bacteria from the lumen of the bowel. Added to this, the operation is often complex and made technically difficult because of repeated previous abdominal surgery. Consequently, graft rejection and infection remain a major problem after small bowel transplantation and the results obtained are inferior to those seen after other types of organ transplantation. Small bowel transplantation is a treatment option for patients with intestinal failure as defined by the loss of intestinal function to the extent that long-term parenteral nutrition is required. Intestinal failure may result from short bowel syndrome after resection of the intestine or from intestinal dysfunction. The conditions that may give rise to intestinal failure include the following:

• intestinal atresia;
• necrotising enterocolitis;
• volvulus;
• disorders of motility;
• mesenteric infarction;
• Crohn’s disease;
• trauma;
• desmoid tumours.

Because of the substantial risks associated with small bowel transplantation, the procedure should be considered only for those patients where long-term total parenteral nutrition (TPN) has failed, usually because venous access has become impracticable or because of frequent life-threatening line sepsis. The need for small bowel transplantation is estimated at around 0.5—1.0 patients per million population and around 50 per cent of cases are children.

Small bowel transplantation may be carried out as an isolated procedure, performed together with a liver transplant or undertaken as a component of a multivisceral transplant. Around half of all small bowel transplants are performed in children. Where possible, isolated small bowel transplantation is undertaken because patient survival is higher.

A small bowel transplant from a cadaveric donor comprises the entire small bowel but it is no longer considered advisable to include the ascending colon in the graft. The superior mesenteric artery of the graft (with an aortic patch is anastomosed to the recipient aorta and the superior mesenteric vein is anastomosed to the inferior vena cava or to the side of the portal vein. The proximal end of the small bowel graft is anastomosed to the recipient jejunum or duo-denum. The distal end of the graft is anastomosed to the side of the colon (with a loop ileostomy) or is fashioned as an end ileostomy. A gastrostomy tube (to overcome delayed gastric emptying) and a feeding jejunostomy tube are inserted.

About half of all patients who require small bowel transplanta-tion have cholestatic liver disease secondary to TPN and require combined liver and small bowel transplantation. Cholestatic liver disease due to TPN is especially common in children. When combined liver and small bowel transplantation is carried out the two grafts are transplanted en bloc. The donor aorta is fashioned into a conduit including the superior mesenteric and coeliac arteries, and anastomosed to the recipient aorta. The portal vein anastomosis is as for isolated liver transplantation.

Multivisceral or ‘cluster’ transplants may be necessary in the case of large desmoid tumours where excision of both the small bowel and adjacent organs is required, when there has been extensive thrombosis of the splanchnic vessels and for generalised disorders of gastrointestinal motility.

The 1-year graft survival rate after small bowel transplantation is about 60 per cent for both isolated small bowel transplantation and combined liver and small bowel transplanta-tion. After 3 years the graft survival rate is around 40 per cent. As already noted, however, patient survival is better after isolated small bowel transplantation than after combined liver and small bowel transplantation, where loss of the graft usually equates with death of the recipient. Most of the mortality after small bowel transplantation is due to sepsis and multiorgan failure. The risk of infection after small bowel transplantation is heightened by the additional requirements for immunosuppression in order to control graft rejection. This accounts for the relatively high incidence of lymphoproliferative disease (around 10 per cent) observed in patients who have undergone small bowel transplantation. Because of the large amount of donor lymphoid tissue transplanted graft-versus-host disease (GVHD) may occasionally be an added complication. Despite the hazards, small bowel transplantation offers patients with intestinal failure a chance to lead an active life free from the constraints of long-term nutritional support.
Thoracic organ transplantation

Heart transplantation

Dr Christiaan Barnard performed the first human heart transplant in Cape Town, South Africa, in 1967. The operation was based on the experimental work of Richard Lower and Norman Shumway in Stanford, and Shumway subsequently went on to pioneer successful cardiac transplantation in the clinic. Heart transplantation is now considered an effective treatment for selected patients with end-stage cardiac failure. The most common indications for heart transplantation are idiopathic cardiomyopathy and ischaemic heart disease, but other indications include valvular heart disease, myocarditis and congenital heart disease.

Transplantation is considered only in patients with end-stage heart disease which has failed to respond to all other conventional therapy and where predicted survival without transplantation is only 6—12 months. Suitable candidates are New York Heart Association (NYHA) class III (symptoms on mild exertion) or class IV (unable to perform any physical activity without discomfort, which may occur at rest). Transplantation is usually limited to patients under the age of 65 years who do not have irreversible damage to other organ systems. The preoperative assessment is rigorous and measurement of pulmonary vascular resistance is mandatory because when it is raised the perioperative mortality is high.

Technique of heart transplantation

A median sternotomy is performed and the patient is given systemic heparin, placed on cardiopulmonary bypass and cooled to 28°C. After cross-clamping the aorta, the recipient heart is excised at the mid-atrial level. The donor heart is then removed from ice and the left atrium is then opened by making incisions (Fig. 11.21) in the posterior wall between the orifices of the pulmonary veins to create an atrial cuff. The left and then right atrial anastomoses are performed and the aortic and pulmonary arterial anastomoses are then completed (Fig. 11.22). The patient is then re-warmed and weaned from cardiopulmonary bypass. Total orthotopic cardiac transplantation is an alternative but rarely used procedure in which the entire recipient heart is excised and the donor heart is implanted by caval (superior and inferior), pulmonary vein (right and left), aorta and pulmonary arterial anastomosis. Occasionally, heterotopic cardiac transplantation is undertaken where the donor heart is placed adjacent to and augments the recipient’s own heart.

Heart—lung, single-lung and double-lung transplantation

Pulmonary transplantation became a clinical reality when Dr Bruce Reitz performed the first successful combined heart—lung transplant in 1981. Combined heart—lung transplantation is still sometimes used, especially for patients with pulmonary vascular disease where there is cardiac dysfunction due to congenital (e.g. Eisenmenger’s syndrome) or acquired cardiac dysfunction. For most patients with end-stage pulmonary disease, however, single- or double-lung transplantation has now replaced heart—lung transplantation. Lung transplantation is more economical in terms of organ usage, although if heart—lung transplantation is undertaken for isolated respiratory disease, the healthy native heart can be used for transplantation — the so-called ‘domino procedure’. Heart—lung transplantation is performed through a median sternotomy taking particular care to avoid injury of the phrenic and vagus and recurrent laryngeal nerves during excision of the recipient heart and lungs. The recipient right atrium and aorta are divided as for orthotopic cardiac transplantation and the donor heart—lung block is readied for implantation, incising the right atrium from the divided inferior vena cava. An end-to-end tracheal anastomosis is performed, and the right atrial and aortic anastomoses are performed as for cardiac transplantation.

Single- and double-lung transplantation is an effective therapy for selected patients with end-stage chronic lung disease where declining lung function limits life expectancy. Suitable candidates typically have NYHA class III or IV symptoms and a life expectancy of less than 2 years despite optimal medical therapy. Common indications are pulmonary fibrosis, pulmonary hypertension and cystic fibrosis. Single-lung transplantation is performed for pulmonary fibrosis. Patients with cystic fibrosis and other forms of septic lung disease require excision of both native lungs and bilateral or en bloc double-lung transplantation, because single-lung transplantation results in soiling of the transplant from the native diseased lung. Single-lung transplantation is performed through a posterolateral thoracotomy, and double-lung transplantation through bilateral thoracotomy or median sternotomy. During lung transplantation the donor pulmonary veins on a left atrial cuff are anastomosed to the recipient left atrium. Next, the bronchial anastomosis and the pulmonary arterial anastomosis are completed. Cardio-pulmonary bypass is usually required if pulmonary hypertension is present. Dehiscence of the airway anastomosis used to be common after heart—lung and lung transplantation but improvements in organ preservation and surgical technique have dramatically reduced the incidence of this often fatal complication to < 5 per cent. Late airway stenosis at the bronchial anastomosis due to ischaemia occurs in around 10 per cent of bronchial anastomoses and is treated by dilatation.

Outcome after thoracic organ transplantation

One- and 5-year graft survival after heart transplantation is around 85 and 70 per cent, respectively. The results after heart—lung and lung transplantation are less good with 1-year graft survival rates of around 75 per cent and 5-year survival rates of around 40 percent.
**Future prospects**

The two major problems in organ transplantation are:

- Chronic graft rejection and the side effects of
  - nonspecific immunosuppression
- the shortage of organs for transplantation.

A long-standing goal in organ transplantation has been the development of strategies for inducing specific immunological tolerance. Transplantation tolerance would eliminate the need for long-term nonspecific immunosuppressive agents, leaving the immune system intact for defence against infection. It has long been possible to induce transplant tolerance in experimental animals by a variety of preconditioning regimens that often involve antigen pretreatment schedules. So far, however, there is no clinically applicable strategy for inducing transplant tolerance.

The demand for human organs for transplantation is so great that cadaveric donors cannot ever satisfy it. Many consider that the solution is to perfect xenotransplantation, and there is general agreement that the pig is the most suitable source of xenogeneic organs. However, all humans have preformed antibodies directed against carbohydrate antigens expressed by pig organs and these result in hyperacute rejection. The dominant carbohydrate antigen responsible is galC1,3-gal. Progress has been made towards circumventing hyperacute xenograft rejection, for example by using organs from pigs that have been made transgenic for human complement regulatory proteins. However, such organs are still rejected within a few weeks by primates, despite the use of potent immunosuppressive agents. In addition to the complex immunological problems posed by xenotransplantation, there is a risk that pig organs may transmit infectious agents, and there is particular concern about the risks posed by porcine endogenous retrovirus (PERV). Finally, there are unanswered questions regarding the extent to which pig organs are able to fulfil the physiological demands required of them after transplantation into a human.

Tumours

A tumour is a new growth of tissue (a mass) which can refer to an inflammatory swelling such as Pott's puffy tumour (Chapter 35) or to a neoplastic growth. A neoplastic tumour is an uncontrolled proliferation of a clone of cells without useful function.

Causation

Cancer is a disease of genes. The cell is the basic unit of organization and control. The genetic code is contained within the deoxyribonucleic acid (DNA) molecule present within the cell nucleus. Genes make proteins which govern the function and structure of a cell. There are around 100,000 genes (human genome) representing approximately 10 per cent of the DNA; each cell expresses 5—150,000 genes. Since all genes are present in each cell nucleus, any gene may be expressed if the gene promoter is switched on, as occurs in neoplasia. Cancer is caused by disease of genes which control production of daughter cells from stem cells, cell proliferation, terminal differentiation and programmed cell death (apoptosis); from the Greek — shedding of autumn leaves. There are three important classes of genes involved in cancer:

- tumour suppressor genes, which control the cell cycle by slowing down the cycle or triggering apoptosis (TP53, P16, APC, RB1);
- oncogenes, which promote cell proliferation by increasing signalling activity from the cell surface to the transcription apparatus on gene promoters (KRAS, ErbB2, C-MYC);
- growth factors and their receptors which are switched on by oncogenes or switched off by tumour suppressor genes (EGF, TGFα, IGF, FGF).

A benign tumour grows by expansion without invasion of the extracellular matrix. A malignant tumour (cancer) grows by invasion into the extracellular matrix; most solid tumours also invade the basement membrane of endothelium and metastasise. The unit of cancer is the altered malignant cell which proliferates (clone). Different clones usually arise with different characteristics, such as the ability to metastasise via blood vessels or lymphatics. Cancer is a disease of genes which may be inherited or acquired (Table 12.1). Inherited cancers are caused by a specific DNA mutation of a tumour suppressor gene inherited in all cases. In cells of the organ affected, the (second) homologous gene is lost, initiating a sequence of genetic mutations culminating in cancer. Chemical carcinogens probably account for the majority of sporadic (acquired) cancers. Natives of Kashmir are prone to cancer of the skin of the thighs and lower abdomen. This is due to their habit of keeping warm by squatting and hugging earthenware pots containing glowing charcoal [the pot being termed a fangri (Fig. 12.1)], with the result that the adjacent skin is irritated by heat and fumes. 'Chimney-sweep's' cancer' (Chapter 68), 'countryperson's lip', and 'far workers' cancer' (Fig. 12.2) are other examples of carcinoma due to chemical carcinogens. DNA strand breaks are induced by ultraviolet and ionising radiation which, if not repaired, lead to cancer. Cellular instability from ageing of stem cell-lines (many common cancers) or chronic inflammation leads to increased cell proliferation and reduced apoptosis. This results in malignant transformation. Squamous cell carcinoma occasionally occurs in a chronic ulcer (Fig. 12.3) or in a scar (Chapter 13, 'Marjolin's ulcer'). A fibrosarcoma also may arise in a scar. At least 20 per cent of cancers world-wide are caused by oncogenic viruses.

Environmental cofactors are also important. Helicobacter pylori is linked to the development of gastric cancer by an unknown mechanism. A diet high in calories and rich in saturated fats (from red meat) is implicated in many cancers including those of the colorectum and pancreas. Viral carcinogenesis there are specific cofactors for different cancers: malaria (Burkitt's lymphoma), immunosuppression (post-transplant lymphomatous proliferative disease — PTLPD), human immunodeficiency virus (Kaposi's sarcoma — see Chapter 13), smoking (cervical cancer) and aflatoxins (liver cancer).

Definitions

- Hypertrophy is an increase in the size of an organ without an increase in cell numbers.
- Hyperplasia is an increase in the size of an organ due to an increase in cell numbers.
- Metaplasia. The epithelium from which the tumour grows has already changed its characteristics: bladder transitional epithelium to squamous epithelium, gallbladder columnar to squamous epithelium, bronchial columnar to squamous epithelium, gastric columnar epithelial pattern to intestinal epithelial pattern and oesophageal squamous to columnar epithelium (Barrett's oesophagus).
- Dysplasia. This represents the earliest changes of neo-plastic transformation than can be detected at the microstructural level (e.g. by light microscopy). In fact, genetic mutations are detectable at an earlier stage. Alterations in intracellular organisation, the individual size and shape of the nucleus, cellular size and shape and intercellular three-dimensional organisation indicate dysplasia. These changes may be classified as mild, moderate or severe dysplasia. Any grade of dysplasia may revert to normal due to elimination of the neoplastic clone, but is least likely with severe dysplasia.
- Carcinoma in situ. Severe dysplasia may progress to carcinoma in situ: the cellular, nuclear and three-dimensional architecture resemble cancer but without invasion into the extracellular matrix.
- Genotype. This is the molecular structure of any cell. A malignant genotype will have losses and mutations of tumour suppressor genes and the presence of oncogenes.
- Phenotype. This is the appearance of a cell at a microstructural level (microscopic phenotype) and its functional state (biological phenotype). A changed genotype will always precede a particular phenotype: for a time the cell may appear to be normal even though it has already acquired a malignant genotype.
- Differentiation. Depending on the degree to which the cells and organisation (morphology) of tumours resemble the parent tissue they are divided into well-differentiated, moderately differentiated and poorly differentiated forms.
- Anaplasia. Tumours are usually composed of cells which resemble those of the tissue from which they arise. Complete loss of differentiation (anaplasia) is associated with an aggressive cancer.
- Teratomas arise from embryonic stem cells containing representative cells from all three embryonic layers: ectoderm, endoderm, mesoderm (Fig. 12.4). Teratomatous dermoids contain hair and teeth, muscle and gland tissue. An unusual type is the sacrococcygeal teratoma (Fig. 12.5), which can be considered as foetus in foeto (an 'included' foetus).
- Blastomas develop from 'unipotent' cells, and arise from any one of the three embryonic layers (e.g. neuro-blastoma).
- Dermoid cysts. 'Dermoid' is a loose term given to cysts lined by squamous epithelium occurring in various parts of the body. Sebaceous cysts
are lined by superficial squamous cells and should more accurately be called ‘epidermoid’.

— **Teratomatous dermoids** (see above) are found in the ovary, testis retroperitoneum, superior mediastinum and the presacral area. Malignant change (carcinomatous or sarcomatous) can occur.

— **Sequestration dermoids** (see Cysts, below) are not new growths, but are formed by the inclusion of epithelial ‘nests’ beneath the surface at places where lines of developing skin meet and join: midline, external angular process (Fig. 12.6), root of nose (Chapter 37), branchial cysts (Chapter 43).

— **Implantation dermoids** (see Cysts, below) may follow puncture wounds, commonly of the fingers, when living epithelial cells are implanted beneath the surface.

*Benign tumour. A benign tumour is usually encapsulated, and does not disseminate or recur after complete removal. Symptoms and effects, which can be harmful, are due to its size, position, and pressure. Certain adenomas secrete a hormone which may affect bodily functions. Benign tumours are often multiple.*

**Malignant tumour.** The characteristics of malignancy are:

— invasion of surrounding tissues;

— pleomorphism (variable shapes) of cells and nuclei;

— rapid growth;

— the tendency to spread to other parts of the body (metastasis) by the lymphatics, the bloodstream, along nerve sheaths and across body cavities;

— general weight loss (cachexia in advanced disease).

At an early stage, evidence of invasion is the most important sign of malignancy. Many cells of a malignant tumour have an abnormal number of chromosomes which is not a multiple of the usual haploid number (= ‘aneuploidy’).

It has been suggested that the division of tumours into these two major groups imposes a concept which is too rigid (Walter). A third group of intermediate tumors exists which includes some carcinoid tumours, adenoma of the bronchus, ‘mixed’ salivary tumours and basal-cell carcinoma. These intermediate types invade locally, but are much less inclined to lymphatic or especially vascular dissemination.
Benign tumours

Adenoma

Adenomas arise in secretory glands, and resemble the structure from which they arise. They are encapsulated, and sometimes they secrete hormones which profoundly influence metabolism, as in the case of the thyroid, parathyroid and pancreas. Occasionally an adenoma contains a large proportion of fibrous tissue, e.g. the hard fibro-adenoma in the breast, while in other situations, notably the pancreas and thyroid gland, cystic degeneration is common. Those arising from superficial glands of mucous membrane are liable to pedunculation, as in the case of a rectal ‘polyp.’

Papilloma

A papilloma consists of a central axis of connective tissue, blood vessels and lymphatics; the surface is covered by epithelium, either squamous, transitional, cuboidal or columnar, according to the site of the tumour. The surface may be merely roughened, or composed of innumerable delicate villous processes, as in the case of those occurring in the kidney, bladder and rectum. In these situations, papillomas resemble malignant tumours, as secondary growths arise by implantation and, sooner or later, the tumour becomes frankly malignant (Chapter 65). Other common sites for papillomas are the skin, the colon, the tongue and lip, and the vocal cords and the walls of cysts (particularly those of the breast and ovary).

Fibroma

A true fibroma (containing only fibrous connective tissue) rare. Most fibromas are combined with other mesoderm tissues such as muscle (fibromyoma), fat (fibrolipoma) or nerve sheaths (neurofibroma). Multiple tumours are uncommon, as, for example, in neurofibromatosis (von Recklinghausen’s disease, Fig. 12.7).

Fibromas are either hard or soft, depending on the proportion of fibrous to the other cellular tissue. Soft fibromas are common in the subcutaneous tissue of the face, and appear soft, brown swellings.

Desmoid

[Fibroma is a common tumour occurring in the abdominal wall (see Chapt 62). An intraperitoneal form is associated with familial adenomatous polyposis (see Chapter 57).

Keloid

This overgrowth of fibrous tissue commonly occurs in scars, especially black people.

Lipoma

A lipoma is a slowly growing tumour composed of fat cells adult type. Lipomas may be encapsulated or diffuse. They occur anywhere in the body where fat is found and earn titles of the ‘universal tumour’ or the ‘ubiquitous tumour’. The head and neck area, abdominal wall and thighs are particularly favoured sites.

Encapsulated lipomas are among the commonest of tumours. The characteristic features are the presence of a definite edge and lobulation. A sense of fluctuation may be obtained. As would be expected, a lipoma deeply situated is liable to be mistaken for other swellings. Most lipomas are painless, but some give rise to an aching sensation which may radiate.

Multiple lipomas are not uncommon. The tumours remain small or moderate in size, and are sometimes painful, in which case the condition is probably one of neurofibromatosis. Dercum’s disease (adiposis dolorosa), characterised by tender deposits of fat, especially on the trunk, is an associated condition.

Should the lipoma contain an excessive amount of fibrous tissue, it is termed a fibrolipoma. In other cases, considerable vascularity is present, often with telangiectasis of the over-lying skin, in which case the tumour is a naevolipoma. Large lipomas of the thigh (Fig. 12.8), the shoulder (Fig. 12.9) and the retroperitoneum occasionally undergo sarcomatous changes. Myxomatous degeneration, saponification and calcification sometimes occur in lipomas of long duration.

Clinically, circumscribed lipomas are classified according to their Situation.

- **Subcutaneous.** Commonly found on the shoulders or the back, although no part of the body is immune. A lipoma may be present over the site of a spina bifida. Subcutaneous lipomas occasionally become pedunculated (lipoma arborescens).

- **Sub fascial.** Occurring under the palmar or plantar fascia, they are liable to be mistaken for tuberculous tenosynovitis, as the tough, overlying fascia masks the definite edge and lobulation of the tumour. Difficulty is encountered in complete removal as pressure encourages the tumour to ramify. Subfascial lipomas also occur in the areolar layer under the epicranial aponeurosis and, if of long duration, they erode the underlying bone, so that a depression is palpable on pushing the tumour to one side.

- **Sub xynovial.** From the fatty padding around joints, especially the knee. In the knee, they are apt to be mistaken for Baker’s cysts but are easily distinguished as, in distinction to a cyst or bursa, their consistency is constant whether the joint is in extension or flexion.

- **Intra-articular.**

- **Intemmuscular.** Mainly in the thigh or around the shoulder. Owing to transmitted pressure, the tumour becomes firmer when the adjacent muscles are contracted. Weakness or aching results, owing to mech-anical interference with muscular action. The condition is often difficult to distinguish from a fibrosarcoma.

- **Panosteal** occasionally occur under the periosteum of a bone.

- **Subserous** are sometimes found beneath the pleura, where they con-stitute one variety of innocent thoracic tumour. A retroperitoneal lipoma may grow to enormous dimensions, and simulate a hydro-nephrosis or pancreatic cyst.

- **Submucous** occur under the mucous membrane of the respiratory or alimentary tracts. Rarely a submucous lipoma in the larynx causes
respiratory obstruction. A submucous lipoma can occur in the tongue. One situated in the intestine is likely to cause an intussusception, which may be the first indication of its presence.

- **Central nervous system.** Lipomas may occur anywhere within the extradural spaces, the spinal cord and brain; they usually arise from the pia mater, within the central subarachnoid spaces (especially the quadrigeminal cisterns); a lipoma of the corpus callosum may be accompanied by calcification on the convex margins.

- **Intraluminal.** Lipomas have been found occasionally in the pancreas, under the renal capsule and in the breast (Chapter 46).

- **Retropitoneal.** Large lipomas are seen not infrequently in the retroperitoneal tissues. Some of them turn out to be liposarcomas.

**Treatment**

If a lipoma is causing trouble on account of its site, size, appearance or the presence of pain, removal is indicated.

During operation, any finger-like projections of the tumour into the surrounding tissue should also be removed. Although the tumour is relatively avascular, care is needed to obtain complete haemostasis in the resulting cavity otherwise a haematoma is common, which may be followed by infection and delay in wound healing; drainage is often necessary.

**Diffuse lipoma** occasionally occurs in the subcutaneous tissue of the neck, from which it spreads on to the preauricular region of the face. The tumour is not obviously encapsulated, and gives rise to no trouble, beyond being unsightly.

**Neuroma**

True neuromas are rare tumours, and occur in connection with the sympathetic system. They comprise the following types:

- **Ganglioneuroma**, which consist of ganglion cells and nerve fibres. It arises in connection with the sympathetic ganglia, and therefore is found in the retroperitoneal tissue, or in the neck or thorax.

- **Neuroblastoma**, which is less differentiated than the ganglioneuroma, the cells being of an embryonic type. The tumour somewhat resembles a round-celled sarcoma, and disseminates by the bloodstream. It occurs in infants and young children. It may occasionally undergo spontaneous remission.

- **Myelinic neuroma** is very rare, being composed only of nerve fibres, as the ganglion cells are absent. They arise in connection with the spinal cord or pia mater.

**Neurilemmoma** (syn. Schwannoma)

These lobulated and encapsulated tumours arise from the neurilemmal cells. They are soft and whitish in appearance. They displace the nerve from which they arise and can be removed (Fig. 12.10).

**Neurofibroma**

Neurofibroma arise from the connective tissue of the nerve sheath. The following varieties are described.

A single neurofibroma is usually found in the subcutaneous tissue. The ‘painful subcutaneous nodule’ forms a smooth firm swelling which may be moved in a lateral direction, but is otherwise fixed by the nerve from which it arises. Paraesthesia or pain is likely to occur from the pressure of the tumour on the nerve fibres which are spread over its surface. Cystic degeneration or sarcomatous changes occur occasionally.

Neurofibromas may also grow from the sheath of a peripheral nerve or a cranial nerve, e.g. the acoustic tumour (Chapter 35). As the nerve fibres are ‘part and parcel’ of the tumour they are difficult to remove without removal of the nerve itself. In major nerves recurrence is a problem, as is malignant (sarcomatous) change.

**Generalised neurofibromatosis**

(syn. von Rechlinghausen’s disease of nerves)

In this inherited (autosomal-dominant) disease, any cranial, spinal or peripheral nerve may be diffusely or modularly thickened (Fig. 12.7). The overgrowth occurs in connection with the endoneurium. Associated pigmentation (cafe au lait) of the skin is common, and sarcomatous changes may occur.

**Plexiform neurofibromatosis**

This rare condition usually occurs in connection with branches of the fifth cranial nerve (Fig. 12.11), although it may occur in the extremities (Fig. 12.12). The affected nerves become enormously thickened as a result of myxofibromatous degeneration of the endoneurium.

**Elephantiasis neuromatosa**

Elephantiasis neuromatosa is a rare variant congenital condition. The skin is coarse, dry and thickened, resembling an elephant’s hide, and the subcutaneous tissues become greatly thickened. If a leg is affected, the patient finds walking increasingly difficult. A famous patient of the London Hospital with this condition (the ‘Elephant Man’) was befriended by his surgeon, Sir Frederick Treves (see also Fig. 12.11 and Fig. 12.12).

**False neuroma**

Arises from the connective tissue of the nerve sheath after injury to a nerve (lacerations or amputation). These swellings consist of fibrous tissue and coiled nerve fibres.

**Haemangiomas**

Haemangiomas are described in Chapter 13. They are represented in various forms, capillary, cavernous and plexiform being common.
Glomangioma (syn. glomus tumour)

These rumours arise from a cutaneous glomus composed of a tortuous arteriole which communicates directly with a venule, the vessels being surrounded with a network of small nerves. These specialised organs regulate the temperature of the skin, and are found in the limbs, especially the nail beds. The tumour is compressible. The associated pain is out of all proportion to the size of the tumour, which may be only a few millimetres in diameter. The pain is burning in nature and radiates peripherally, and is more often noticeable when the limb is exposed to sudden changes in temperature.

On section the tumour consists of a mixture of blood spaces, nerve tissue and muscle fibres derived from the wall of the arteriole (angio-myoneuroma). Large cuboidal cells are frequently seen (glomal cells). Cutaneous glomus rumours grow very slowly, and do not become malignant. They should be excised.

Hamartoma

The term hamartoma is roughly translated from the Greek as a ‘fault’, and its original meaning was ‘missing the mark in spear throwing’. It is a developmental malformation consisting of overgrowth of tissue or tissues proper to the part. The possible range therefore is very wide and the lesions are often multiple. Common lesions that are hamartomas are benign pigmented moles, and the majority of angiomatas and neuro-fibromas. On rare occasions a malignant change occurs in a hamartoma, but for practical purposes the lesion is benign (Peters).
Malignant tumours

Carcinomas arise from cells which are ectodermal or endodermal in origin, and they are classified squamous, basal-celled or glandular (adenocarcinomas). Sarcomas occur in connection with structures of mesoblastic origin, hence fibrosarcoma, osteosarcoma. Germ cell tumours arise from germ cells (teratoma, seminoma, thecoma). Ovarian cancer is an adenocarcinoma: it does not arise from oocytes.

Carcinoma

Squamous cancer arises from surfaces covered by squamous epithelium, particularly as a result of ultraviolet or ionising radiation and chronic irritation. Chronic irritation of transitional cells (e.g. by a stone in the renal pelvis) or columnar cells (e.g. the gall bladder) will cause a change in these cells to a squamous type (squamous metaplasia), which may lead on to carcinoma. The regional lymph nodes are likely to be invaded, and may also be infected from the sepsis attendant upon the primary growth. Blood-borne metastases occur, but uncommonly from skin squamous cell carcinoma.

Macroscopically, squamous cell carcinomas are either proliferative or ulcerative. On section solid masses of polyhedral cells are seen, which invade the deeper structures. 'Cell-nests' are usually apparent in slowly growing cases, and are due to deeper cells becoming flattened and undergoing keratinisation. 'Prickle' (acanthotic) cells are characteristic, and resemble those present in the epidermis.

Basal-celled (syn. rodent ulcer)

See Chapter 36.

Glandular

Glandular carcinoma commonly occurs in the alimentary tract, breast and uterus, and less frequently in the kidney, prostate, gall bladder and thyroid. Three types of glandular carcinoma may be recognised:

- **carcinoma simplex**, in which the cells are arranged in circumscribed groups, no glandular structure being recognisable. This type commonly occurs in the breast, and the majority of cells are spheroidal or polygonal in shape;

- **adenocarcinoma**, so called from the tendency of the cells to form acini, which resemble those of the gland from which they are derived. The alveoli are ductless, and the walls are composed of layers of cells which invade the surrounding tissues. The cells of the primary growth, and even of the metastases, sometimes retain secretory powers; bronchial adenocarcinomas are well known for this;

- **colloid (mucoid)** is a degenerative process which develops in tumours arising from mucin-secreting cells. The mucin permeates the stroma of the growth, which appears as a gelatinous mass and is typically seen in the colon and stomach.

Glandular carcinoma is also subdivided into various types, e.g. encephaloid (soft), scirrhous (hard) and atrophic scirrhous (stony-hard). These distinctions depend clinically on their rate of growth, and pathologically on the relative proportions of fibrous tissue and gland elements. Examples occur in the breast (Chapter 46). All these glandular types of cancer are best regarded as adenocarcinomas.

Methods of spread

Direct spread (local extension). Invasion takes place readily along connective tissue planes, but no structures are resistant. Veins are invaded commonly. Arteries are rarely invaded. Muscle is less susceptible to invasion or metastatic deposits than other tissues. Fascia also limits direct extension, e.g. Denovillier's fascia for rectal carcinoma.

Lymphatics by invasion and by embolism.

- **Invasion**. The malignant cells grow along the lymphatic vessels from the primary growth (permeation). This may even occur in a retrograde direction. The cancer cells stimulate perilymphatic fibrosis, but this does not stop the advance of the disease. In some instances, notably malignant melanoma (Chapter 13), groups of cells may so overcome the surrounding fibrosis that they give rise to intermediate deposits between the primary growth and the lymph nodes.

- **Embolism**. Cancer cells which invade a lymphatic vessel can break away and are carried by the lymph circulation to a regional node, so that nodes comparatively distant from the tumour may be involved in the early stages.

Blood stream. Cancer cells may be detected in the venous blood draining an organ involved in carcinoma. A carcinoma of the kidney may invade the renal vein and grow inside the lumen into the vena cava. Malignant emboli may be arrested in the lungs, liver and bone marrow (secondary deposits — metastases). Thyroid, breast and bronchial cancers also commonly disseminate via the blood stream.

Implantation. Implantation of carcinoma has been observed in situations where skin or mucous membrane is in close contact with a primary growth. Examples of this 'kiss cancer' are carcinoma of the lower lip affecting the upper, and carcinoma of the labium majus giving rise to a similar growth on the opposite side of the vulva. Recurrence after operation is occasionally due to implantation of malignant cells in the wound. Examples of this mischance are the appearance of a malignant deposit in the scar after suprapubic removal of a primary carcinoma of the bladder, and nodules of carcinoma in the scar of the incision after mastectomy for a carcinoma of the breast. When a cavity is involved, free-floating cells from a carcinoma may spread like snowflakes all over its serous surface. For the abdomen, transcoelomic spread is specially notable when cells from a colloid carcinoma of the stomach gravitate on to an active ovary and give rise to malignant ovarian tumours (Krukenberg's tumour, Chapter 51); intracavitary dissemination can also take place within the pleura and cerebrospinal spaces.

Nerve sheaths. Adenocarcinomas, especially pancreas, may disseminate along nerve sheaths.

Grading and staging

Grading and staging are used to assess the degree of malignancy of the tumour as an indication of the prognosis, and may be used as a guide to determine the type and the extent of the treatment which is required. Advanced staging and grading may indicate the need for adjuvant methods of treatment, e.g. by chemotherapy or irradiation.

Grading. Grading predicts the aggressiveness of a malignant neoplasm by characterising its microscopic appearance taking into account the degree of differentiation, nuclear and cellular appearance, architectural integrity and the proportion of active mitoses.
• Grade 1: well differentiated;
• Grade 2: moderately well differentiated;
• Grade 3: poorly differentiated.

Staging. (i) TNM classification. This has been adopted by the International Union against Cancer (UICC) and has been extended to many sites of cancer. This is a detailed clinical staging which is arrived at simply by the clinician ascertaining the following points. What is the extent of the primary Tumour? Are any lymph Nodes affected? Are there any Metastases? The information so obtained is scored, e.g. ii carcinoma of the breast, as follows:

<table>
<thead>
<tr>
<th>Tumour</th>
<th>Nodes</th>
<th>Metastasis</th>
</tr>
</thead>
<tbody>
<tr>
<td>T1 2 cm or less.</td>
<td>N0 No nodes</td>
<td>M0 No metastasis</td>
</tr>
<tr>
<td>No skin fixation</td>
<td></td>
<td></td>
</tr>
<tr>
<td>T2 More than 2 cm, but less than 5 cm.</td>
<td>N1 Axillary nodes</td>
<td>M1 Metastases present including</td>
</tr>
<tr>
<td>Skin tethered or dimpled. No pectoral fixation</td>
<td>movable (a) not significant, (b) significant</td>
<td>involvement of skin beyond breast, and contralateral nodes</td>
</tr>
<tr>
<td>T3 More than 5 cm, but less than 10 cm.</td>
<td>N2 Axillary</td>
<td>M1 Metastases present including</td>
</tr>
<tr>
<td>Skin infiltrated or ulcerated. Pectoral fixation</td>
<td>nodes fixed</td>
<td></td>
</tr>
<tr>
<td>T4 More than 10 cm.</td>
<td>N3 Supraclavicular</td>
<td></td>
</tr>
<tr>
<td>Skin involved but not beyond breast, Chest-wall fixation</td>
<td>nodes of Oedema</td>
<td></td>
</tr>
</tbody>
</table>

(i) Thus, for example, one patient may have an early carcinoma which is T1N0M0, while in another late case the extent of the disease may be T3N2M1.

(ii) Manchester staging. This is a method of staging clinical spread of carcinoma of the breast (see Chapter 46).

(iii) Dukes’ staging. This is a method of classifying the spread of carcinoma of the rectum and colon and is described in Chapter 60.

Sarcomas

Sarcomas differ from carcinomas, not only in their derivation, but in their earlier age incidence, as they are most common during the first and second decades. Sarcomas often grow rapidly and dissemination occurs early via the blood-stream (e.g. ‘cannon-ball’ secondary deposits in the lung from an osteogenic sarcoma).

The macroscopic appearance of a sarcoma varies considerably. As the word implies, most tumours appear as a fleshy mass, but their consistency depends on the relative proportion of fibrous and vascular tissue. Haemorrhage commonly occurs owing to the very thin walls of the veins, which in some places are represented merely by venous spaces.

Sarcomatous cells may reproduce tissue similar to that from which the tumour originated, e.g. osteosarcoma or chondrosarcoma. Sometimes a sarcoma develops in pre-existing benign tumours, such as fibroma or a uterine fibroid, and also in bones which are affected by osteitis deformans (Chapter 26).

Fibrosarcoma

Fibrosarcoma is composed of spindle cells of varying lengths (the rounder they are the more malignant they are), and occurs in muscle sheaths, scars and as a fibrous epulis. A fibrosarcoma of a muscle sheath presents as an elastic or firm and slowly growing swelling. Dilated veins over the tumour suggest malignancy, and if not obvious they may be demonstrated by infrared photography. On palpation the tumour often feels warm and pulsation may even be detected. Fibrosarcomas not uncommonly arise in scar tissue, sometimes many years after the scar developed. Sir James Paget described this as a ‘recurrent fibroid’.

Treatment of sarcoma

The spread of a fibrosarcoma is hastened by incomplete removal. The moral is that wide excision with surrounding healthy tissues should be practised in all cases. This may mean amputation in the case of a limb. If untreated or if wide local excision is unsuccessful, a fibrosarcoma eventually fungates through the skin. Metastases are widely scattered and, unfortunately, radiotherapy has but little effect on either the primary growth or the secondary deposits. Sarcomas are often susceptible to anticancer drugs, but fibrosarcomas are more resistant than other types. Sarcoma of bone is sensitive to radiotherapy, which is used in some cases as an alternative to amputation (Chapter 25).

Lymphomas

Lymphomas arise in lymph nodes, tonsils, Peyer’s patches or lymph nodules in the intestines. Lymph nodes of the neck or mediastinum are most commonly affected (Chapter 17). They have a bad prognosis.

Synovioma

This rather uncommon tumour may arise in any synovial joint or tendon sheath, especially those of the hand. It appears as a soft, painless swelling, and sarcomatous changes can occur. The diagnosis can only be established by excision and biopsy of the tumour.

Naevus and melanoma
Naevus and melanoma are described in Chapter 13.

**Endothelioma; mesothelioma**

The endothelial linings of blood vessels, lymphatic spaces and serous membranes occasionally give rise to neoplasms. They can be malignant. They arise from the pleura (Chapter 47) and rarely from the pericardium or peritoneum. Asbestos inhalation may provoke their development. ‘Blue’ asbestos fibres especially have been shown to be a cause. The original cells are flattened, but they become spheroidal or cuboidal when neoplastic changes occur. The ‘endothelioma’ (meningioma) of the dura mater is thought to arise from the arachnoid membrane, which is not an endothelial structure (Chapter 35).

**Peritheliomas**

Peritheliomas are tumours arising in the endothelial lining of small blood vessels or lymphatics. Carotid body tumours are probably of this nature (Chapter 43).
Benign to malignant transformation

Certain benign neoplasms are prone to undergo malignant changes, and it is important, for both treatment and prognosis, to realise when this occurs. Some or all of the following changes may be recognised:

- increase in size: comparatively rapid enlargement is always suspicious, e.g. a neurofibroma which is becoming sarcomatous;
- increased vascularity: dilated cutaneous veins, ulceration and bleeding in the case of a superficial growth (e.g. melanoma);
- fixity: due to invasion of surrounding structures;
- involvement of adjacent structures: e.g. facial palsy suggests malignant change in an otherwise longstanding parotid pleomorphic adenoma;
- dissemination: discovery of secondary deposits.
Cysts

The word cyst is derived from the Greek word meaning 'bladder'. The pathological term 'cyst' means a swelling consisting of a collection of fluid in a sac which is lined by epithelium or endothelium.

True cysts

True cysts are lined by epithelium or endothelium. If infection supervenes, the true lining may be destroyed and replaced by granulation tissue. The fluid is usually serous or mucoid and varies from brown-staining by altered blood to almost colourless. In epidermoid, dermoid and branchial cysts the contents are like porridge or toothpaste, as a result of the shedding of desquamated cells. Cholesterol crystals are often found in the fluid of branchial cysts.

False cysts (pseudocysts)

Walled-off collections of fluid not lined by epithelium are not regarded as true cysts. A pseudocyst of the pancreas is an encysted collection of pancreatic enzymeric fluid lined by granulation tissue or fibrous tissue. Pancreatic pseudocysts are often in the retroperitoneum deep to but bulging into the lesser sac; they may occur anywhere in the abdominal cavity and even track into the mediastinum and pleural cavities. In tuberculous peritonitis, fluid may collect in the centre of a tumour (cystic degeneration), due to haemorrhage or necrosis. This can also happen in the brain as a result of ischaemia, and an ‘apoplectic cyst’ is formed. In acute pancreatitis fluid collections loculated by viscera and fibrin are called ‘acute fluid collections’; these often occur in the lesser sac but are neither cysts nor pseudocysts as they are not lined by either epithelium, granulation tissue or fibrous tissue.

**Congenital cysts**

The sequestration dermoid is due to dermal cells being buried along the lines of closure of embryonic clefts and sinuses by skin fusion. The cyst therefore is lined by epidermis and contains paste-like desquamated material. The usual sites are:

- the midline of the body — especially in the neck;
- above the outer canthus (external angular dermoid, Chapter 35);
- in the anterior triangle of the neck (branchial cyst, Chapter 43).

Tubuloembryonic (tubulodermoid) cysts occur in the track of an ectodermal tube used in development, e.g. a thyroglossal cyst from the thyroglossal duct or a postanal dermoid from the postanal gut. In the brain, ependymal cysts arise from the sequestration of cells of the enfolding neuroectoderm.

Cysts of embryonic remnants. These arise from embryonic tubules and ducts which normally disappear or are only present as remnants. They should not be confused with teratomatous cysts, e.g. dermoid. There are many examples in the urogenital system, e.g. in the male from remnants of the paramesonephric duct (Müllerian) — the hydatid of Morgagni, or from the mesonephric body and duct (Wolffian) (Chapter 64). Cysts of the urachus and the vitellointestinal duct are other examples of cysts of embryonic remnants (Chapter 65).

**Acquired cysts**

Retention cysts are due to the accumulated secretion of a gland behind an obstruction of a duct. Examples are seen in the pancreas, the parotid, the breast, the epididymis and Bartholin’s gland. A sebaceous cyst starts with the obstruction of a sebaceous gland, but this is followed by the down-growth and the accumulation of desquamated epidermal cells, thus turning it into an epidermoid cyst. In the epididymis, if the retention cyst contains sperms, it is known as a ‘spermatocele’.

Distension cysts occur in the thyroid from dilatation of the acini, or in the ovary from a follicle. Lymphatic cysts and cystic hygromas are distension cysts. Exudation cysts occur when fluid exudes into an anatomical space already lined by endothelium, e.g. hydrocele, a bursa, or when a collection of exudate becomes encrusted.

Cystic tumours. Examples are cystic teratomas (dermoid cyst of the ovary) and cystadenomas (pseudomucinous and serous cystadenoma of the ovary).

Ganglia. See Chapter 29.

Implantation dermoids arise from squamous epithelium which has been driven beneath the skin by a penetrating wound. They are classically found in the fingers of women who sew assiduously and metal workers (Fig. 12.13).

**Trauma**

A haematoma may resolve into a cyst. This sometimes happens to haematomas of muscle masses in the loin and anterolateral aspects of the thigh or the skin. They are located between muscle, facial or subcutaneous planes and contain straw- or brown-coloured fluid containing cholesterol crystals. They become lined by endothelium and calcium salts may be laid down. Aspiration is only of temporary value, and a cure depends upon complete excision of the lining. Within the cranium, a haematogenous cyst can cause the same problems as any expanding,
Degeneration cysts
These have already been discussed under false cysts.

Parasitic cysts
These are encrusted forms in the life cycle of various worms:

- **Hydatid cyst of Taenia echinococcus.** This is described later according to the organ involved, e.g. liver, Chapter 52; lung, Chapter 47.
- **Trichiniasis.** Cysts of *Trichina spiralis,* affecting muscle.
- **Cysticercosis.** Cysts of *Taenia solium.* A disease of the pig, humans being rarely affected. Eosinophilia is present. The cysts occur in any organ. They calcify and may cause clinical effects according to their situation, especially in the brain. Only those cysts which are actually causing symptoms should be excised.

Clinical features
The swelling usually has a smooth, spherical appearance. **Fluctuation** depends upon the pressure of fluid within: a tense cyst feels like a solid tumour, although careful palpation between two fingers may elicit a characteristic elasticity. **In addition, a solid tumour is most hard at the centre; a cyst is least hard at the centre.** If fluctuation is present, a cyst may be confused with a cold abscess or a lipoma. A cold abscess usually has a peculiar rim of thickening surrounding the soft centre. A lipoma may well test clinical acumen. **Transillumination,** while brilliantly clear in cysts containing serous fluid, does not really distinguish between a lipoma and a dermoid or branchial cyst. There is even an old axiom that 'when in doubt, hedge on fat.' According to circumstances, ultrasonography, computerised tomography (CT) or magnetic resonance imaging (MRI), a test aspiration or excision reveals the true nature of the swelling.

Cysts may be painful, especially when infection or haemorrhage causes a sudden increase in intracystic tension. Sometimes they change in size for no apparent reason. Occasionally, they diminish owing to rupture through a facial plane.

Effects are according to site and size. As with benign tumours, a cyst may compress ducts and blood vessels, e.g. the main bile duct may be obstructed by a choledochal cyst, a renal cyst or a hydatid cyst. The pelvic veins may be obstructed by an ovarian cyst, the patient presenting for treatment of her varicose veins. The sheer size of an ovarian cyst (**Fig. 12.14**) may so increase intra-abdominal tension as to bring the patient to hospital with symptoms of a hiatus hernia.

Complications

**Infection**
The cyst becomes tense and painful, and adherent to surrounding tissues. An abscess may form and discharge on the surface and result in an ulcer or a sinus (viz. Cock’s peculiar tumour, Chapter 13). Healing will not occur until the whole lining of the cyst or the embryonic track is excised.

**Haemorrhage**
Sudden haemorrhage, as may occur in a thyroid cyst, causes a painful increase in size. In this particular case, breathing may be difficult because of pressure on the trachea.

**Torsion**
Torsion may occur in cysts which are attached to neighboring structures by a vascular pedicle. Ovarian dermoids are sometimes brought to notice in this way as acute abdominal emergencies. The cyst (or cysts — they may be bilateral) turns to a purple or black colour as the venous and then the arterial supply is cut off.

**Calcification**
Calcification follows haemorrhage, or infection, and may be the result of reaction to a parasite, e.g. hydatid cyst.

**Cachexia ovarica**
Enormous cysts are rarely seen nowadays (**Fig. 12.14**).
Ulcers

An ulcer is a discontinuity of an epithelial surface. There is usually progressive destruction of surface tissue, cell by cell, as distinct from death of macroscopic portions, e.g. gangrene or necrosis. Ulcers are classified as nonspecific, specific (e.g. tuberculous or syphilitic) or malignant.

Nonspecific ulcers are due to infection of wounds, or physical or chemical agents. Local irritation, as in the case of a dental ulcer, or interference with the circulation, e.g. varicose veins, are predisposing causes.

Trophic ulcers (trophe (Greek) = nutrition) are due to an impairment of the nutrition of the tissues, which depends upon an adequate blood supply and a properly functioning nerve supply. Ischaemia and anaesthesia therefore will cause these ulcers. Thus, in the arm, chronic vasospasm and syringomyelia will cause ulceration of the tips of the fingers (respectively painful and painless). In the leg, painful ischaemic ulcers occur around the ankle or on the dorsum of the foot. Neuropathic ulcers due to anaesthesia (diabetic neuritis, spina bifida, tabes dorsalis, leprosy or a peripheral nerve injury) are often called perforating ulcers (Fig. 12.15). Starting in a corn or bunion, they penetrate the foot, and the suppurative may involve the bones and joints and spread along fascial planes upwards, even involving the calf.

The life history of an ulcer consists of three phases.

Extension

During the stage of extension the floor is covered with exudate and sloughs, while the base is indurated. The discharge is purulent and even blood stained.

Transition

The transition stage prepares for healing. The floor becomes cleaner, the sloughs separate, induration of the base diminishes and the discharge becomes more serous. Small, reddish areas of granulation tissue appear on the floor and these link up until the whole surface is covered.

Repair

The stage of repair consists of the transformation of granulation to fibrous tissue, which gradually contracts to form a scar. The epithelium gradually extends from the now shelving edge to cover the floor (at a rate of 1 mm per day).

This healing edge consists of three zones — an outer of epithelium, which appears white, a middle one, bluish in colour (where granulation tissue is covered by a few layers of epithelium), and an inner reddish zone of granulation tissue covered by a single layer of epithelial cells. The red colour of granulation tissue is due to the high density of new capillaries (neo-angiogenesis).

Clinical examination of an ulcer

This should be conducted in a systematic manner. The following are, with brief examples, the points which should be noted.

Site, e.g. 95 per cent of rodent ulcers occur on the upper part of the face. Carcinoma typically affects the lower lip, while a primary chancre of syphilis is usually on the upper lip.

- Size, particularly in relation to the length of history, e.g. a carcinoma extends more rapidly than a rodent ulcer, but more slowly than an inflammatory ulcer.

- Shape, e.g. a rodent ulcer is usually circular. A gummatous ulcer is typically circular, or serpiginous due to the fusion of multiple circles. An ulcer with a square area or straight edge is suggestive of ‘dermatitis artefacta’ (Fig. 12.16).

- Edge (Fig. 12.17). A healing, nonspecific ulcer has a shelving edge. It is pearly, rolled or rampant if a rodent ulcer, and raised and everted if an epithelioma, under-mined and often bluish if tuberculous, vertically punched out if syphilitic.

- Floor. The floor is that which is seen by an observer, e.g. watery or apple-jelly granulations in a tuberculous ulcer, a wash-leather slough in a gummatous ulcer.

- Base. The base is what can be palpated. It may be indurated as in a carcinoma or attached to deep structures, e.g. a varicose ulcer to the tibia.

- Discharge. A purulent discharge indicates active infection. A blue—green coloration suggests infection with Pseudomonas pyocyaneus. A watery discharge is typical of tuber-culosis. It is bloodstained in the extension phase of a nonspecific ulcer. Bacteriological examination may reveal colonisation by coagulase-positive staphylococci. Spirochetes are found in a primary chancre (Chapter 8).

- Lymph nodes are not enlarged in the case of a rodent ulcer, unless due to secondary infection. In the case of carcinoma, they may be enlarged, hard and even fixed. The inguinal nodes draining a syphilitic chancre of the penis are firm and ‘shotty’, but contrarily the submandibular nodes draining a chancre of the lip are greatly enlarged.

- Pain. Nonspecific ulcers in the extension and transition stages are painful (except for the anaesthetic trophic type). Tuberculous ulcers vary, that of the tongue being very painful. Syphilitic ulcers are usually painless, but an anal chancre (of a homosexual) may be painful (cf. anal fissure, Chapter 61).

- General examination. Evidence of debility, cardiac failure, all types of anaemia, including sickle-cell anaemia, or diabetes must be sought.

- Pathological examinations, e.g. biopsy, will confirm carcinoma. The serological and Mantoux tests may be of value for syphilis and tuberculosis, respectively.

- Marjolin’s ulcer. See Chapter 13.

Local (topical) treatment of nonspecific ulcers

Any underlying cause is treated, e.g. varicose veins (Chapter 16), diabetes, arterial disease. Many lotions and nonadhesive applications are used to aid the separation of sloughs, hasten granulation and stimulate epithelialisation. The basic requirements of an ideal dressing are that
should:

• maintain a high humidity between the wound and the dressing;
• remove excess exudate and toxic compounds;
• permit gaseous exchange of oxygen, carbon dioxide and water vapour;
• provide thermal insulation to the wound surface and be impermeable to microorganisms;
• be free from particles and toxic wound contaminants
• allow easy removal with no trauma at dressing change;
• be safe to use and be acceptable to the patient;
• be cost-effective.

**Antisepsics and topical antibiotics**

Antiseptics can do more harm than good when used inappropriately. They can interfere with the normal healing process, are toxic to fibroblasts and may permit more virulent organisms to dominate. The routine use of antisepctic and hypochlorite solutions should be avoided. If a wound needs cleaning, this can be achieved safely and more economically with normal saline warmed to body temperature prior to use. If a topical antiseptic is necessary, aqueous chlorhexidine 1 in 5000 solution is effective against a wide range of Gram-positive and -negative organisms and some fungi, but not spores. Povidone iodine has a broad spectrum of activity but its antibacterial effect is reduced by contact with pus or exudate. It should not be used on patients who are sensitive to iodine. Topical antibiotics are not recommended routinely as resistance and sensitisation following application may arise. Flamazine is a hydrophilic cream containing silver sulphadiazine 1% which is a broad-spectrum antibacterial agent and very effective against *Pseudomonas,* useful for the prevention of Gram-negative sepsis in patients with severe burns.

**Wound dressings**

Hydrocolloid dressings such as Granuflex or Comfeel consist of a thin polyurethane foam sheet bonded on to a semipermeable polyurethane film, which is impermeable to exudate and microorganisms. When the dressing comes into contact with wound exudate it interacts to form a gel which expands into the wound. The moist conditions produced under the dressing promote angiogenesis and wound healing without causing maceration. They can be used in the treatment of leg ulcers, pressure sores, minor burns and many types of granulating wound. A hydrocolloid dressing can be applied to small wounds containing dry slough or necrosis: the dressing prevents the loss of water vapour from the surface of the skin, and this effectively rehydrates the dead tissue which is then removed by autolysis.

Hydrogel (Intrasite gel) is a pale yellowColourless transparent aqueous gel. When it comes into contact with a wound, the dressing absorbs excess exudate and produces a moist environment at the surface of the wound without causing tissue maceration. It may be applied to many different wounds including leg ulcers, pressure sores, surgical wounds and granulating tissue. It is particularly useful in the treatment of dry, sloughy or necrotic wounds, promoting rapid débridement by facilitating rehydration and autolysis of dead tissue. It reduces the feeling of pain and can be used as a carrier of other medicines, e.g. metronidazole, for the control of odour caused by infection with sensitive organisms. (It is useful in fungating tumours where the aim is not to heal the wound but to manage the distressing symptoms caused by it.) Intrasite should be secured with a secondary dressing such as an absorbent pad or Tegaderm depending on the wound.

Alginates (Kaltostat) consist of an absorbent fibrous fleece composed of the mixed sodium and calcium salts of alginic acid. In the presence of exudate or other body fluids containing sodium ions, the fibres absorb liquid and swell, calcium ions present in the fibre are partially replaced by sodium, causing the dressing to take on a gel-like appearance which promotes healing. The fibres are held in place with a secondary dressing such as an absorbent pad or Tegaderm depending on the amount of exudate. Algin ate dressings can be used for the management of bleeding wounds including cuts and lacerations and also for a wide range of exuding lesions including leg ulcers, pressure sores and other granulating wounds. Most suitable for heavy to moderately exudating wounds. In the presence of low exudate the Kaltostat must be moistened with saline before application to avoid adherence. The alginates are biodegradable so it is not necessary to remove every fibre if it will damage the healing tissue.

Lyfoam is a low-adherent conformable polyurethane foam sheet. The side of the dressing that is to be placed in contact with the skin has been heat treated to render it hydrophobic, whilst the outer surface remains hydrophobic. The dressing is freely permeable to gases and water vapour but resists the penetration of aqueous solutions and exudate. The dressing absorbs blood and any other tissue fluids but the aqueous component is lost by evaporation through the back of the dressing. Strike-through occurs laterally and not at the top of the dressing. The dressing maintains a moist warm environment at the surface of the wound, which is conducive to granulation and epithelialisation. Foam sheet dressings may be used on a variety of exuding wounds including leg ulcers, pressure sores, sutured wounds, burns and donor sites.

Tegaderm consists of a thin polyurethane membrane coated with a layer of an acrylic adhesive. The dressing allows for a moist environment at the surface of the wound by reducing water vapour loss from the exposed tissue. It is permeable to both water vapour and oxygen and impermeable to microorganisms, providing an effective barrier to external contamination. Scab formation is prevented and epidermal regeneration takes place at an enhanced rate, compared with that which occurs in wounds treated with traditional dry dressings. Tegaderm may be used in the treatment of minor burns, pressure areas, donor sites, postoperative wounds and a variety of minor injuries. It is also effectively used as a protective cover to prevent skin breakdown due to friction or continuous exposure to moisture.

Allevyn cavity wound dressing is a highly comfortable absorbent dressing consisting of a soft, polymeric outer membrane with a three-dimensional honeycomb-like structure containing a mass of hydrophilic polyurethane chips. The outer membrane is perforated to allow exudate to be drawn into the interior of the dressing where it is absorbed and retained by the ‘chips’. This type of dressing is used for heavily exudating, full-thickness sloughy wounds, usually combined with Intrasite gel; it can be used alone with clean, deep, ex- danging wounds.

Most of the above dressings are also available with added properties which improve their basic function, such as Kaltocarb. This is Kaltostat with a layer of activated charcoal cloth attached. This is effective as a primary dressing in the management of infected malodorous wounds.

As the wound heals if granulation tissue continues to grow past the epidermal layer, the dressing used to stimulate granulation should be discontinued and a Lyfoam dressing should be applied. If after 1 week there is no improvement Tetra-corti ointment containing hydrocortisone and oxytetracycline applied sparingly to the wound may be effective. This should be covered with a Lyfoam dressing and should be used for no longer than 5 days. Silver nitrate may be used with heavy over-granulating tissue but it is not recommended, usually
because of its toxicity and the risk of sensitivity and staining.

**Oriental sore (syn. Delhi boil, Baghdad sore, etc.)**

This disease is due to infection by a protozoal parasite, *Leishmania tropica*, and is a common condition in Eastern countries which is occasionally imported to Western zones. An indurated papule appears on an exposed surface, usually the face. If untreated, this breaks down to form an indolent ulcer, which eventually leaves an ugly, pigmented scar. The condition readily responds to intravenous injections of antimony tartrate, but very small lesions can be treated by carbon dioxide snow, and also curettage.

**Bazin’s disease (syn. erythema induratum)** is due to localised areas of fat necrosis and particularly affects adolescent girls. Symmetrical purplish nodules appear, especially on the calves, and gradually break down to form indolent ulcers, which leave in their wake pigmented scars. Tuberculosis may be a cause in many instances, the ulcers responding to antituberculous drugs (Fig. 12.17) (Chapter 8).
Sinuses and fistulas

A sinus (Latin a hollow; a bay or gulf) is a blind track (usually lined with granulation tissue) leading from an epithelial surface into the surrounding tissues. Pathological sinuses must be distinguished from normal anatomical sinuses (e.g. the frontal and nasal sinuses). A fistula (Latin = a pipe or tube) is an abnormal communication between the lumen or surface of one organ and the lumen or surface of another, or between vessels. Most fistulas connect epithelial-lined surfaces (Fig. 12.18). Sinuses and fistulas may be congenital or acquired. Forms which have a congenital origin include preauricular sinuses (Chapter 37), branchial fistulas (Chapter 43), tracheo-oesophageal fistulas (Chapter 50) and arteriovenous fistulas (Chapter 15). The acquired forms often follow inadequate drainage of an abscess. Thus, a perianal abscess may burst on the surface and lead to a sinus (erroneously termed a blind external ‘fistula’). In other cases, the abscess opens both into the anal canal and on to the surface of the perineal stem resulting in a true fistula-in-ano (Chapter 61). Acquired arteriovenous fistulas are caused by trauma or operation (for renal dialysis).

Persistence of a sinus or fistula

The reason for this will be found among the following:

- a foreign body or necrotic tissue is present, e.g. a suture, hairs, a sequestrum, a faecolith or even a worm (see below);
- inefficient or nondependent drainage: long, narrow, tortuous track predisposes to inefficient drainage;
- unrelieved obstruction of the lumen of a viscus or tube distal to the fistula;
- high pressure, such as occurs in fistula-in-ano due to the normal contractions of the sphincter which force faecal material through the fistula;
- the walls have become lined with epithelium or endothelium (arteriovenous fistula);
- dense fibrosis prevents contraction and healing;
- type of infection, e.g. tuberculosis or actinomycosis;
- the presence of malignant disease
- ischaemia;
- drugs, e.g. steroids, cytotoxics;
- malnutrition;
- interference, e.g. artefacta;
- irradiation, e.g. rectovaginal fistula after treatment for a carcinoma of the cervix;
- Crohn’s disease;
- high-output fistula, e.g. duodenocutaneous fistula.

Treatment

The remedy depends upon e removal or specific treatment of the cause (see appropriate pages).

Guinea worm (syn. dragon worm, Dracunculus medinensis) (Fig. 12.19)

This is a cause of a persisting sinus on the lower leg. The larval form enters through the wall of the stomach or duodenum in drinking water contaminated by a tiny cyclops crustacean which has consumed the larvae. Settling in the abdominal connective tissue, the male and female mate, the pregnancy lasting about a year, and the female wanders in the subcutaneous tissues to select for egg laying a part of the anatomy likely to be submerged in water (containing the cyclops), usually the lower leg. Cellulitis, abscesses, ulcers and sinuses follow, through which the embryos are discharged, hopefully to be eaten by the cyclops. Baid travelled the interior of India and in 500 cases discerned a syndrome of the infestation, presenting with conjunctivitis (allergic) in 11 per cent, fibrous contracture of joints in 19 per cent, periostitis with osteomyelitis in 21 per cent and acute arthritis in 65per cent.

Plastic surgery

Plastic surgery is defined as ‘repair or reconstruction of lost, injured or deformed parts of the body chiefly by transfer of tissue’. The term plastic concerns moulding and reshaping of tissues and comes from the Greek plastikos (‘that may be moulded’). When tissues are moved or reshaped the most important principle governing this process is respect for their blood supply. The two fundamental methods by which tissues are moved are grafts or flaps. A graft is a piece of tissue that is moved without its blood supply and relies on its recipient bed to re-establish a blood supply. A flap is a piece of tissue that is moved maintaining its blood supply and is not reliant on the recipient site for its vascularity. Historically reconstruction was complex and multistage, with ample opportunity for vascular complications to arise. In the last 30 years there has been a revolution in our understanding of the blood supply of the skin and of other tissues(1). Flaps can now be reliably designed on single named blood vessels, greatly increasing their power and versatility. Plastic surgical techniques are used in a wide variety of surgical procedures in all parts of the body, and in the treatment of a wide variety of pathologies. These techniques can be learnt and used by other specialists, but most plastic surgeons would feel that optimal care is provided where the plastic surgeon works together with a surgeon from another discipline to each bring their own expertise to bear on the problem.

Priorities in reconstruction

When presented with any defect it is important to recognise that the most important priority is to achieve primary healing. The purpose of reconstructive procedures is to avoid the adverse consequences of healing by second intention in terms of delay and poor function. If one can achieve quiet primary healing and thereby restore the patient to function a superior result in terms of appearance will usually result. It is essential, however, that these three priorities are observed in the correct order: first healing, then function and lastly appearance. Where these aims cannot be achieved by direct closure of a wound a more complex technique is selected from the reconstructive toolbox. Planning and selection are central to the practice of plastic surgery. In any one patient there is a number of reconstructive options. The reliability and quality of the reconstruction must be balanced against the donor site morbidity.

Priorities in plastic surgery
1. Healing
2. Function
3. Cosmetic

(1) In part this has been a rediscovery since much work was done by Manchot in the nineteenth century by means of cadaver dissections and Salmon in the 1930s and 1940s by means of meticulous radiographs of injected cadaver skin.)
Skin grafts

Skin grafts are harvested from a donor site and transferred to a recipient site on which they must survive, a process known as take. All skin grafts initially adhere to the recipient bed by the formation of fibrin. Oxygen and nutrients diffuse through by a process known as plasmatic imbibition to keep the graft alive. New blood vessels then grow from the recipient site and link up with dermal capillaries to re-establish a blood supply, a process known as inosculation. Thin skin grafts are more likely to survive by imbibition and will revascularise readily and are therefore more likely to take than thicker grafts. Thicker grafts, however, will have more dermis, more sebaceous glands, greater structural integrity and a lesser tendency to contract.

Partial-thickness skin grafts

Partial-thickness skin grafts consist of epidermis and a variable thickness of dermis. There remains some dermis on the donor site that heals by epithelialisation from the cut ends of hair follicles and sweat glands in a manner similar to the healing of a graze or a superficial burn. The thigh, is most frequently used as a donor site, but almost anywhere else can be used. Grafts are harvested using a skin graft knife or a power dermatome. These consist of a blade and a guard that can be adjusted to determine the thickness of the graft. Hand knives require practice to use and the graft obtained remains dependent on the tension in the donor site skin, the pressure that the surgeon applies, the speed and length of the strokes used and the angle of application of the blade (Fig. 13.1). With air- or electric-powered dermatomes these factors become less important and more consistent results can be obtained. Partial-thickness grafts are used to resurface relatively large areas of skin defect and are particularly useful in burns (Fig. 13.2a and b).

Full-thickness grafts

Full-thickness grafts consist of epidermis and all of the dermis; the donor site will not epithelialise and must be closed, usually directly. Suitable donor sites are postauricular, supra-clavicular and groin. Full-thickness grafts are most commonly used in repairing defects on the face (Fig. 13.3a—c). Grafts taken from above the clavicles retain the ability to blush and can provide a very good colour match for facial skin, whereas grafts from below the clavicles will tend to look pale. Full-thickness grafts are harvested using a scalpel and forceps, dissecting at a level just below the dermis. As they are thick special care is needed to ensure good apposition to a well-vascularised bed to ensure good take.

Composite grafts

Composite grafts consist of skin and some underlying tissue such as fat and cartilage. Again, donor sites must be closed directly. Composite grafts carry the highest risk of failure yet potentially can repair complex defects. These grafts have to be carefully designed to be as thin as possible and have a large area of inset in order to survive. Their maximum thickness can only be a few millimetres; it is futile to replace larger portions of composite tissues — for larger defects flap repairs are needed. Portions of ear, skin and cartilage can be used to reconstruct nasal defects. Amputated fingertip pulp in children will sometimes survive if carefully replaced as a composite graft.

Other tissues

Other tissues can also be transferred as grafts. Cartilage grafts are commonly used in nasal and ear reconstruction. Cartilage is an avascular tissue; survival of transplanted chondrocytes depends entirely on diffusion of nutrients. Bone grafts are widely used for skeletal reconstruction. Nerve, tendon, vein, fascia and cornea are also all in common use.

Technical aspects

Graft take is only possible at well-vascularised recipient sites. Grafts will not take on bare bone, bare tendon or cartilage, but can survive on periosteum, paratenon and perichondrium. The graft must remain adherent to the bed until it revascularises; shearing forces must be eliminated. Meti-culous care with suturing and dressings is essential. Where grafts are applied over mobile areas appropriate splintage must be used. Limbs that have been grafted should be elevated to reduce venous pressure during the process of revascularisation. Haemostasis at the recipient site must be good to prevent bleeding beneath the graft resulting in its elevation by clot and failure of take. Skin grafts can be stored in a refrigerator at 4°C for 2 weeks for delayed application. Grafts take well on granulation tissue, but excessive contamination with bacteria will prevent take. Streptococci at levels above $10^5$ microorganisms per gram of tissue will result in graft loss. Preparation of the bed with dressings may help; it may be necessary to excise the granulation tissue.
Terminology

The definitions of flaps and grafts used above describe the vascular basis of the tissue transfer and the constituents of the transferred tissue. Most tissue transfer is from one place to another in the same person. However, there are other forms of transfer and further terminology is needed to explain the genetic basis of these transfers. An autograft is tissue transferred from one location to another on the same patient. An isograft is tissue transferred between two genetically identical individuals, such as the first successful renal transplant that was between identical twins. An allograft is tissue transferred between genetically different members of the same species. Most solid organ tissue transplantation involves this type of transfer. Rejection of the transplanted tissue will occur unless immunosuppressant drugs are used. A xenograft is tissue transferred from a donor of one species to a recipient of another species. Xenografts are usually small amounts of tissue rendered acellular before implantation to prevent rejection.
Flaps

More complex defects and avascular defects require flap cover. Flaps can consist of skin only, or be complex compos-ites of skin, muscle, bone or other tissues. As their complexity increases so do their power and ability to reconstruct more complex defects. Flaps can be classified according to the geometry of their transfer such as rotation, advancement or transposition. A more useful classification is provided by their vascular basis. The vascular supply of a flap is known as its vascular pedicle; some flaps have more than one vascular pedicle. The term pedicle is also used to describe the base or attachment of a flap, which may also contain skin and other tissues as well as the vascular pedicle. Where the skin is divided all the way around a flap it is called an island flap.

2 Flaps from the cheek and forehead were used in India as early as 1000 ec for nasal reconstruction. Tagliacozzi in 1597 published his method using flaps from the arm. Multitudes of flaps were utilised in the nineteenth century. Tansini in 1896 described the latissimus dorsi flap for breast reconstruction. The significance of the vascular basis of these flaps was not appreciated during the development of modern plastic surgery after World War I and World War II.

The development of flap surgery

Flaps have been used since ancient times, often to repair complex defects. In the first half of the twentieth century, however, the only flaps that were considered possible were skin flaps consisting of rectangular portions of skin and subcutaneous tissue with length to breadth ratio of 2 to 1.5:1. Such flaps were of limited arc of transfer and their use to reconstruct distant defects involved multistage surgery. Bipedicled flaps were tubed to form tubed pedicle flaps that were attached to an arm carrier and then transferred in several stages using multiple delays to a recipient site. It was possible to perform complex reconstructions using these methods, but each stage risked vascular compromise and flap loss, and donor site scarring was considerable. This all took a long time and such flaps, when the transfer was completed, depended on the local vascularity of the recipient site and did not bring in an independent blood supply of their own. Modern flap practice has developed since the discovery of the vascular anatomy of potential flap territories and the vascular patterns of skin blood supply.

Random pattern flaps

The vascular basis of random pattern flaps is the subdermal plexus of blood vessels. These flaps are widely used for local repair of adjacent defects, particularly on the face. Many geometric designs are possible. A particularly useful pattern is a rhomboid flap (Fig. 13.4a—d). The Z-plasty is a local flap technique that can be employed in a variety of situations, in particular treatment of contractures and scar revision. A Z-plasty or a combination of Z-plasties can lengthen a contracture, change the direction of a scar, alter tension, reposition specialised structures and improve the appearance of a scar (Fig. 13.5). It involves the transposition of triangular flaps. The maximum lengthening is achieved by using 600 angles of flap design. Lengthening depends on laxity at right angles to the contracture since it occurs at the expense of shortening in a perpendicular direction.

Axial pattern flaps

Skin flaps with a known direct superficial vascular pedicle passing along their long axis are known as axial pattern flaps. These defy previously accepted length-to-breadth ratios that applied to random pattern flaps and thereby long flaps can reliably be designed with longer axes of rotation. The forehead flap, the deltopectoral flap and groin flap all share this vascular pattern.

3 In a series of experiments in the I 960s raising flaps in pigs, Milton discovered that flaps made under similar conditions survive to the same length regardless of width. He realised that the most important factor was including a dominant vessel in the pedicle. He further discovered that islanded flaps with a segmental vessel in their base survived to a greater length than random skin flaps. Thus, he predicted the flap revolution that was about to occur.

Fasciocutaneous flaps

In many parts of the body blood vessels pass along the deep fascia or, in association with intermuscular septae, pass perforating vessels to supply the overlying skin. These flaps are raised along with the vascular pedicle by dissecting along the relevant fascial plane. Long vascular pedicles can be created, often with quite large vessels at their base. Fasciocutaneous flaps can be transferred loco-regionally, or the vascular pedicle divided, the flap transferred to a distant site and the flap revascularised by microsurgical anastomosis to recipient vessels adjacent to the defect. This technique of free tissue transfer has further extended the versatility of flap reconstruction. Fasciocutaneous flaps can be skin only or can include associated tissue to provide vasculated bone or nerve. Examples include the radial forearm flap, the scapular flap and the lateral arm flap (Fig. 13.6a—c). Almost any perforating blood vessel can be used as the vascular basis for a flap if carefully identified and dissected out. These so-called perforator flaps are the latest extension of flap design.

Muscle and musculocutaneous flaps

Muscles have predictable patterns of vascular anatomy that permit the elevation of a muscle on one or more of its vascular pedicles for use as a muscle flap, either locally or as a free tissue transfer. Many muscles also have perforating vessels passing from their substance into the overlying skin enabling musculocutaneous flaps to be designed. Musculocutaneous flaps based on the latissimus dorsi and rectus abdominis muscles are particularly useful in breast reconstruction (Fig. 13.7a and b). These same muscles are widely used as free muscle flaps to repair defects in the lower limb associated with open tibial fractures (Fig. 13.8a—c). Glatue maximus and tensor fascia lata flaps are used for pressure-sore closure. Muscle flaps can be used as functional transfers where their nerve supply is left intact or re-established at the recipient site. Such techniques are applied to the rehabilitation of brachial plexus injury, anal incontinence and facial palsy.
Freetissue transfer

The development of high-quality binocular operating microscopes, swaged microsutures and microsurgical instrumentation has, along with advances in the understanding of flap vascular anatomy, enabled reliable free flap surgery. The first successful microsurgical free tissue transfer was a toe transfer to reconstruct the thumb. Microsurgical transfer of toes or portions of toes to reconstruct hand defects has now become a routine procedure in hand surgery. Most of the other types of flaps described above can be reliably transferred micro-surgically. Free tissue transfer allows the design of customised composite flaps without the constraints of loco-regional flap transfers. Successful free flap transfer requires careful planning of the most appropriate flap to reconstruct the defect. Of prime importance is selection of the recipient vascular axis; the operation is designed to ensure the microvascular anastomosis is done to the largest available vessels, thus maximising blood flow. Other factors such as keeping the patient warm, ensuring the patient has a good circulating volume, providing perioperative and postoperative analgesia where possible with regional anaesthesia are also important. Technical issues such as ensuring atraumatic dissection and vessel handling, avoiding tension and kinking of vascular pedicles and gentle irrigation of the vessel lumen with heparinised solutions are essential.

Experienced teams can expect success rates in excess of 95 per cent for most free tissue transfers, placing it amongst the most reliable of techniques. Flap failure is best detected by regular observation of the flap by experienced individuals. If there is any doubt the patient must be rapidly returned to theatre and the microvascular anastomoses inspected. Prompt re-exploration will usually salvage a failing flap.
Tissue expansion

A recent addition to the reconstructive surgeon's options is tissue expansion. Here, a silicone balloon is placed beneath the planned donor site. The balloon is then inflated by percutaneous injections of saline over several weeks in order to increase the area of the expanded flap. It is then possible at a second operation to remove the silicone balloon and utilise the expanded tissue. Tissue expansion has the advantage of creating large flaps of tissue at sites where this might otherwise be impossible. Where expansion is done adjacent to a defect, the flap will often have ideal properties to reconstruct that defect. It can often be transferred by simple techniques, and sensation can be preserved. Often the donor site can be closed directly if sufficient tissue has been created.
Skin lesions

The skin is the largest organ of the body, with a surface area of between 10,000 and 18,000 cm² in the average adult, accounting for approximately 15 per cent of the total body weight. The multiple functions of the skin allow humans to adapt to a wide variety of environmental conditions. An important aspect of the function of skin is that of protecting deeper structures. It also has an important role in thermoregulation, metabolism (vitamin D production), immunological defence, a sensory interface with our surroundings and a psychological expression of an individual to their surroundings. The skin as an organ is vulnerable to a wide variety of diseases and conditions. Ageing is accompanied by a loss of elasticity and wrinkling. Degenerative changes result from excessive exposure to ultraviolet radiation and environmental factors. Reactions to chemicals and drugs are also common, and the skin is probably susceptible to more different types of turnouts than any other organ. Lesions arise from any of the structures that are present in the skin.
Skin infections

Staphylococcal infections

Most skin infections are staphylococcal and relatively minor. They will settle with no specific treatment; topical antiseptics may be used or systemic antibiotics if the infection does not settle or spreads. Patients with unexplained infections should be checked for diabetes mellitus. The sensitivity of the organisms is determined so that the appropriate antibiotic can be chosen should the need arise. Incision and drainage are indicated when pus is present. If severe, lymphangitis or cellulitis can develop. Various clinical presentations exist.

Boil (syn. furuncle) is an infection of a pilosebaceous unit with perifolliculitis, which usually proceeds to suppuration and central necrosis. A ‘blind boil’ is one that subsides without suppuration. Boils are common on the face, head and neck. Boils are frequently associated with overwork, worry, debility or other undermining influences. They may be the presenting symptom of diabetes mellitus.

Furunculosis of the external auditory meatus is extremely painful, as the skin is attached to the underlying cartilage, and swelling is accompanied by considerable tension.

Stye (syn. hordeolum) is due to infection of an eyelash follicle. Should softening occur around a hair follicle, particularly an eyelash, removal of the hair allows the pus to escape.

Carbuncle is an infective gangrene of the subcutaneous tissues, which often occurs in the nape of the neck. The subcutaneous tissues become painful and indurated, and the overlying skin is red (Fig. 13.9). Unless the condition is aborted by prompt treatment, extension will occur and, after a few days, areas of softening appear, the skin sloughs and discharges pus. Usually there is one central large slough, surrounded by a ‘roselle’ of smaller areas of necrosis. The general treatment and organism identification are similar to those described for boils. Many carbuncles are aborted if antibiotics are used adequately in the early stages.

Impetigo is an intradermal infection (Fig. 13.10). The primary lesion is bullous, and soon ruptures to form an erosion and then a crust.

Necrotising fasciitis (syn. Meloney’s steptococcal gangrene, Fournier’s gangrene)

Necrotising fasciitis is a destructive invasive infection of skin, subcutaneous tissue and deep fascia, with relative sparing of muscle. Bacteriology can be polymicrobial involving a synergistic combination of anaerobes and facultative species such as coliforms or nongroup A streptococci; or monomicrobial due to group A beta-haemolytic streptococci. Common sites are the genitalia, groins and lower abdomen (Fig. 13.11a), although necrotising fasciitis has been reported at almost any site. Patients are unwell, febrile, with areas of subcutaneous induration and erythema; surgical emphysema is palpable if gas-forming organisms are involved; necrotic patches of skin develop. Treatment is by wide surgical excision of all affected soft tissues; very large defects can be created (Fig. 13.11b). Antibiotics and supportive therapy are also administered. Mortality is high and is increased if surgical treatment is delayed or insufficiently radical. Necrotising fasciitis can arise without any history of injury, but can also follow operations or more localised infections. Risk factors for the development of this condition include diabetes mellitus, malnutrition, obesity, corticosteroid drugs and immune deficiency.

Hydradenitis suppurativa

Hydradenitis suppurativa (apocrinitis) is a chronic cicatrizing supplicative process caused by apocrine gland hyperplasia (Fig. 13.12). It is common in the second and third decades of life and three times more common in women than men. It occurs most commonly in the axilla, but can also affect the groins and perineum. Locally, duct obstruction from keratin plugging occurs leading to rupture of apocrine glands into the dermis and subdermal tissues with subsequent superimposed infection. Pain can be severe. A course of metronidazole has been found to be useful owing to the fact that Bacteroides is a common causative organism; a prolonged course of erythromycin can be curative. If the condition does not respond, then surgical excision is necessary. If a wide area of skin needs to be removed, the wound needs to be covered by a split-skin graft.

Lupus vulgaris

Lupus vulgaris (tuberculosis of the skin) usually occurs between the ages of 10 and 25, the face being the site of election. One or more cutaneous nodules appear, with congestion of the surrounding skin (Fig. 13.13). When blood is expressed with a glass slide, the brownish (apple-jelly) nodules of individual tubercles can be seen. Extension occurs very slowly, but ulceration is likely to follow sooner or later. The resulting ulcer tends to heal in one situation as it extends to another. The mucous membranes of the mouth and nose are sometimes attacked, either primarily or by extension from the face. Oedema occurs if the fibrosis caused by the lupus obstructs the normal lymphatic drainage. Infection in the nasal cavity may be followed by necrosis of underlying cartilage. Treatment is with anti-tuberculous chemotherapy; the lesion should be excised if healing is slow. Squamous cell carcinoma is prone to occur in a lupus scar (Fig. 13.14).
Cysts

Epidermoid cyst (syn. sebaceous cyst, wen)

These cysts contain keratin and its breakdown products, surrounded by a wall of stratified squamous keratinising epithelium (the commonly used term sebaceous cyst is incorrect — these cysts only rarely have associated sebaceous glands and do not contain sebum). Epidermoid cysts often have a punctum. They are inherited in an autosomal dominant fashion. The common sites are the face, neck, shoulders and chest, areas favoured by acne vulgaris. Lesions may be solitary but are commonly multiple. They enlarge slowly and may become inflamed and tender from time to time. Suppuration may occur. The contents of an infected cyst become semiliquid and usually very foetid. Recurrent infective episodes cause the cyst wall to become adherent to surrounding subcutaneous tissue, and consequently more difficult to remove. If ulceration occurs it can resemble squamous cell carcinoma to which the term ‘Cock’s peculiar tumour’ may be applied (Fig. 13.15). The contents of a cyst sometimes escape slowly from the duct orifice and dry in successive layers on the skin, forming a ‘sebaceous horn’ (Fig. 13.16). Treatment is by surgical excision (except if inflamed, when it is better incised and drained). This can be performed under local anaesthesia; an ellipse of skin including the punctum is removed with the cyst. Unless the wall is completely removed, recurrence is likely.

Pilar cysts

Pilar cysts are usually multiple and occur on the scalp, and they have no punctum. Histologically, their lining is similar to the external root sheath of the hair follicle.

Implantation dermoids

Implantation dermoids may result from deep implantation of a fragment of epidermis by a penetrating injury. Traumatic inclusion cysts usually appear on the palmar or plantar surfaces of the hands, or on the buttocks or knees.

Callosities, corns and warts

Callosity (French: ‘callosite’) is a localised thickened or hardened part of skin which is an acquired, superficial, circumscribed, yellow—white, flat, thickened patch of hyperkeratotic material. They occur at the regions of pressure or friction on the hands and feet and they are usually not painful. They are commonly occupational, occurring, for instance, on a gardener’s hands. There is no need for treatment, although paring may be necessary and should be carried out by a fully trained chiropodist.

Corn (Old French: com = grain) is a horn-like induration of the cuticle with a hard centre, caused by undue pressure, chiefly affecting toes and feet. They are circumscribed, horny thickenings, cone-like in shape with their apex pointing inwards and their base on the surface. They occur at sites of frictional pressure and usually will spontaneously disappear when the aetiological factor is removed. Skilled treatment is important in patients with diabetes or with a poor peripheral circulation when a secondary infection may precipitate gangrene.

Wart (Old English: wearte) is a dry, rough excrescence on the skin (Fig. 13.17). It is a virus-induced tumour that undergoes spontaneous resolution. Transmission is by direct or intimate contact, the virus material usually being inoculated through an abrasion. It is well recognised that patients with immune deficiencies develop widespread resistant warts. They tend to occur on sites of trauma, such as the beard area, hands, genital region and feet. All warts first appear as small, smooth nodules often more easily palpable than seen. Warts are more common in children and young adults, but can be present at any age, causing pain and even difficulty in mobility. Plantar warts occur on the sole and are usually multiple. They may be so tender as to render standing or walking exceedingly uncomfortable. Treatment ranges from folk remedies to sophisticated modern techniques, but the important factor remains that there is no 100 per cent cure. Surgical removal is contraindicated as it leads to scarring and recurrences are frequent. Curettage and diathermy give excellent results, as does cryotherapy, but the latter is often accompanied by pain. The irritant 50 per cent podophyllin in liquid paraffin gives good results. Use of liquid nitrogen is probably easier and is more effective. Recalcitrant lesions may respond to 585-nm pulsed dye laser irradiation.

Venereal warts and moist warts (papillomata acuminata) occur in the genital region.

Herpes simplex is a viral skin infection that is recurrent in about 1 per cent of the population. An immunosuppressed patient may show dissemination with viraemia and may become seriously ill, requiring treatment with acyclovir infusions. Topical or oral acyclovir is available for the treatment of localised disease.

Orf is caused by the virus that produces pustular dermatitis in sheep. Those infected will have been in contact with sheep in one form or another. The lesions are usually single but may be multiple. The initial lesion is a dusky red papule that enlarges to 1—2 cm in diameter and then resembles a large domed pustule. This is a self-limiting condition that resolves in 5—8 weeks.
Benign growths

Congenital naevi

Congenital (verruous, epidermal) naevi(6) are common entities which may be single or multiple, and appear at birth or in early childhood. They are warty growths of brownish colour, but large horny excrescences may be present.

Keratin horn (Fig. 13.18)

This is also seen in old people and is a papilloma with excess keratin formation.

6 Naevus (Latin) = a birthmark but often used to mean simply a mark or blemish on the skin.

Seborrhoeic keratosis (basal cell papilloma, seborrhoeic wart or senile wart)

This is a benign tumour caused by overgrowth of epidermal keratinocytes. They are frequently pigmented and often develop in large numbers on the trunk, face and arms of persons in or past middle life and are most common in the elderly. Seborrhoeic keratoses are very common in Caucasians and often are not mentioned by the patient, being accepted as harmless and part of the inevitable ageing process. Both sexes are equally affected. Usually they look like a verrucous plaque stuck on the epidermis, varying from dirty yellow to black and have loosely adherent, greasy keratin on the surface. They are usually ovoid, measuring from 1 mm to several centimetres. An eruption of seborrhoeic warts may be preceded by an inflammatory dermatosis. The superficial type has to be distinguished from simple and malignant lentigo. The domed pigmented variety may resemble a melanoma, especially if it is inflamed. However, with local antibacterial treatment and protection from injury, it returns to its normal state after a few days. If the lesions are asymptomatic removal is not required. Where treatment is indicated shave excision or curettage and diathermy leaves a flat surface that covers with normal epithelium in 1 week. Cryosurgery is also successful.

Dermatofibroma (sclerosing angioma, histiocytoma, fibroma simplex, subepidermal nodular fibrosis)

This occurs in skin as firm, indolent, single or multiple nodules. Some follow minor trauma or insect bites, which may have acted as a trigger to this tissue reaction. It may possibly be a tumour of the dermal dendrocyte. In adults, the nodules are situated most commonly on the extremities, occurring in both sexes of all age groups after puberty (Fig. 13.19). They usually present as a small, well-defined nodule that may or may not be elevated above the surface of the skin. It is hard, button-like and freely mobile over the underlying tissues that touch the epidermis. They often itch, vary in size and are frequently pigmented. Excision is only recommended for symptomatic nodules.

Molluscum fibrosum

Molluscum fibrosum are polypoid or filiform soft fleshy skin tags that occur on the neck, trunk and face. They are frequently found together with seborrhoeic warts. They are always pedunculated and frequently constricted at their base. They are round, soft, elastic and frequently pigmented. Treatment is by excision or cautery.

Pilomatrixoma

Pilomatrixoma (calcifying epithelioma of Malherbe) is a benign hair-follicle-derived tumour. These are solitary, hard tumouts that appear to be growing from the deep surface of the skin. They occur mostly on the face (Fig. 13.20), neck and arms. The size usually varies between 0.5 and 3 cm in diameter. The tumour may arise at any age but 60—80 per cent occur in the first two decades. Clinically, it resembles a rather hard epidermoid cyst.

Sebaceous adenoma

Isolated lesions are very rare. Multiple sebaceous adenomas occur in association with epilepsy in the condition tuberose sclerosis.

Cylindroma

Cylindroma (syn. 'turban' tumour) is so called from the arrangement of the stroma in peculiar transparent cylinders, which are thought to be of apocrine origin. The tumour gradually forms an extensive, turban-like swelling extending over the scalp (Fig. 13.21). Ulceration is uncommon and the tumour is relatively benign. Cryotherapy may control the progression of this condition.

Rhinophyma (syn. potato nose) (Fig. 13.22)

This is a glandular form of acne rosacea. The skin of the nose, particularly the distal part, becomes immensely thickened and the openings of the sebaceous follicles are easily seen. The capillaries become dilated and the nose assumes a bluish-red colour. Surgical treatment, by paring away the excess tissue, gives a great improvement. Rarely, basal cell carcinomas are associated with this lesion.

Sarcoid (Boecks)

This is a generalised disease that may affect skin. In the skin it occurs as reddish-brown nodules which are soft and rarely ulcerate. Giant cells are found, but tubercule bacilli can never be isolated.

Cutaneous horns (Bland-Sutton)

These may be sebaceous horns (Fig. 13.16), wart or corn horns (Fig. 13.23), cicatrix horns (Fig. 13.24) or nail horns.
Vascular anomalies

Many different and confusing terms have been used to describe vascular lesions. Mulliken and Glowacki’s classification based on endothelial characteristics, helps in diagnosis, planning, management and predicting the course of these lesions. This classification has three major categories:

• haemangiomas: show endothelial hyperplasia;
• malformations: have normal endothelial turnover;
• ectasias: have normal endothelial turnover, but also have vascular dilatation.

Haemangioma (Fig. 13.25)

These are the most common tumours of infancy and have a typical history. The baby is normal at birth and at the age of 1—3 weeks is noted to have a red mark. This increases rapidly for some weeks or even up to 3 months, until the typical 'strawberry' or raspberry-like swelling is present. Clinically, the sign of emptying may be demonstrable. The lesion is composed of immature vasoformative tissue. The subcutaneous tissue as well as the skin is often involved, and in severe cases the muscles may be affected. From the age of 3 months to 1 year the haemangioma grows with the child, and then it ceases to grow. Eventually the colour fades and flattening occurs so that at the age of 9 years 90 per cent demonstrate complete involution. Bleeding is rarely a problem and responds to local pressure. Ulceration occurs in about 5 per cent of the cases, particularly in those areas that are commonly abraded, e.g. lips and perineum. Wound care will prevent infection and promote re-epithelialisation. Pulsed dye laser therapy has also been used to promote the involution of the superficial vessels. Visual obstruction from periorbital haemangiomas (Fig. 13.26) can result in amblyopia or anisometropia if total visual obstruction occurs for more than a week in the first year. Nasopharyngeal obstruction may cause obstruction in infants who are obligate nose breathers. Auditory canal obstruction is seen occa-sionally with lesions affecting the parotid gland. Intervention should be considered in bilateral conditions which last beyond 1 year of age.

Kasabach—Merritt syndrome occurs owing to platelet trap-ping within the lesions. Congestive cardiac failure with multiple cutaneous haemangiomas or large visceral haemangiomas results from dilated vessels and arteriovenous shunting. Skeletal distortion and cosmetic deformities in the form of telangectasias, hypopigmentation and contour abnormalities have been observed. The final result (Fig. 13.27) is better if natural involution is allowed to occur rather than if an attempt is made to hasten regression by any operative or physical methods. Many interventions are possible and should be considered only in special circumstances. Intra-lesional or oral steroids have been demonstrated to produce involution of these lesions. Surgical debulking and laser photocoagulations — both superficially and intraleisionally — have also been used. Radiation therapy carries a high risk of disturbance of growth and is dangerous.

Vascular malformations

These are structural and morphological anomalies due to faulty embryological morphogenesis. The lesions are present at birth, grow commensurate with the child and do not regress. They can lead to underlying soft tissue or bony hypertrophy, nodular development and discoloration as a consequence of blood vessel ectasia with age. The natural history of these lesions is determined by their haemodynamic and lymphodynamic characteristics.

• High-flow lesions include arterial malformations and arteriovenous malformations (arterial plexiform angioma, cirsoid aneurysm).
• Low-flow lesions include lymphatic (LM) venous (VM) and capillary (CM — port-wine stain). Frequently these lesions combine arterial, venous and lymphatic elements.

Port-wine stains

Port-wine stains (Fig. 13.28) are intradermal capillary mal-formations that change very little throughout life, although the colour may alter a little and they may become nodular in some areas. Treatment is for reason of appearance. Treatment of choice for these lesions is the use of the pulsed tunable dye laser.

Glomus tumours

Glomus tumours, frequently in the subungal regions, repre-sent arteriovenous anastomoses (Suquet—Hoyer canals). They are frequently removed because of the pain and to obtain a diagnosis.

Ectasias

These represent acquired lesions such as telangiectasias (spider naevus). Lesions on the lower extremities are venular (thread veins); however, facial telangiectasia is mostly due to arteriolar vasodilatation. Lower extremity lesions respond to either microsclerotherapy or laser photoablaition. Those on the face can be treated by photoablation using a pulsed dye laser.

Miscellaneous vascular lesions

Pyogenic granuloma

Pyogenic granulomas (Fig. 13.29) are common acquired, reactive, proliferative vascular lesions of the skin and mucous membranes, arising after minor trauma. The lesion looks like a haemangioma, but has a typical natural history. Usually single, it consists of a red, soft or moderately firm, more or less pedunculated nodule that grows rapidly to a size varying from 0.5 to 2.0 cm in diameter. Most commonly it is seen on the face, the fingers and toes. Treatment is excision.

Macular stains

Macular stains (salmon patch, also called ‘stork bites’; not to be confused with the ‘patch’ in syphilis) are present at birth over the forehead in the midline, and over the occipit. They disappear by the age of 1 year and so may represent a physiological process rather than a pathological lesion.
Benign pigmented lesions

Simple melanocytic tumours

The melanocyte is generally believed to be derived from the neural crest. In normal skin, melanocytes appear as clear cells in the basal layer of the epidermis. They may become increased in number in the layers of the skin to form benign pigmented naevi (moles) which include:

- lentigo, which are present within the basal layer of the epidermis;
- junctional naevi, which occur as localised aggregations projecting into the dermis;
- dermal naevi, which occur entirely within the dermis;
- compound naevi, which show the features of both the junctional and dermal naevi.

These simple melanocytic tumours may arise anywhere in the skin including the nail bed. They are seen occasionally in the conjunctiva of the eye, but are rare in other mucous membranes. Pigmented naevi may occur at any age but commonly appear in childhood and adolescence as small, brown, flat or slightly raised lesions in the skin. These are usually of junctional or compound type, but with increasing age they either atrophy or mature into dermal naevi. One or more melanocytic naevi are present in over 95 per cent of white adults. Naevi on the palms, soles and genitalia have an evil reputation as they were thought at one time to be especially prone to become malignant but, in fact, site is not a risk factor.

The blue naevus (Fig. 13.30) is a tumour of dermal melanocytes and occurs most commonly on the face, on the dorsum of the hands and feet, and over the sacrum in certain races (Mongolian blue spot). It is very darkly pigmented and because of its overlying layer of normal, although sometimes thinned, epidermis, looks shiny and blue or slate-grey in colour. Malignant change is exceptionally rare. Congenital naevi are rare. They are often darkly pigmented and may be hairy and papillary in appearance (Fig. 13.31). Occasionally, they cover extensive areas of skin, up to 25 per cent or more of the body surface. They may undergo malignant change even during childhood. With this exception, naevi are virtually always benign before puberty. Treatment may be indicated for cosmetic reasons, if by reason of its position the lesion is subject to the nuisance of repeated trauma, e.g. cut when shaving or rubbed by clothing. Although there is no evidence that trauma causes malignant change, if the history suggests that malignant change has occurred (see below under Malignant melanoma), surgical excision is the only acceptable treatment; all lesions must be sent for histological examination.

Cafe-au-lait macules are light-brown flat macules that are often apparent at birth. They are present as solitary lesions, or in increased numbers in syndromes such as neurofibromatosis and Albright’s syndrome.
Premalignant lesions

Actinic keratoses

Actinic keratoses (senile keratoses, solar keratoses) are areas of epidermal dysplasia giving rise to cutaneous scaling, usually observed in sun-exposed fair skin. These lesions are potentially malignant. Superficial lesions are best removed by rapid and even freezing with carbon dioxide or liquid nitro-gen on a cotton wool bud. Diathermy preceded by curettage of horny lesions is equally effective, but more likely to leave superficial scarring. Indurated lesions are best excised. Multiple lesions may clear with topical 5-fluorouracil cream. An effective sunscreen is important as improvement follows avoidance of sunlight, which is also important prophylactically. Radiotherapy should not be used for solar keratoses.

Bowen’s disease

Bowen’s disease is an intraepidermal squamous cell carcinoma that is potentially malignant and appears as a persistent, progressive, usually flat, red, scaly or crusted plaque (Fig. 13.32). It is more frequently seen in the elderly. It is triggered mainly by solar radiation, but if those keratoses with Bowen’s features are separated off, the cause most frequently found is arsenic ingestion. Most patients are unaware of having been exposed to arsenic as its presence in a mixture taken medically may have been concealed from them or forgotten. The rate of transformation of Bowen’s disease to invasive squamous cell carcinoma is still disputed. Untreated, 3—5 per cent of patients will develop an invasive squamous cell carcinoma. The possibility of a viral cause of Bowen’s disease has been postulated. The lesions most likely to be mistaken for Bowen’s disease are solar keratoses, psoriasis, multifocal (superficial) basal cell carcinoma and squamous cell carcinoma. If the diagnosis is uncertain on the first examination, the lack of improvement when steroids are applied is suggestive of Bowen’s disease. Distinction from the flat type of solar keratosis may be impossible clinically. A biopsy may be necessary to establish a diagnosis. Locally destructive therapy such as cryotherapy or curettage and cauterisation is often used. Recurrence may be due to inadequate treatment of the superficial tumour or failure to destroy deeper extensions down appendage structures such as hair follicles. Radiotherapy, if used, has to be in full tumour doses. Chemotherapy with local cytotoxic agents such as 5-fluorouracil can be applied to small lesions with good effect. Surgical excision is the best treatment if the lesion is not too large.

Erythroplasia of Querat

Erythroplasia of Querat describes Bowen’s of the glans penis. It occurs most commonly in uncircumcised males.

Radiodermatitis

This is an area of skin damaged by excessive exposure to X-irradiation. Early erythema occurs which goes on to desquamation and pigmentation. If the dose is very great ulceration may occur. Later atrophy, irregular hyperpigmentation, telangiectasia and hair loss occur. Eventually, squamous cell carcinoma may develop.

Chronic scars

A carcinoma which develops in a scar (Marjolin’s ulcer) (Fig. 13.33) presents the following characteristics. It grows slowly, as the scar is relatively avascular. It is painless, as scar tissue contains no nerves. Secondary deposits do not occur in the regional lymph nodes as lymphatic vessels have been destroyed. If the ulcer invades normal tissue surrounding the scar, it extends at a normal rate, and lymph nodes are then liable to be involved.

Sebaceous epidermal naevus

Sebaceous epidermal naevus (of Jadassohn, organoid naevus) (Fig. 13.34) is a common condition, frequently affecting the scalp. It initially appears as a raised papular yellow area, developing into a papillomatous area as the child matures. Up to 10 per cent of these may develop into basal cell carcinomas. Very rarely these develop into syringo-cystadenoma papilliferum — an anomaly of the apocrine gland. Treatment consists of complete excision.

Porokeratosis

Porokeratosis (of Mibelli) is characterised by annular plaques with horny borders. About 13 per cent may transform into basal cell or squamous cell carcinomas.
Malignant lesions

Basal cell carcinoma

Basal cell carcinoma (BCC, rodent ulcer) is the commonest form of skin cancer and typically affects individuals between the ages of 40 and 79 years; more than 50 per cent are male and more than 85 per cent of these lesions occur in the head and neck region. These tumours are thought to originate from pluripotential epithelial cells of the epidermis and hair follicles. BCCs grow slowly, but become locally invasive and penetrate deeper tissues — hence the term rodent ulcer (Fig. 13.35 and Fig. 13.36). Metastasis is rare. The patient gives a history of a ‘spot’ that fails to heal. Typically these tumours have a nodular appearance with a pearly rolled edge (which is apparent on stretching the skin) and telangiectatic vessels. Histologically, 26 different varieties of BCC have been described. However, clinically the following are recognised, in order of frequency:

- nodular: 50—54 per cent;
- superficial: 9—11 per cent;
- cystic: 4—8 per cent;
- pigmented: 6 per cent;
- morpheic: 2 per cent.

Several treatments are possible, as follows.

- Surgical excision — the treatment of choice with cure rates between 85 and 95 per cent.
- Electrodessication and curettage commonly used for small superficial lesions (2—5 mm in diameter) gives cure rates between 85 and 100 per cent.
- Radiotherapy. BCC is very radiosensitive and has an overall response of 92 per cent in selected patients. This is reserved for elderly patients who are not suitable for surgery or for specialised anatomical sites.
- Mob’s micrographic surgery (chemosurgery) involving serial horizontal excision and mapping of the tumour. Usually reserved for recurrent lesions, tumours in difficult areas or those with indistinct borders (morpheiform).

Following complete excision it is unnecessary routinely to followup these patients unless they have a familial disposition for BCC formation (Gorlin’s syndrome).

Squamous cell carcinoma

Squamous cell carcinoma (SCC) is a malignant tumour that arises in an area that has had some premalignant change. These tumours appear more inflammatory, feel more indurated and ulcerate sooner compared with BCC. The malphigian or squamous cell layer of the skin is implicated in the development of this cancer. There is a strong correlation with damage to the skin by the sun (Fig. 13.37a and b), and can be experimentally produced by ultraviolet light. Occasionally it arises as a complication of long-standing chronic granulomas, such as syphilis, lupus vulgaris and leprosy. Chronic ulcers, osteomyelitis, Hydradenitis suppurativa, long-standing venous ulcers or old burn scars. Histologically, these tumours are characterised by invasive nests of cells showing variable central keratinisation and horn cell formation. There is no peripheral palisading as occurs in BCC. The cells vary from large, well-differentiated cells to completely anaplastic cells. Lesions of the ear and lip metastasise much earlier even when they are relatively well differentiated. Regional nodes may become enlarged, either as a result of infection of the ulcer or from metastases. Treatment should primarily involve complete eradication of the tumour by the following methods.

- Surgical excision is the most appropriate treatment for SCC of the skin, with the surgical margin being dependent on the tumour diameter and on the site of the lesion.
- Radiotherapy should be used for massive unresectable tumours in critical anatomical sites. Postoperatively it may be used for persisting tumour or where clearance is doubtful.

Verrucous carcinoma

Verrucous carcinoma are well-differentiated SCC which invade locally but rarely metastasise. These commonly occur on the palm and soles; here they are known as carcinoma cirinculum

Keratoacanthoma

Keratoacanthoma (molluscum sebaceum) (Fig. 13.38) arises as a rapid proliferation of squamous epidermal cells. The nodule grows rapidly for 6—8 weeks at which time it usually begins to resolve spontaneously. Keratoacanthoma must be distinguished from BCC. Usually rapid evolution to relatively large size, irregular crater shape and keratotic plug, and the undamaged surrounding skin make a distinction possible. Spontaneous healing further confirms the diagnosis. Histologically, it is difficult to differentiate between a keratoacanthoma and SCC. There is also a possibility of a highly anaplastic SCC behaving like a keratoacanthoma. Excision biopsy is mandatory if the diagnosis is in doubt as curetted specimens yield poor sections.

Melanoma

Cutaneous melanoma is a malignant neoplasm arising from epithelial melanocytes. The earliest description is in the writings of Hippocrates in the fifth century BC. John Hunter described a ‘cancerous fungous excrescence’ in 1787, which has subsequently been diagnosed as a melanoma. It has been considered a rare tumour with unpredictable behaviour. It varies from spontaneous regression to rapid progression and death. However, the disease is no longer rare. The rate of increase in the incidence of melanoma is greater than for any other cancer in Caucasians with the exception of bronchogenic carcinoma. Its incidence has doubled every 10 years in countries close to the equator and every 10—15 years in more temperate zones. Incidence has quadrupled in Australasia and doubled in Norway, Britain, America and Canada in the last 30 years. This increase in incidence is not observed in other skin cancers. The incidence is 40 per 100 000 in Queens land, Australia, but only 4 per 100 000 in Scotland. It accounts for almost all the deaths from skin cancer.

It is likely that between a third and a half of all melanomas develop in a benign naevus of many years’ standing. Melanoma does not exhibit
any overall sex predilection. The commonest site for females is the lower leg and in males the front or back of the trunk. In the Bantu, the sole of the foot is the most frequent site; they can also occur on the palms and other depigmented areas, but do not arise in the black skin of the remainder of the body for a reason that is not understood. Rarely, melanoma arises in the eye, in the meninges or at the mucocutaneous junction zones, e.g. anus and mouth. There is now strong evidence that the increase in exposure to sunlight is mainly responsible for the rapid increase in this skin cancer. It is well known that solar irradiation, which is now much more dangerous as a result of the decreasing ozone layer, is associated with all skin cancers. Ethnic origin, climate, socioeconomic status and lifestyle are all risk factors interacting with sun exposure. The other evidence with reference to sun exposure is that patients with pathological conditions, such as albinism and xeroderma pigmentosa, are susceptible to forming melanomas. A proportion will arise in a Hutchinson’s freckle (see below). Clark et al in 1975 produced a concept of a ‘radial growth phase’ to describe the atypical proliferation of intraepidermal melanocytes which precedes the development of dermal invasion (vertical growth phase) in all except nodular melanoma.

**Four parameters of histological grading are used, as follows.**

1. The most important parameter is the depth of invasion as measured by the thickness (Fig. 13.39). The thickness is measured by an optical micrometer from the top of the granular layer of the epidermis to the deepest melanoma cells in the dermis (Breslow, 1975). There is good evidence that tumour thickness is a better measure of prognosis than level of invasion, and also more reproducible by different observers. Lesions less than 0.76 mm in thickness have a very favourable prognosis.

2. Ulceration, and

3. a high mitotic rate carry a poor prognosis.

4. Regression, if present, for some thin melanomas may have an appreciable risk of metastases, presumably because the lesion at some point in the past had been of a sufficient thickness to have metastasised.

**Clinical features**

Clinically, five types are recognised:

- lentigo maligna;
- superficial spreading;
- nodular;
- acral-lentiginous;
- amelanotic.

Superficial spreading melanomas are the most common (64 per cent). They occur on any part of the body and are usually greater than 0.5 mm in diameter. A variegated coloured pattern and an irregular edge are characteristic. The lesion is usually palpable.

Nodular melanoma. This is the most malignant, occurring in about 12—25 per cent of cases and found in the younger age groups. It may occur on any part of the body, and is always palpable and usually convex in shape. The colour is commonly uniform and is usually blue, grey or black. It sharply delineates from the surrounding tissue, and has a smooth surface and an irregular outline. Ulceration may occur earlier, leading to weeping or bleeding.

Lentigo maligna melanoma (Hutchinson’s melanotic freckle) is the least common (7—15 per cent) and least malignant. It occurs most frequently on the face in people aged over 60 years. It may occur on any part of the body habitually exposed to the sun. It begins as an irregularly pigmented, flat, brown macule which grows very slowly over a period of 1—15 years, advancing and regressing in various areas. There is a great variation in colour from brown to tanned black within the tumour itself. Malignant change is recognised by thickening and the development of discrete tumour nodules. They may ultimately grow to 5 cm and a very irregular outline is also characteristic (Fig. 13.40a and b).

Acral-lentiginous melanomas. These occur on the palms and soles and also include subungual melanomas (Fig. 13.41). They are the most common type of melanoma found in Japan. They carry a poor prognosis similar to nodular melanoma.

Amelanotic. In this form, the lesion may be pink but usually close inspection will reveal some pigmentation at the base (Fig. 13.42). Amelanotic melanoma seem to carry an even worse prognosis than nodular pigmented melanoma. They may often present with regional lymph node metastases.

**Clinical recognition**

Malignant melanoma is almost unknown before puberty. The development of a malignancy in a mole should be suspected if any of the following changes occur:

<table>
<thead>
<tr>
<th>Major signs</th>
<th>Minor signs</th>
</tr>
</thead>
<tbody>
<tr>
<td>Change in size</td>
<td>Inflammation</td>
</tr>
<tr>
<td>Change in shape</td>
<td>Crusting or bleeding</td>
</tr>
<tr>
<td>Change in colour</td>
<td>Sensory change, e.g. itch</td>
</tr>
<tr>
<td>Diameter 5 mm or more</td>
<td></td>
</tr>
</tbody>
</table>

Suspicious lesions should be removed completely with a 2 mm margin; use of incision or punch biopsies is deprecated since accurate histological staging is impossible, and the treatment is dependent on the histology.

**Spread**

Malignant melanoma may spread by local extension, by the lymphatics or by the bloodstream. Tumour cells may reach the regional lymph nodes by embolism but spread by lymphatic permeation is also seen, producing local satellite (Fig. 13.43a) and/or in-transit deposits between the primary growth and the regional nodes (Fig. 13.43b) resulting in secondary lymphoedema. Blood-borne metastases are seen in the lungs, liver, brain, skin and rarely in the bones. They may also involve unusual sites, e.g. the small intestine, heart and breasts. Secondary deposits
are typically black, but sometimes contain little or no melanin, even when the primary tumour is heavily pigmented. Extensive visceral involvement may cause melanuria.

**Staging**

Using the American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC) staging system is recommended (Table 13.1).

**Treatment**

This is primarily surgical.

- There should be complete surgical excision.
- Minimum margin of 1.0 cm and a maximum of 2.0 cm should be made. This represents the clinical margins at surgery and not histopathological margins.
- Wide excision was advocated first by Handley in 1907 based on his pathological studies of the frequency of centrifugal dermal lymphatic permeation into the surrounding skin. Surgeons recommended a 5-cm margin of excision around primary malignant melanomas; this is no longer advocated.
- Do not excise beyond the deep fascia.
- Margins may have to be altered for cosmetic or functional reasons, e.g. periorbital region.

Survival from primary melanoma management falls with increasing tumour thickness (Table 13.2).

**Treatment of lymph nodes**

Lymph node biopsy. Fine-needle aspiration cytology (FNAC) is preferable to excision biopsy. Open biopsy may increase risk of tumour spillage, but if needed the incision should be placed so that it can be excised in continuity with the lymph node field.

Elective node dissection. This is not recommended for the large majority of patients. A report of satellitosis or lymphatic invasion should warrant consideration of node dissection. Clinically involved nodes require therapeutic node dissection.

Therapeutic dissection for clinically positive nodes requires radical clearance by those with expertise in the surgery of this condition. Limited dissection or ‘node picking’ is not acceptable. Adequate clearance gives a good prognosis with a 10-year survival of 50 per cent when one node is involved. However, with more nodes involved or extranodal spread the survival rates decrease and radiotherapy may be considered. Groin dissections may be complicated by the development of lymphoedema.

Lymphatic mapping and sentinel node biopsy is a technique initially described by Cabannas in 1974 for penile carcinoma and popularised by Morton in 1994 for melanoma. This may provide an approach to identify those patients who may be appropriate for elective lymph node dissection by detecting the presence of micrometastases in the sentinel node. This technique identifies the first echelon nodes (‘sentinel node’) using lymphoscintigraphy following an intradermal injection of radioactive colloid around the primary site. The position of these nodes is marked on the skin and identified intraoperatively by injecting patent blue dye around the site of the primary and using a hand-held gamma probe to help to identify the position of these nodes. This accurately indicates the presence or absence of micrometastases in a nodal field.

**Loco-regional recurrent melanoma**

Loco-regional recurrent melanoma involving skin and soft tissues when isolated should be treated surgically. Patients with multiple local or in-transit recurrences should be considered for specialist treatment with isolation perfusion with high-dose cytotoxic agents (Fig. 13.44). Carbon dioxide laser ablation may be used for multiple small cutaneous lesions; or surgical resection for isolated pulmonary, cerebral, intestinal and intraperitoneal recurrences. In some patients it is advisable not to resect subsequent cutaneous metastases as they can be used as an indicator of response to systemic therapies or monitoring that of new local treatments.

**Melanoma in childhood**

Melanoma in childhood is rare; however, the clinical behaviour is similar to that in adults. The differential diagnosis is of the pigmented Spitz naevus (juvenile melanoma) which has previously been confused as a melanoma. This is a variant of the compound naevus in childhood. In cases of malignant melanoma in childhood the treatment is exactly the same as that for melanoma in adults.
Other malignancies

**Dermatofibrosarcoma protuberans (Fig. 13.45)**

This is a locally malignant tumour arising in the dermis and composed of more or less mature fibroblasts. It is usually situated on the trunk, particularly in the flexural regions, and in its early stages can look very similar to a histiocytoma. Treatment is by wide excision with a margin of 3 cm. Local recurrence invariably follows inadequate surgery.

**Kaposi’s sarcoma**

This is a neoplasm of multifocal origin derived from proliferating capillary vessels and perivascular connective tissue cells. In Europeans, it is a disease of late adult life, running an indolent course affecting the legs of elderly men. Amongst the immunocompromised population it appears much earlier. There is an endemic form in various parts of Africa. The tumour also occurs in association with acquired immuno deficiency syndrome (AIDS). The AIDS-related form runs a rapid course with painful lesions at multiple sites and metastatic spread. The lesions have a dark blue or purplish colour. At first they are macular, and when they become tumid, pressure may produce blanching to reveal a brown tinge. The process usually begins on the extremities, most commonly on the feet, but occasionally on the hands, ears or nose. Treatment is by radiotherapy.

**Angiosarcoma**

This is a rare tumour largely seen in elderly males. The lesions occur most commonly on the scalp or face and may present either as a subcutaneous plaque in the skin, as a nodule, particularly on the scalp, or as a single or multiple bluish-purple discoloration of the skin. Metastatic disease is largely to the cervical lymph nodes and lungs.

**Lymphangiosarcoma**

This is a long-standing complication of lymphoedema and it occurs on the brawny oedematous arm of the postradical mastectomy patient or in a lower limb following groin dissection. Conservative breast surgery and the use of special elastic compression stockings have made this condition much less common. It is usually fatal.

**Primary cutaneous malignant lymphoma**

This is rare and can be divided broadly into three types:

- mycosis fungoides and Sezary syndrome (a rare and fatal reticulosis with unusual giant cells in the blood and skin);
- primary cutaneous non-Hodgkin’s lymphoma;
- primary cutaneous Hodgkin’s lymphoma.

Mycosis fungoides is a term given to a condition characterised by initial infiltration of the skin by malignant lymphocytes with subsequent involvement of lymph nodes, spleen, liver, bone marrow and other organs. Patients usually present between the ages of 40 and 60 years with a long-standing history of dermatitis, exfoliative erythroderma or a papular rash, which in time progresses to plaque and then tumour formation. The diagnosis of lymphoma of the skin should be made by a biopsy and treatment is by radiotherapy and/or chemotherapy.

**Merkel cell tumour**

Merkel cell tumour (trabecular cell carcinoma, primary neuroendocrine carcinoma) arises from Merkel cells as an enlarging blue—red nodule (Fig. 13.46). Local metastases occur in 75 per cent and distant spread in 25 per cent of cases. Treatment is by surgical excision of the primary with a 2—5-cm margin followed by radiotherapy to the site of the primary and the regional nodal basin.

**Metastatic malignant tumours**

These are tumours formed by malignant cells originating from another site, and frequently from another tissue, conveyed to the skin by the blood and lymphatic circulation. The skin is not uncommonly secondarily involved by malignant lymphoma and leukaemia as a manifestation of generalised disease. Most malignant tumours can produce cutaneous metastases, but some seed to the skin more than others. Hypernephroma, an uncommon malignancy, accounts for 9 pen cent of skin metastases. The most frequent primary sites are breast, stomach, lung, uterus, large intestine, kidney, prostate gland, ovary, liver and bone.

Introduction

The arrival of the victim of a burning accident at the emergency department is one of the most dramatic events in surgical practice. The suddenness of the accident, the visibility of the damage, the pain, fear and the reactions of onlookers all combine to create an atmosphere of tension. The immediate needs of the patient for resuscitation and pain relief may temporarily interfere with the usual assessment of the patient by history and examination. However, the history of the mechanism of burning is of major importance in assessing its likely severity. Detailed inquiry must be made as soon as the patient’s condition allows, information being gained from either the patient or a third party. Clinically, the severity of the burn is estimated from the area of the burned surface and the depth of the burn wound.

On arrival a burns case should be treated like any other trauma case. There may be problems with the airway, a broken cervical spine and internal injuries. ABC (airway, breathing, circulation) applies as usual. If there is soot or charring around the mouth and nose, the possibility of smoke or even flame inhalation must be considered. Laryngeal oedema can develop rapidly and lung function can deteriorate. Endotracheal intubation should be considered early, but this should only be attempted by a highly experienced anesthetist. A needle cricothyroidotomy set should be assembled and ready for use. There will only be one chance at Endotracheal intubation and if that fails because of laryngeal oedema a surgical airway will be needed immediately. If laryngeal oedema is possible early intubation is prudent, and mandatory if a transfer to another unit is required. The airway must be secure before transfer.
Assessment of the burn area

An approximate clinical rule in wide use is the ‘rule of nines’ which acts as a rough guide to body surface area (Fig. 14.1). The examining doctor should assess the total area involved and how much of the area is partial thickness and how much full thickness. As a general rule, an adult with more than 20 per cent of the body surface involved or a child with more than 10 per cent of body surface area involved will require intravenous fluid replacement. However, an intravenous access line may be necessary for adequate analgesia for much smaller areas of burn and many children in particular will require fluid replacement because of vomiting. For smaller percentages than the above, it is necessary to maintain an adequate oral intake of fluid. The prognosis depends upon the percentage body surface area burned. A rough guide is that if the age and percentage add together to a score of 100 then the burn is likely to be fatal. A child may therefore survive a large burn, but even a small burn in an elderly patient is potentially fatal.

Intravenous access in a burnt child may be difficult. Both rectal and intraosseous infusion (into the upper third of the tibia) offer useful alternatives.
Assessment of burn depth

Burn depth depends, in thermal injury, upon:

• the temperature of the burning agent;
• the mode of transmission of heat;
• the duration of the contact.

Much of this information can be obtained from taking a good history of the injury. Clinical examination of the burn wound may also show characteristic features.

Skin anatomy

The epidermis is the most superficial layer of the skin and provides the waterproofing layer. It is constantly replaced from the basal layer. The dermis is the thicker underlying area that supplies the strength and integrity of the skin. It has a rich blood supply from the subdermal capillary network. It contains the adnexal structures — hair follicles, sebaceous glands and sweat glands. These adnexal structures contain epithelial cells that can proliferate and heal a partial-thickness wound by epithelialisation.

Superficial burns

These have the ability to heal themselves by epithelialisation alone. Epidermal burns look red, are painful, blisters are not present, and they heal rapidly without sequelae. Superficial dermal burns are blistered and painful; they should heal by epithelialisation within 14 days without scarring, but some-times leave long-term pigmentation changes.

Deep burns

These have lost all adnexal structures and if left can only heal by second intention with scarring. Deep dermal burns may be blistered and have a blotchy red appearance with no capillary return on pressure and absent sensation to pinprick. Full-thickness burns have a white or charred appearance; again sensation is absent. This charred layer consists of denatured, contracted dermis and is called an eschar.

In practice most burns contain areas of differing burn depth. Decision making is easy where burns are obviously superficial or obviously deep, with difficulties arising in the distinction between the deeper superficial burns and deep dermal burns.
Mechanisms of injury

A burn is a tissue injury from thermal (heat or cold) application, or from the absorption of physical energy or chemical contact (Table 14.1). Each has its own distinctive features and management problems.

Scalds

Hot water produces a particularly well-defined type of skin damage (Fig. 14.2). The temperature of boiling water (100°C) or steam is constant and the major determinant of the severity of injury is the duration of contact. In the home, spills from kettles or cooking pots are common injuries of childhood. As with all burning accidents, those least able to protect themselves (the very young, the very old and the very drunk) are particularly vulnerable. Children reaching up to grab the spout of an electric kettle, or a pot handle, can drench themselves in boiling water, and the larger the volume, the more severe the injury in terms of area and depth. Even a cup of tea or coffee can cause considerable scalding. In predicting the outcome, it is worthwhile knowing whether milk has been added, thus lowering the temperature, although this question may seem frivolous to an anxious parent. Common areas involved are the face, neck and upper trunk or limbs. Although spills cool rapidly, limiting the duration of damage, the worst injuries of this type may leave permanent scarring. Immersion in boiling water, or prolonged steam exposure as in some industrial accidents (where superheated steam may have a temperature above 100°C), are particularly dangerous and likely to cause deeper burns. Fat burns

Cooking fat or oil has a much higher temperature (180°C) than boiling water and hot fat cools slowly on the skin surface. Spills therefore cause deep burns (Fig. 14.3).

Flame burns

Flame burns have a varied aetiology: house fires, clothing fires, spills of petrol on the skin, butane gas fires. They often occur in confined spaces and may be associated with inhalation injury (Fig. 14.4). It is important to know whether the clothing ignited and how the flames were extinguished (did clothing burn away?). Generally, deep burns will result. Some garments may protect, but if clothing ignites there is a protracted flame contact with the skin. Flame-retardant clothing may burn under extreme conditions.

Electrical burns

The passage of electric current through the tissues causes heating that results in cellular damage. Heat produced is a function of resistance of the tissue, the duration of contact and the square of the current. Bone is a poor conductor of electrical current, whereas blood vessels, nerves and muscles are good conductors. Bone can therefore become very hot and cause secondary damage to tissues near to the bone. Low voltage (<1000 V) such as from a domestic supply (240 V, 50 Hz) causes significant contact wounds and may induce cardiac arrest, but no deep tissue damage (Fig. 14.5). High-voltage burns (>1000 V) cause damage by two mechanisms:

flash and current transmission. The flash from an arc may cause a cutaneous burn and ignite clothing, but will not result in deep damage. High-voltage current transmission will result in cutaneous entrance and exit wounds and deep damage. Lightning strikes cause very high-voltage, very short-duration discharge. A direct strike has a high mortality. A side strike may cause superficial burns to the skin and deep exit burns to the feet. Internal damage is not common, but respiratory and then cardiac arrest occur. Some 'electrical' injuries are not associated with the passage of current through the tissues, such as bar-fire burns, where a child grasps a heated and unguarded element of an electric fire and the damage is due to heat alone.

Cold injury

Tissue damage from cold can occur from industrial accidents due to spills of liquid nitrogen or similar substances. The injuries cause acute cellular damage with the possibility of either a partial-thickness or full-thickness burn. Severe cooling can freeze tissues and ice formation is particularly likely to cause cellular disruption. Freezing injuries, however, seem to be less damaging to the connective tissue matrix than heat injuries. Frostbite is due to prolonged exposure to cold and there is often an element of ischaemic damage. Vasocostriction reduces the resistance of the tissue to cold exposure as the warming effect of the circulation is reduced. There is therefore combined tissue damage from freezing, together with vasospasm. Such injuries occur after exposure to severe cold such as that encountered in mountain regions or arctic conditions. It is a rare injury in the UK.

Friction burns

The tissue damage in friction burns is due to a combination of heat and abrasion.

There is generally a superficial open wound that may progress to full-thickness skin loss. Friction burns may be associated with degloving injuries where the damage is judged to be deep. Early surgical excision and skin cover is the best means of management.

Ionising radiation

X-irradiation may lead to tissue necrosis. Such injuries are exceedingly rare if industrial and medical safety precautions are working. The tissue necrosis may not develop immediately. These injuries are generally limited in area and surgical excision, and flap reconstruction may be appropriate management. Of greater significance is the long-term cumulative effect of ionising radiation in the induction of skin cancers and other tumours.

Chemical burns

Numerous chemicals in industrial and domestic situations can cause burns. Tissue damage depends on the strength and quantity of the agent and the duration of contact. Some agents penetrate deeply or may have specific toxic effects. Chemicals cause local coagulation of proteins and necrosis, and some also have systemic effects (e.g. liver and kidney damage with tannic, formic and picric acids). The harmful effect will continue until the chemical is diluted or neutralised. The most important initial treatment is dilution with running water. Some specific agents cause particular problems or have specific remedies (Table 14.2).
Effects of burn injury

The effects of the burn upon the patient can be considered as:

• local;
• regional;
• systemic.

Local effects

Tissue damage

Heating of tissue results in direct cell rupture or cell necrosis. At the periphery the cells may be viable, but injured. In addition, collagen is denatured and damage to the peripheral microcirculation occurs. The capillaries are either thrombosed where the damage is severe or in less damaged areas there is increased capillary permeability such that the tissues become oedematous and there is external leakage of serous fluid. The essential difference between a partial-thickness and full-thickness skin loss is the depth of injury, but it is possible that the former may progress to the latter.

Inflammation

There is a marked and immediate inflammatory response. In the areas least damaged by burning, this is manifest simply as erythema. The precise cause of this immediate vasodilation may represent a neurovascular response similar to Lewis’s triple response. Mild areas of erythema resolve within a few hours. More severely damaged tissue may develop a more prolonged inflammatory response. Macrophages produce inflammatory mediators or cytokines (e.g. transforming growth factor-β) and phagocytose necrotic cells. Neutrophils and later lymphocytes provide protection against infection.

Damaged tissue separates by an active cellular process described as desloughing, generally complete by 3 weeks.

Infection

The damaged tissue represents a nidus for infection. Burn wounds will almost inevitably be colonised by microorganisms within 24—48 hours and this may remain as a local wound or regional infection. There may in addition be a bacteraemia or septicemia and metastatic infections may develop at other sites. Bacteraemia is a common cause of fatality in a severe burn and may occur at any time from the first day until the point when all the wounds have entirely healed. Beta-haemolytic streptococci and pseudomonas produce protease enzymes that prevent skin graft adhesion.

Regional problems in burns

Circulation

Limb circulation may be compromised. Direct damage to a main limb vessel is unlikely, although it may occur from high-tension electrical burns. If there is gross oedema in a limb following burning, the swelling and tissue tension may lead to venous obstruction. This is particularly likely where there is circumferential burn tissue (eschar) which is incapable of distending. There is also the possibility of a muscle compartment syndrome affecting the flexors and/or extensor compartments of the upper limb or any compartment of the lower limb. The circulation of the intrinsic muscles of the hand may be compromised by oedema alone and this may lead on to ischaemic fibrosis and contractures. The accumulation of large quantities of interstitial fluid in the hand will inflate the elastic tissues of the hand, tending to drive it into a claw posture (metacarpal—phalangeal joint extension, proximal interphalangeal joint flexion).

Systemic effects from burning

Fluid loss

Fluid may be lost from damaged capillaries either by visible external loss or internally into the tissues from oedema in the region of the burn. In addition, there may be more extensive oedema of the region or even of the entire body. It is likely that this is mediated by cytokines acting on the microcirculation. Prevention of hypovolaemia is the most important function in early burn resuscitation. Effective fluid replacement will minimise the risk of other systemic complications.

Multiple organ failure

There may be progressive failure of renal or hepatic function or heart failure. The precise cause of these complications is uncertain and has often been attributed to fluid loss, ‘toxaemia’ from infection, or uncontrolled overreaction of the inflammatory response to sepsis. Multiple organ failure may, however, occur without obvious systemic infection.

Inhalation injury

These occur in those trapped in enclosed spaces. They are particularly common in association with burns of the head and neck. Various parts of the respiratory tract may be injured. The inhalation of hot gases causes a thermal burn to the upper airway. This is manifest early on by stridor, hoarse-ness, cough and respiratory obstruction. Inhalation of the products of combustion causes a chemical burn to the bronchial tree and lungs. This is manifest by hypoxia, acute respiratory distress syndrome and respiratory failure; it may be of delayed onset. Systemic absorption of, in particular, carbon monoxide (but also hydrogen cyanide from burning plastics) causes poisoning. Carbon monoxide displaces oxygen from haemoglobin to form carboxyhaemoglobin, reducing the oxygen-carrying capacity of the blood. It also has intracellular effects. Patients who survive the original incident may arrive confused or unconscious. Inhalation injury has an additive effect on mortality in all burns.

Systemic complications

There are well-documented systemic complications in association with burns such as Curling’s (gastric or duodenal) ulcer that may result in acute haematemesis. Immunosuppression increases the risk of septic complications. Later, there is a catabolic response to trauma with severe weight loss. Nonspecific complications include urinary tract infection from catheterization, deep vein thrombosis and pulmonary embolism.
Clinical features of burn injuries

Pain

Pain is immediate, acute and intense with superficial burns. It is likely to persist until strong analgesia is administered. With deep burns there may be surprisingly little pain.

Acute anxiety

The patient is often severely distressed at the time of injury. It is frequent for patients to run about in pain or in an attempt to escape, and secondary injury may result.

Fluid loss and dehydration

Fluid loss commences immediately and, if replacement is delayed or inadequate, the patient may be clinically dehydrated. There may initially be tachycardia from anxiety and later a tachycardia from fluid loss.

Local tissue oedema

Superficial burns will blister and deeper burns develop oedema in the subcutaneous spaces. This may be marked in the head and neck, with severe swelling which may obstruct the airway. Limb oedema may compromise the circulation.

Special sites

Burns of the eyes are uncommon in house fires as the eyes are tightly shut and relatively protected. The eyes, however, may be involved in explosion injuries or chemical burns. Burns of the nasal airways, the mouth and upper airway may occur in inhalation injuries.

Coma

Following house fires, the patient may be unconscious and the reason for this must be ascertained. Asphyxiation or head injury must be excluded. Burning furniture is particularly toxic and the patient may suffer from carbon monoxide or cyanide poisoning.
Management of the burned patient

First aid

Stop the burning process

Flames from burning clothing or from burning inflammable substances on the skin surface should be extinguished by wrapping the patient in a fire blanket or any other readily available garment such as the bystander’s own clothing. Some fine extinguishers are suitable for extinguishing flames on the skin surface. With electrical burns it is important that any live current is switched off, and with chemical burns the first-aid worker must avoid contact with the chemical. Burned or water-soaked clothing should be removed.

Cool the burn surface

Immediate cooling of the part is beneficial and should continue for 20 minutes. With scalds, irrigation with cold water under a tap is best and many a child has had scald damage successfully limited by pouring a readily available jug of cold water or milk immediately over the scalded area. Irrigation in cold water is particularly valuable for chemical burns. Hypothermia must be avoided. Do not use ice or iced water. The ideal temperature of cooling water is 15° C, but 8—25° C is effective. The burn should then be wrapped in any clean linen or plastic ‘cling film’ and the patient transported immediately to hospital.

Emergency examination and treatment

The order of priorities in the management of a major burn injury is:

• A: airway maintenance;
• B: breathing and ventilation;
• C: circulation;
• D: disability — neurological status;
• E: exposure and environment control — keep warm;
• F: fluid resuscitation.

Many of these observations and maneuvers are shared with those considered good practices in any trauma situation. In severe facial and neck burns early endotracheal intubation or tracheostomy should be considered. Early escharotomy may be needed in circumferential chest or limb burns where respiratory or circulatory disturbance is observed. An altered conscious level may be caused by carbon monoxide poisoning.

Fluid resuscitation

It is important at an early stage to secure large-bore intra-venous lines. Samples are taken for haemoglobin, urea and electrolytes, and blood cross-matching. Blood gases and blood analysis for carbon monoxide or cyanide poisoning are required in the unconscious patient. Having estimated the percentage burned surface area and measured the body weight, initial fluid resuscitation can be planned. The simplest formula (for adults) is: 3—4 ml/kg body weight/% burn/in the first 24 hours.

Half of this volume is given in the first 8 hours and the rest in the next 16 hours. Timings begin from the time of the burn, not the start of resuscitation. Hartmann solution is preferred, but other isotonic fluids may be used. Metabolic fluid requirements are also needed. Formulae are only a guide and the adequacy of fluid resuscitation is monitored by regular clinical assessment. A urinary catheter is essential. Urine output is the best guide to adequate tissue perfusion; in an adult one should aim for 30—50 ml/hour.
Further management

It is important to complete a detailed history of pre-existing problems and of the burn injury. A detailed physical examination and examination of the burned area is carried out. Adequate pain relief must be provided, usually by means of intravenous morphine. Good notes and a drawing of the burn area are needed. Smaller burns may be managed satisfactorily on an outpatient basis with arrangements for further dressing either at a hospital follow-up clinic or by the general practitioner. Patients with major burns should ideally be treated in a specialised burns unit. Indications for referral include:

• burns of special areas (face, hands, feet, perineum, genitalia);
• full-thickness burns >5 per cent body surface area;
• circumferential limb or chest burns;
• electrical burns;
• chemical burns;
• burns in children or the elderly;
• where nonaccidental injury is suspected in the case of a child;
• associated medical conditions or pregnancy;
• associated other trauma.

Adequate assessment, resuscitation and fluid administration should be secured before transfer of the patient. The trend towards early surgical excision and closure of the wound dictates that any patient with a wound which is unlikely to heal spontaneously should have the benefit of a plastic or burns surgical opinion at the earliest possible stage. A burns unit is often the most convenient place to undertake regular dressings. Dressing changes in an appropriate area are likely to minimise cross-infection, although formal isolation is rarely used unless a patient is shown to have an antibiotic-resistant organism, such as methicillin-resistant *Staphylococcus aureus*. The burns unit provides facilities for immediate physiotherapy and occupational therapy to minimise limb stiffness. Nutritional support is available. Early establishment of normal feeding appears to protect the small bowel mucosa and prevent translocation of Gram-negative bacteria. Inhalation injuries often require ventilation and monitoring by blood gases and bronchoscopy. These are best managed in a respiratory intensive care unit with appropriate surgical support for the management of the burn wound.

Dressings

Epidermal burns with erythema and no blisters do not need dressings. Analgesia and moisturising cream are used. Burns the face are generally treated by exposure, largely because the difficulty of dressing (Fig. 14.6). Where there is much crusting it may be necessary to apply an ointment such as petroleum jelly, particularly around the eyes, and frequent toilet of the eyes and orifices may be needed. Burns of the trunk and limbs are usually dressed. Where possible the burns should be inspected by an experienced doctor to check on the assessment of area and depth before the application of dressings, as appearances may subsequently be difficult to interpret. Superficial dermal burns with blistering are usually dressed to absorb exudate, prevent desiccation, provide pain relief, encourage epithelialisation and prevent infection. Appropriate dressings are plastic films, hydrocolloids, pre-served cadaver or pig skin, alginates or paraffin gauze. A thick layer of gauze may then be placed on top to allow transudation of any fluid and layers of wool or padding are applied over this to act as a sump for exudate. Dressing changes are painful and should not be performed more than necessary. Partial-thickness skin injuries heal within 2—3 weeks. Any wound that remains unhealed or granulating at 3 weeks will not heal satisfactorily without surgical intervention. Plastic surgical advice should certainly be sought by 3 weeks or at an earlier stage if the wound is extensive or showing evidence of considerable slough formation. Enzyme preparations may be used to facilitate sloughing. Where deep burns are being managed with dressings a topical antimicrobial agent such as silver sulphadiazine cream is used.

Infections

There is controversy about the use of routine antibiotic administration. It is almost inevitable that a burned surface will become colonised by microorganisms. The administration of broad-spectrum antibiotics on a routine basis is likely to encourage the emergence of resistant organisms. Children suffering from burn wounds are often given routine antibiotics to limit the possibility of metastatic infection. Almost any organism may colonise a wound. *Beta-haemolytic streptococci* are likely to delay healing and should be treated. *Staphylococcus aureus* is a frequent pathogen and *Pseudo-monas* particularly grows on raw surfaces. These organisms may be best treated by local antiseptic preparations, although where there is any evidence of cellulitis, antibiotics should be administered. Frequent wound swabs should be cultured and where there is any rise in temperature, blood cultures should be taken.

Whether to administer an antibiotic before an organism is cultured from the blood is an individual clinical decision that depends on the severity of the patient’s condition.

Monitoring for the onset or progress of infection should consist of:

• routine temperature measurement;
• frequent wound swab cultures;
• wound inspection by an experienced doctor or nurse at the time of dressing change;
• blood cultures.

**Toxic shock syndrome**

Toxic shock syndrome (TSS) is a life-threatening, exotoxin-mediated disease caused by *S. aureus*. It can occur in children who often have small body surface area burns. It presents with fever, a rash, myalgia, diarrhoea and vomiting and can progress rapidly to hypotension and multiorgan failure. Treatment is by dressing change, fluid resuscitation, antibiotics and immunoglobulin. Mortality can be high, but prompt active intervention appears to be effective. It is important to have a high index of suspicion regarding this condition when treating burned children.
Surgical treatment

Partial-thickness burns should heal without surgical intervention, but full-thickness burns require surgical management. There are two alternative policies for deep burns. One can await spontaneous desloughing and apply split-skin grafts at 3 weeks. This policy has the advantage that early operation can be avoided, but has the disadvantage of slow healing and greater scarring that follows a granulating wound. Alternatively, early excision of the burn is carried out with the application of skin cover, usually a skin graft, but where indicated a flap. This has the advantage of obtaining rapid healing and early restoration of function, and minimises the risk of adverse scarring. Where facilities allow, a policy of early operation for deep burns is preferred. Early tangential excision of skin grafting is a technique used for deep dermal burns, usually performed within 48 hours. Successive layers of the burned tissue are shaved with a split-skin grafting knife until a healthy bleeding dermal bed is reached upon which the skin grafts are applied. The rationale of this treatment is that deep dermal burns will heal slowly with considerable scarring. The healing process can be expedited by this method. It is a technique that requires considerable experience in the interpretation of the wound bed. Any surgery of this type is associated with considerable blood loss and limbs should be operated on with the assistance of a tourniquet. On the trunk it may be necessary to use a dilute infusion of adrenaline subcutaneously. Following excision of burned tissue, skin cover is by split-skin autograft cover (Fig. 14.7). This is harvested from a donor site on an unburned area of skin. Care should be taken in selecting the donor site to produce the least possible cosmetic deficit. All grafts in children should be harvested from the buttocks. With extensive burns, the thighs are the first choice and other sites on the limbs and trunks may be necessary in addition. The skin graft can be meshed to expand its area. This is a system by which the graft is expanded by passing it through a machine that places multiple cuts in the skin. The skin can then be stretched and the cuts open out into small, diamond-shaped wounds. In this way the skin can be expanded 1/2—3 times depending on the expansion of the diamonds. Meshed skin also has the advantage that it allows free drainage of fluid from beneath the graft area (Fig. 14.8). Cadaveric allografts may be used for temporary cover. Cadaveric dermis has also been used as definitive cover with the addition of cultured autografts of keratinocytes. Keratinocyte grafting may have a larger role in establishing skin cover in the future. It is possible to grow large areas of keratinocyte autografts that facilitate healing, although the long-term future of the grafted skin cells remains uncertain. In deep burns, those with exposed structures (nerves, tendons, and vessels) or those overlying joints primary flap cover may be needed (Fig 14.9 and Fig 14.10). Localised burns can usually be excised and closed in a single episode. Patients with extensive burn injuries may need repeated operations over many weeks to achieve healing. Once healed the process of rehabilitation can be more actively pursued.

Mobilisation and rehabilitation

The move towards earlier excision and skin cover and early mobilisation of the patient succeeds in reducing the incidence of complications such as infection and deep vein thrombosis. Most burns units have an intensive programme of physio-therapy and mobilisation without which limb oedema would progress to joint contractures.

Surgical reconstruction of the burn injury

The major complication of burn injury is scarring (Fig. 14.11). Lumpy hypertrophic or keloid scars can be limited by the application of pressure, and patients are routinely fitted with Lycra pressure garments. Topical silicone sheeting may also be beneficial in limiting scar hypertrophy. Surgery is usually inappropriate for hypertrophic scars since they gradually improve with time (Chapter 3). Where burn scars cross surfaces near-joint scar contractures may occur. Late surgical reconstruction may be needed to release these contractures (Fig. 14.12). Broad contractures require releaser and insertion of skin grafts; such operations are particularly valuable in restoring the range of motion of a joint, but often leave a less than pleasing aesthetic result. Where there is a localised linear contracture a better technique may be Y—V plasty (Fig. 14.13). In some circumstances contractures can be released and burn scar area reduced by means of tissue expansion. This technique allows gradual stretching of marginal skin by implanting expander balloons under the adjacent normal skin. These are serially injected with saline through a port, thereby enlarging the expander and stretching the overlying skin. At a second operation the expander is removed and the excess skin stretched over the grafted area to aid reconstruction (Fig. 14.14). Tissue expansion is particularly useful in reconstruction of burn alopecia. Missing eyebrows can be reconstructed by hair-bearing grafts or flaps. Extensive procedures may be necessary to reconstruct facial features such as the eyelids, lips and nose. In the long term, areas healed by skin grafting may be unstable and chronic ulceration in a grafted area may rarely lead on to a squamous carcinoma.

Arterial stenosis or occlusion

Cause and effect

Arterial stenosis or occlusion is commonly caused by atherosclerosis, but can occur acutely as a result of emboli or trauma. Stenosis or occlusion produces symptoms related to the organ which is supplied by the artery: e.g. lower limb — claudication, rest pain and gangrene; brain — transient ischaemic attacks and hemiplegia; myocardium — angina and myocardial infarction; kidney — hypertension or infarction (Fig. 15.1); intestine — abdominal pain and infarction. The severity of the symptoms is related to the size of the vessel occluded and the alternative routes (collaterals) available (Fig. 15.2).

Symptoms and signs of lower limb arterial stenosis or occlusion

**Intermittent claudication**

Intermittent claudication is a cramp-like pain felt in the muscles that:

- is brought on by walking;
- is not present on taking the first step (contrast osteoarthrosis, Chapter 26);
- is relieved by standing still (contrast lumbar intervertebral disc nerve compression, Chapter 33).

The distance walked is called the claudication distance. It is a very subjective distance which varies only slightly from day to day in the same patient. It is altered by walking up hill or against a wind, the speed of walking, or by changes in general health such as anaemia or heart failure.

The pain of claudication is most commonly felt in the calf, but can affect the thigh or buttock. Pain in the buttock occurring on exercise (walking) and associated sexual impotence, which result from arterial ischaemia, are given the eponymous title ‘Leriche syndrome’.

Claudication less commonly occurs in the upper limb in subclavian, axillary or brachial artery obstruction, the pain being brought on by such activities as writing or manual labour.

**Rest pain**

Rest pain is severe pain felt in the foot at rest, made worse by lying down or elevation of the foot. Characteristically, the pain is worse at night; it may be somewhat relieved by hanging the foot out of bed or by sleeping in a chair. Night cramps, which are short, severe muscle cramps of unknown origin, should not be confused with rest pain.

**Coldness, numbness and paraesthesia**

Coldness, numbness and paraesthesia are common in moderate as well as severe ischaemia but, in the absence of colour changes, it is essential to exclude a neurological cause.

**Colour changes** (Fig. 15.3)

Moderate or severely ischaemic limbs become blanched on elevation and develop a purple discoloration on dependency. Any bright red speckling is due to the extravasation of red cells through capillary walls. The angle of elevation at which blanching first occurs gives a rough guide to the degree of ischaemia.

**Ulceration and gangrene**

Ulceration occurs with severe arterial insufficiency and often presents as a painful, superficial erosion between toes. Alternatively, small, shallow, indolent nonhealing ulcers may occur on the dorsum of the feet, on the shins and especially around the malleoli. The blackened mumified skin and tissues of frank gangrene are unmistakable to the observer (Fig. 15.4), but it must be remembered that in acute ischaemia a dead, white limb which becomes mottled means impending gangrene and not an improvement in the circulation. (Fig. 15.5) shows a typical case.

**Pregangrene**

The combination of rest pain, colour changes, oedema and hyperaesthesia, with or without ischaemic ulceration, is frequently referred to as pregangrene.

**Temperature**

A severely ischaemic foot is usually cold but sometimes paradoxically may feel warmer than the noninvolved foot. The acutely ischaemic limb tends to take on the temperature of its surroundings and may feel quite warm under the bedclothes.

**Sensation and movement**

Acutely ischaemic limbs are frequently paralysed and without sensation. These are ominous physical signs and such a limb has a poor prognosis in the absence of active treatment. Severe chronic ischaemia does not produce paralysis, but hyperaesthesia is common, especially in those areas of skin on the borderline of gangrene. Gentle handling of such limbs is essential.

**Arterial pulsations**

Arterial pulsations below an occlusion in a main artery are usually absent or, in the presence of good collaterals, diminished. In patients with vascular symptoms, it is standard practice to feel the pulsations in the radial arteries, the carotid arteries, the abdominal aorta, the femoral arteries in the groins, the popliteal arteries behind the knees (an easily palpable popliteal artery may be aneurysmal), the posterior tibial arteries behind the medial malleoli and the dorsalis pedis arteries on the dorsum of the feet. Diminution of a pulse can best be appreciated by comparing it with the pulse in the other limb, provided that the latter is normal. Expansile arterial pulsation with a mass may indicate an aneurysm. In arterial occlusion with a highly developed collateral circulation, or in main artery stenosis, the distal pulses may be normal to
palpation. The following physical sign is then useful.

**The ‘disappearing pulse’**

Where peripheral pulses are apparently normal, exercising the patient to the point of claudication may unmask the effect of an arterial obstruction by causing the previously palpable pulse to disappear. After a minute or two of rest the disappearing pulse reappears. The explanation is that exercise produces vasodilatation below the obstructing lesion and the arterial inflow reduced by the lesion, cannot keep pace with the increasing vascular space; arterial pressure falls and the pulse disappears.

**Arterial bruits**

A vascular examination should include auscultation of the subclavian arteries in the supraclavicular fossae, the carotid arteries behind the angle of the mandibles, the abdominal aorta and the femoral arteries in the groins and over the adductor (subsartorial) canals. A systolic bruit over an artery is due to turbulence and indicates a stenosis of the artery.

**Systolic bruits**

Systolic bruits are conducted distally. Thus a bruit in the neck at the level of the angle of the mandible without any supraclavicular bruit frequently means a carotid artery stenosis. Where, however, a bruit is heard at both sites, its origin may be more proximal, e.g. aortic valve, aortic arch, brachiocephalic or subclavian arteries. Under these circumstances the carotid artery may prove quite normal. The patient with renal artery stenosis shown in (Fig. 15.1) had a bruit over the renal artery. A continuous ‘machinery’ murmur over an artery usually indicates the presence of an arteriovenous fistula.

**Venous refilling**

The limb should be elevated for 30 s and then laid flat on the bed. Normal refilling occurs within seconds. Reduced venous filling is often present in the severer forms of arterial insufficiency, but is also common in vasospastic disease and in cold weather.

**Harvey’s sign**

If the two index fingers are placed firmly side by side on a vein and the finger nearer the heart is moved so as to empty a short length of vein, the release of the distal finger will allow the speed of venous refilling to be observed. Increased venous return and varicosities of veins are associated with arteriovenous fistulas.

**Impotence**

Impotence from failure to achieve an erection is often a feature in male patients with an occlusion in the region of the bifurcation of the aorta and the internal iliac arteries (Leriche’s syndrome).

**Relationship of clinical findings to the site of disease**

By associating the symptoms and signs found in a case of arterial disease, the site of the major arterial obstruction can be determined (Table 15.1).

**Double blocks**

The presence of another (secondary) obstruction can usually be inferred. For example, a patient with signs of iliac artery obstruction, but with rest pain and pregangrene of the foot, must have a secondary obstruction as collateral circulation around an isolated iliac artery obstruction is usually excellent. The severe symptoms indicate a secondary obstruction, probably in the femoral or popliteal arteries.

**Investigation of arterial stenosis or occlusion**

Many patients with symptoms due to arterial disease without stenosis or occlusion do not need active treatment. This decision can often be made without submitting the patient to a series of special investigations. Active treatment includes angioplasty and surgical reconstruction.

**General**

Patients with arterial disease tend to be elderly and atherosclerosis is a generalised disease. If surgery is indicated, a full assessment is essential.

**Investigations**

Investigations relevant to diabetes, abnormalities of lipid metabolism, anaemia, conditions causing high blood viscosity, e.g. polycythaemia and thrombocythaemia (in small-vessel disease), include a full blood count (including erythrocyte sedimentation rate and platelets), plasma fibrinogen, protein electrophoresis, blood and urine glucose and blood lipid profile. A plain radiograph of the abdomen will show the presence of arterial calcification and flecks of calcium may outline an aneurysm (Fig. 15.6). Heart failure, myocardial ischaemia, hypertension and age-related diseases such as bronchial problems and neoplasia should also be excluded.

*Electrocardiography (ECG)*

Although a normal ECG does not exclude severe coronary artery disease, a grossly abnormal ECG may influence the decision for surgery in patients with lower limb disease.

*Exercise ECG*

This gives a more accurate cardiac assessment, although many of the patients are severely limited in their ability to exercise.

*Radioisotope ventriculography*

This is an isotope technique measuring left ventricular ejection fraction which correlates well with cardiac function.

*Echocardiography*

This noninvasive technique is often useful in assessing left ventricular function.
A continuous wave ultrasound signal is beamed at an artery and the reflected beam picked up by a receiver. The change in frequency in the reflected beam compared with that of the transmitted beam is due to the Doppler shift, resulting from the reflection of the beam by moving blood cells. The frequency change may be converted into an audio signal and, in arteries, a pulsatile sound typically results. Doppler ultrasound equipment can, therefore, be used as a very sensitive type of stethoscope in conjunction with a sphygmomanometer to assess the systolic pressure in relatively small vessels. This is often possible even at sites where the arterial pulse cannot be palpated.

The ankle:brachial pressure index (ABPI) is the ratio of systolic pressure at the ankle to that in the arm. Generally, the higher of the recordings of pressure in the dorsalis pedis and posterior tibial arteries serves as the numerator, with the higher systolic pressure between the brachials serving as the denominator. The resting ABPI is normally about 1.0; values below 0.9 indicate some degree of arterial obstruction. A value of less than 0.3 suggests imminent necrosis. It must be appreciated, however, that values approaching normality at rest may still be associated with intermittent claudication. Retesting after exercise is useful in this context: in normality ABPI will rise while occlusive disease may result in a depression of ABPI.

A Doppler ultrasound probe can also be used to assess differences in arterial blood pressure between segments of a limb, thereby giving an indication of the site of a stenosis. In the leg, the cuff is commonly placed above the ankle, at midcalf and midthigh, to provide ‘segmental pressures’. Artifacts are due especially to calcified arteries, which may be incompressible and lead to a falsely high limb pressure or ABPI result. This is particularly the case in diabetics.

**Duplex imaging**

This is an investigative technique of major importance in vascular disease. A duplex scanner uses B-mode ultrasound to provide an image of vessels (Fig 15.9 and Fig 15.10). This image is created through the different ability of different tissues to reflect the ultrasound beam. A second type of ultrasound, namely Doppler ultrasound, is then used to insonate the imaged vessels and the Doppler shift obtained is analysed by a dedicated computer in the duplex scanner. Such shifts can give detailed knowledge of vessel blood flow turbulence, etc. Some scanners have the added sophistication of colour coding which allows visualisation of blood flow on the image. The various colours indicate change in direction and velocity of flow; points of high flow generally indicate a stenosis. It should be appreciated that modern duplex scanning is at least as accurate as angiography in certain circumstances. In terms of cost-effectiveness and safety, duplex scanning is generally to be preferred to angiography if they are considered to be equally useful in any given clinical context.

**Plethysmography**

Plethysmography assesses changes in volume of a limb or digit over the cardiac cycle. Air-filled cuffs or mercury in rubber strain gauges have typically been used. For most clinical purposes the test has been superseded by duplex scanning, although plethysmography may still have certain research uses.

**Oculeoplethysmography**

Oculeoplethysmography (OPG) uses fluid- or air-filled cups attached to the eye by suction to investigate carotid artery disease. Once again, the technique has largely been superseded by duplex scanning.

**Treadmill**

A treadmill with a slight incline is a useful diagnostic apparatus in the assessment of walking distance in claudicants. Patients are known to be very poor assessors of walking ability in terms of distance; objective measurement using the treadmill is recommended.

**Arteriography (syn. angiography)**

In lower limb disease it is symptoms and their severity which decide whether intervention is needed. An arteriogram is done only after a decision has been taken that intervention is appropriate. Even then, it may be advisable in some circum-stances to precede the arteriogram with a duplex scan. This is so especially in the field of carotid artery disease where arteriography is associated with a stroke rate of between 1 and 2 per cent. Many surgeons are content to operate on carotid artery disease solely on the results of a duplex scan without arteriography.

Arteriography involves the injection of a radio-opaque solution into the arterial tree, generally by a retrograde per-cutaneous method usually involving the femoral (occasionally the brachial or axillary) artery. This retrograde method is known as the Seldinger technique (Fig 15.11 and Fig 15.12). Direct arteriography, by puncturing, for example, the carotid artery or aorta, is more hazardous; it is outdated and no longer in use. Hazards include thrombosis, arterial dissection, haematoma, neurological dysfunction and anaphylaxis. Anaphylactic reactions can occur even with a trial injection and informed consent should always be obtained for this form of imaging.

**Digital subtraction angiography (DSA)**

This technique, which is in widespread use, employs a computer system to digitise the angiographic information (Fig 15.13). It allows the image before contrast injection to be subtracted from the contrast image, yielding great clarity. DSA may be carried out by arterial or venous injection. The former allows the use of finer catheters and less contrast agent than conventional angiography.

The latter avoids the need for arterial puncture completely, although rather high volumes of contrast agent must be injected into a large vein.

**Management of arterial stenosis or occlusion**

**Explanation and advice**

Patients are worried by the presence of pain on walking. Once told that walking is not doing harm, many are content to live within the limitations imposed by their claudication. Spontaneous improvement occurs in some patients over the first 6 months after an occlusive episode as collateral vessels are developed.

**Adjustment of lifestyle**

Adjustments to everyday habits of transport can increase mobility within the claudication distance, e.g. the use of a bicycle or a car.

**Stopping smoking**

Particularly for patients with Buerger’s disease (see later in this chapter). Progression of the disease and graft failure after surgery are more common in any patient who continues to smoke.

**Taking regular exercise**

Within the limits of the pain.

**Diet**

To reduce weight in the obese and, more specifically, in the treatment of hyperlipidaemia.
Vasodilator drugs are ineffective in the management of arteriosclerotic disease.

- Praxilene (nafidrofuryl oxalate) may alter tissue metabolism, increasing the claudicating distance by allowing a greater oxygen debt to be incurred.
- Trental (poxidiflamine) has some effect on whole blood viscosity.
- Prostacyclin is currently being evaluated and may have a role in the management of the critically ischaemic limb.

**Lipid abnormalities**

The first line of treatment is dietary to reduce weight (if necessary) and to reduce fat intake. Patients who have no primary metabolic disease and who achieve an ideal weight but remain ischaemic should be considered for drug treatment.

**Diabetes and hypertension**

These should be treated by standard methods. In hyper-tension, the overzealous reduction of blood pressure by the use of beta-adrenoeceptor blocking drugs can worsen claudication.

**Care of the feet**

This includes avoiding socks with holes and amateur chiropody, which can spark off gangrene in the toes and heels, particularly in diabetic patients.

**Analgesics and position**

Rest pain can be relieved to some extent in some patients by the use of analgesics and elevation of the head of the bed (Buerger’s position).

**Aspirin**

In dispersible form this may be prescribed for its anti-adhesive effect on platelets. A dose of 150 mg/day is usual.

**Sympathectomy**

Sympathectomy is not effective in claudication but occasionally it may relieve ischaemic rest pain and ulceration. However, it must be recognised that the results of sympathectomy are very much poorer than those of bypass surgery or percutaneous transluminal angioplasty. Sympathectomy can only be justified when it is not technically possible to operate or employ balloon angioplasty. The details of lumbar sympathectomy (operative and chemical) are given at the end of this chapter.

**Transluminal angioplasty** *(Fig 15.14 and Fig 15.15)*

Arterial occlusive disease may be treated by inserting a balloon catheter into an artery and inflating it within a narrowed area. This may be done at the same time as an operation but, more usually, it is carried out percutaneously in the radiology department *(Fig 15.16 and Fig 15.17)*. Percutaneous transluminal angioplasty (PTA) may be used for stenoses or short occlusions; in the latter case the occlusion must first be traversed by a guidewire. Balloon angioplasty has had its major success in dilating the iliac vessels. To a lesser extent the vessels of the leg itself may be dilated with a good outcome.

Technique. A femoral arteriogram is performed and a guidewire inserted through any stenosis to be treated. The balloon catheter is then inserted over the guidewire. The balloon is then positioned within the stenosis (confirmed by angiography). The balloon is then inflated for approximately 1 minute and then deflated. This is repeated before withdrawal of the catheter.

**Atherectomy**

A variety of new devices is available to allow the percutaneous removal of atheroma from within the vessel in the radiology department. These cutting catheters have several styles and their use in certain circumstances, e.g. eccentric plaque, may be efficacious.

**Intraluminal stents** *(Fig 15.18 and Fig 15.19)*

In certain circumstances after balloon dilatation, the vessel fails to stay adequately dilated and it may then be possible to hold the lumen open using a metal stent. Such a device may be introduced on a balloon catheter; the balloon itself when inflated expanding the stent, which acts as a rigid skeleton for the vessel, keeping it widely patent. The catheter balloon is deflated and the catheter removed. An alternative type of self-expanding stent is held compressed by a sheath of plastic in a delivery system. When the stent has been positioned at the appropriate arterial site the sheath is withdrawn and the stent self-expands to hold the lumen open. The results of stenting have not been fully assessed but early results suggest that the technique has considerable promise.

**Operations for arterial stenosis or occlusion**

**Site of disease and type of operation**

Aortoiliac occlusion with good calibre vessels below the site of disease responds well to aortofemoral bypass *(Fig 15.20a)*. If the disease is limited in extent, an iliac endarterectomy might be considered, but PTA with or without a stent is probably a better alternative if technically possible. In the patient who is unable to withstand major abdominal surgery and who has pronounced ischaemia due to aortoiliac occlusion, a femoro—femoral or ilio—femoral crossover bypass may be considered (if only one iliac system is involved with disease) or an axillo—bifemoral bypass may be done (if both iliac segments are diseased).

Superficial femoral and profunda femoris artery occlusive disease often produce unilateral symptoms. For long-distance claudication, conservative treatment is usually suitable. For more severe disease a supervised exercise programme may be appropriate. In certain circumstances, when the occlusive appearance on angiography is favourable and the patient fully understands the risks and benefits of intervention, angioplasty or bypass may be considered. A femoropopliteal bypass graft *(Fig 15.23b)* is the most usual operation (to overcome a blocked superficial femoral artery). Long-term graft patency is related to the inflow and outflow from the graft. It is also related to the material used for the bypass. The patient’s own saphenous vein gives the best results when used either as a reversed conduit or in situ after valve disruption. In some patients a profunda femoris origin stenosis is noted and this situation can be helped by a small patch angioplasty to relieve the diseased site.

Oclusive disease below the popliteal artery used to be widely regarded as unreconstructable but it is increasingly recognised that bypass to the tibial vessels, even down to ankle level, can be met with reasonable success. The most usual and successful conduit is the long saphenous vein used in the in situ fashion after disrupting the valves with a valvulotome. If the saphenous vein is not available from either leg, it may still be realistic to carry out the surgery with a polytetrafluoroethylene (PTFE) graft; many surgeons construct the lower anastomosis using a small collar of vein between the PTFE and the recipient artery. This technique (Miller cuff) may give prolonged patency.

**Prosthetic materials**

For bypass of the aortoiliac segment the favoured material is Dacron *(Fig 15.21a)*. Prostheses come in two types: woven and knitted. Woven grafts tend to leak less
when first exposed to blood flow during surgery, but newer knitted prostheses may be sealed with gelatin or collagen by the manufacturer and may leak even less than the woven counterparts. In the final analysis, there is probably little to choose between any of the styles of Dacron graft; all achieve satisfactory results. For bypass in the femoropopliteal region, if autogenous long saphenous vein (or other veins such as the short saphenous or arm vein) is not available, PTFE (Fig. 15.21b) or glutaraldehyde-tanned, Dacron-supported, human umbilical vein (Fig. 15.21c) may be employed. In general, any vein used requires a diameter of at least 3.5 mm. For profundaplasty, a small piece of vein may be used or, alternatively, PTFE or Dacron.

Suture materials for vascular surgery are usually monofilament in nature; polypropylene has been particularly popular. In the aorta it is usual to use 2/0 or 3/0 polypropylene. In the femoral artery at the groin it is usual to use 4/0 or 5/0 polypropylene. Finer sutures, up to 7/0, may be needed further down the limb. PTFE may (alternatively) be stitched using a suture of the same material. PTFE sutures tend to cause less bleeding through stitch holes in the graft substance.

Operative details

Aortofemoral bypass graft. The aorta is approached through a midline or transverse abdominal incision. The common femoral arteries and their branches are exposed through vertical groin incisions. The small bowel is retracted to the right and the posterior peritoneum opened. Retroperitoneal tunnels are made from the aorta to the groins. Heparin (5000 units) is given intravenously and the vessels are clamped. A vertical incision is made in the anterior aspect of the aorta to which an obliquely cut, bifurcated Dacron graft is sutured. The grafts are then fed downwards to the groins where they are sutured. Thrombosed to the common femoral arteries and or, if there is evidence of profunda stenosis, to an arteriotomy running from the common femoral vessel down into the profunda. The posterior peritoneum is closed carefully over the Dacron to prevent adhesion of the graft to the bowel. The abdomen and groin wounds are closed without drainage.

Femoropopliteal bypass. The popliteal artery above or below the knee is exposed through a medial incision. The femoral artery is exposed at groin level. The long saphenous vein may be treated in two different ways. First, it may be excised, its tributaries tied, reversed and sutured into the limb as a bypass. Second, it may be left in place (in situ) and the valves disrupted with a valvulotome, either blindly or using an angioscope. The graft is then sutured to the femoral artery proximally and to the popliteal vessel distally. Suction drains are rarely necessary.

Femorodistal bypass. This surgery is usually carried out using long saphenous vein in the in situ mode. Great care must be taken at the conclusion of the procedure to assess the conduit and the lower anastomosis. This may be done using completion angiography or angioscopy (Fig. 15.22 and Fig. 15.23).

Femoroiliac bypass. The common femoral artery and its branches are exposed through a vertical incision. After giving intravenous heparin and clamping the vessels, an incision is made into the common femoral artery and carried down into the profunda, effectively dividing the stenotic profunda origin. The arteriotomy is then closed with a vein, Dacron or PTFE patch to widen the narrowed segment.

Other arterial operations and salvage procedures

Femorofemoral crossover graft is useful for relieving an iliac artery occlusion when the other iliac artery is patent with a strong femoral pulse. An 8-mm Dacron or PTFE graft is tunneled subcutaneously above the pubis and anastomosed end-to-side to the common femoral arteries on each side. Blood from the patent iliac system is then carried through this graft to vascularise the ischaemic limb.

Axillofemoral graft is useful for salvaging a pregangrenous limb in a poor-risk patient with bilateral iliac obstruction. A long 8-mm PTFE graft is tunneled subcutaneously, from an end-to-side anastomosis with the axillary artery proximally, to reach the femoral artery of the involved limb in the groin where the distal anastomosis is made. The axillary artery will carry a sufficient volume of blood to maintain the circulation in the arm and revascularise the lower limb. The short-term results are usually good and in these patients with their poor general condition, the poorer, longer-term result is usually less important. An axillofemoral bypass carries twice as much blood flow through its long limb as does an axillo(femoral) bypass; the former has a correspondingly improved patency rate. Salvage operations should not be performed for intermittent claudication alone. Gangrene and loss of limb may result if the operation should fail.

Adjuncts to direct arterial surgery. Blood flow estimations (by Doppler ultrasonography or electromagnetic flowmeter) or on-table arterio-graphy at the completion of the operation are useful techniques for ensuring that there have been no errors of surgical technique before the wound is closed.

Results of operation

The long-term results of aortoiliac reconstructive surgery are good; they are usually only marred by progressive disease producing femoropopliteal occlusions at a later date. Femoropopliteal surgery is less successful. The immediate postoperative success rate for vein bypass exceeds 90 per cent but many cases fail in the first 18 months after operation and, at the end of 5 years, the success rate is usually only between 50 and 60 per cent. The results of femoropopliteal endarterectomy are less good in both the short and long term. Dacron or PTFE bypass also gives a poorer result than vein, with 5-year success rates of less than 50 per cent. The rather poor long-term results of femoropopliteal surgery emphasise that these operations should only be used for direct indications.

Other sites of atherosclerotic obstruction

The principles of arterial surgery as stated above can be applied to other arteries which are stenosed by the disease.

Carotid stenosis may cause transient ischaemic attacks (TIAs). These are recurrent and, by definition, short-lived mini-strokes. Resolution occurs within 24 hours (usually within a few minutes) but TIAs are a warning of impending major stroke. Patients with TIAs should have a duplex scan (not an angiogram) in the first instance. If the scan confirms carotid occlusive disease at an appropriate site, then formal angiography may be considered desirable. Some surgeons operate frequently on duplex scan evidence alone, without angiographic confirmation of disease.

Carotid atheroma classically affects the internal carotid artery origin (Fig. 15.24). The usual procedure is a carotid endarterectomy which involves clamping the vessels, an arteriotomy in the common carotid artery continued up into the internal carotid artery through the diseased segment, removal of the occlusive disease (endarterectomy) and closure of the arteriotomy, often with a patch (vein, PTFE or Dacron). During clamping, some patients will have inadequate cerebral blood flow (especially if the contralateral carotid vessels are compromised). Such a situation may be recognised by recording a low pressure in the distal internal carotid artery above the level of the clamp. It may be necessary in such Circumstances to insert a temporary silicone shunt over the arterial field being worked upon.

Subclavian artery stenosis may cause claudication and (rarely) frank ischaemia of an arm. The subclavian lesion may also have an effect by causing artery-to-artery embolisation. This may lead to loss of digits. The condition may be treated by endarterectomy or bypass but nowadays percutaneous transluminal balloon angioplasty is the treatment of choice. It must be noted, however, that some subclavian artery lesions are associated with neck pathology such as cervical rib. Any underlying pathology must be corrected at the time of arterial repair.

Subclavian steal syndrome. If the first part of the subclavian artery is obstructed, the vertebral artery may provide a collateral circulation into the arm by reversing its direction of flow. This may cause periods of cerebral ischaemia. The classic syndrome of syncopal attack and visual disturbance associated with arm exercise and a diminished blood pressure in the affected limb is rather rare. Asymptomatic reversal of flow in the vertebral artery, recognised by either duplex scanning or angiography, is much commoner. In symptomatic patients, percutaneous transluminal angioplasty may relieve the problem, or the situation may be corrected by endarterectomy or a bypass from the ipsilateral common carotid artery to the third part of the subclavian artery.

Enteric artery occlusive disease. Pain after eating that has no obvious diagnosis in a patient with known atheromatous disease and weight loss may be due to coeliac artery occlusion. In general, two of the three coeliac vessels (coeliac axis, superior mesenteric artery, inferior mesenteric artery) must be occluded to produce 'intestinal claudication'. Great care must be taken to exclude all other diagnoses before contemplating surgical endarterectomy or bypass.

Renal artery stenosis may be responsible for hypertension and, eventually, loss of renal function. In general it is possible to control hypertension using drugs. When this pathology is associated with loss of renal tissue, however, arterial intervention is indicated. Both percutaneous transluminal angioplasty and arterial surgery have their specific place in this disease. A variety of operations is available ranging from endarterectomy, aortorenal bypass, renal artery recanalisation using another vessel (such as the splenic artery), to renal autotransplantation.
Acute arterial occlusion

Sudden occlusion of an artery is commonly due to either emboli or trauma.

Embolic occlusion

An embolus is an object which is foreign to the body and which may become lodged in a vessel and cause obstruction.

Simple emboli

Simple emboli are due to blood thrombosis. The sources are most commonly mural thrombus following a myocardial infarct (a third of cases), mitral stenosis, cardiac arrhythmias (particularly atrial fibrillation) and aneurysms. Emboli may lodge in any organ with resultant ischaemia and symptoms.

- **retina:** amaurosis fugax is fleeting blindness caused by the passage into the central retinal artery of a minute thrombus emanating from an atheromatous plaque in the carotid artery. Complete obstruction causes total and permanent blindness;
- **ears:** emboli causing engorgement and possible gangeone of the corresponding loop of intestine;
- **spleen:** commonly affected with local pain and enlargement;
- **kidneys:** resulting in loin pain and haematuria; The lungs (pulmonary embolism (Fig. 47)) is a catastrophe which may facilitate in convalescence after operation. Haemorrhage and dyspnoea are usual in survivors;

- **lower limbs:** pain, pallor, paresis, paresthesia and paraesthesia (more correctly anaesthesia) (Fig. 15.25).

Acute arterial occlusion due to an embolus differs from atheroembolic occlusion in that the occlusion is sudden. Indeed, the clinical differences between these two causes of occlusion in the lower limb are as set out in Fig. 15.26. It is essential to differentiate these two causes of occlusion, because they may require different forms of treatment. Sometimes acute arterial occlusion is an emergency, generally requiring treatment immediately the diagnosis is made.

Clinical features

In the legs, the dramatic symptoms which occur when major vessels are occluded deserve especial attention — pain, pallor, paresis, loss of pulsation and anaesthesia (Fig. 15.25).

The limb is cold and almost immediately the toes cannot be moved (contrast with venous occlusion when muscle function is not affected). The diagnosis can be made clinically in the majority of cases. The patient, who has no previous symptoms of claudication or limb pain, has a source of emboli, suddenly develops severe pain or numbness of the limb which becomes cold with moistened blue and white discoloration. Movement of the toes becomes progressively more difficult and sensation, to touch is lost. Pulses are absent distally, but the femoral pulse may be palpable (even thrusting) if the clot is lodged in a low bifurcation of the femoral artery. This is because distal occlusion results in forceful expansion of the artery with each pressure wave, despite the lack of flow.

Treatment

Because of the ensuing thrombus, stasis can extend distally and proximally to the embolus. The immediate administration of heparin 5000 units intravenously can reduce this extension and maintain patency of the surrounding (paricularly the distal) vessels until the embolus can be treated. The relief of pain is essential because it is the key symptom and constant. Embolectomy or thrombectomy are the treatments available for patients with limb emboli.

Embolectomy (and thrombectomy)

Local or general anaesthesia is used, depending upon the patient’s general condition and the scope of the proposed operation. The artery, bulging with clot, is exposed and a longitudinal longitudinal incision is made. The femoral muscle is split and the clot begins to extrude and is collected together with the embolus (Fig. 15.28). Arterial clamps are applied as bleeding occurs, special note being made of the degree of retrograde bleeding (back bleeding).

Fogarty catheterisation

This is the most effective method of removing proximal and distal extension thrombus and also allows an embolus or thrombus to be removed from deep veins remote from the arteriotomy. The Fogarty catheter is like a ureteric catheter, with a balloon tip, and is introduced until it is deemed to have passed the limit of the thrombus.

The balloon is inflated and the catheter withdrawn slowly, together with the clot. The procedure is repeated until bleeding occurs. The method is valuable in patients with major embolism, since it permits the insertion of balloon catheters via the common femoral arteries in the groin and the patient is saved from a laparotomy. Postoperatively, anticoagulant therapy is continued.

Prevention of further embolism is achieved by treatment of the cause, whenever possible, and by reducing the chance of further thrombus formation by using long-term anticoagulant with warfarin.

Intra-arterial thrombolysis (Fig. 15.29)

If ischaemia is not so severe that immediate operation is mandatory, it may be possible to treat either embolus or thrombosis by intra-arterial thrombolysis. Because the nature of thrombus as opposed to embolism, thrombolysis is more useful in the former condition. Indeed, it may well be the treatment of choice on many occasions.

Arteriography of the ischaemic limb is carried out (usually via the common femoral artery) in the radiology department and at the conclusion of the procedure a narrow catheter (French gauge) is passed into the occluded vessel and left embedded within the clot. Into this catheter a thrombolytic agent is infused over an hour or so. In addition, heparin 250 units per hour is added to the infusion. Intra-arterial thrombolysis may be carried out in a well-staffed ward, but some workers prefer the safety of either a high dependency unit or an intensive care unit.

The common thrombolytic agents are streptokinase, urokinase and tissue plasminogen activator (TPA). In the UK, the most frequently used agent is now TPA. Streptokinase having fallen into disfavour owing to allergy; TPA also has a more rapid action which may be clinically useful. The speed of thrombus dissolution can be further improved by replacing the infusion technique by a pulse-spray method; this requires a special catheter and delivery system.

Whichever drug is used, regular angiograms are carried out to check on the extent of lysis. Using streptokinase, lysis was usually complete within 48 hours. TPA may achieve lysis within 24 hours and pulse-spray TPA may take less than 6 hours. Lysis should be abandoned if there is no progression of dissolution of clot with time. There are several contraindications to the technique, the most important of which are recent stroke, bleeding diathesis and pregnancy.

Mesenteric artery occlusion

Acute mesenteric occlusion can be either thrombotic (following atheroembolic narrowing) or embolic.

Thrombotic occlusion follows progressive narrowing and so the symptoms also tend to be progressive with weight loss, abdominal pain (usually postprandial) and later, on palpation, the abdominal pain becomes localized. In the left gastric or gastroduodenal artery may be occluded to treat a bleeding ulcer. Occlusion of the hepatic artery often relieves the pain of primary and secondary carcinoma of the liver.

Thrombotic occlusion due to an embolus differs from the mesenteric occlusion due to atheroembolic occlusion. Sometimes the right ventricle should be aspirated by a needle passed upwards and backwards from below the left costal margin. If this fails, the heart is rapidly exposed for direct aspiration.

Embolus or thrombus, on entering the right atrium, is churned up; the foam then enters the right ventricle and causes an air-lock in the pulmonary artery, which may endanger the patient's life if it becomes serious. Arteriography and embolectomy or bypass surgery can reduce the otherwise high mortality in these patients.

Air embolism

Air may be accidentally injected into the venous circulation, e.g. artificial pneumothorax, or sucked into an open vein. Thus venous air embolism occasionally complicates long transverse or axillary vein punctures (see Chapter 19). Air may also be introduced by the passage of a thin needle into a vein, as in withdrawing blood. Air in the veins may act as an embolus, but more commonly it is dissolved and carried in solution back to the lungs. Air in the veins is always a danger level. When air enters the right atrium it is churned up; the foam then enters the right ventricle and causes an air-lock in the pulmonary artery, which may endanger the patient's life if it becomes serious. Arteriography and embolectomy or bypass surgery can reduce this extension and maintain patency of the surrounding (particularly the distal) vessels until the embolus can be treated. The relief of pain is essential because it is the key symptom and constant. Embolectomy or thrombectomy are the treatments available for patients with limb emboli.

Embolectomy and thrombectomy can reduce the otherwise high mortality in these patients.

**Treatment**

Trendelenburg’s position encourages air to pass into the veins of the lower half of the body and the patient is placed on the left side so that air will float into the apex of the ventricle, away from the pulmonary artery. Oxygen is administered to counteract hypoxaemia and to assist in the excretion of nitrogen. In serious cases the right ventricle should be aspirated by a needle passed upwards and backwards from below the left costal margin. If this fails, the heart is rapidly exposed for aspiration under direct vision.

Air may occasionally enter the left side of the heart, e.g. at open heart surgery, following puncture of a pulmonary vein during artificial pneumothorax or through a perforated diaphragm. Fat embolism and gas embolism may also occur in this situation.

Fat embolism

This condition, which is more common than generally supposed, usually follows severe injuries with multiple or major fractures. Cases have also been recorded following atheroembolism. It may result from an ischaemic bowel. If there be a clot, which may cause myotic aneurysms, pyaemia or infected infarcts; parasitic enteritis due to the ovum of *Taenia echinococcus* and *Pilariae sanguinis hominis* (see Chapter 17) and embolus of malignant cells (e.g. hypernephroma, see Chapter 64).

**Therapeutic embolization**

The general goal of arterial embolization is the reduction of the growth of the neoplastic lesion. Arterial embolization requires accurate selective catheterisation using the Seldinger technique.

**Examples**

The left gastric or gastroduodenal artery may be occluded to treat a bleeding ulcer. Occlusion of the hepatic artery often relieves the pain of primary and secondary carcinoma of the liver. It will usually convert a hormone-secreting tumour and will influence the management of patients with inoperable carcinoid (Fig. 15.31). Renal and mesenteric embolisation has been used to devascularise a renal tumour prior to surgery and to arrest persistent haemorrhage from an uncontrolable tumour. In patients with bleeding oesophageal varices, the portal system can be entered by percutaneous catheterisation through the liver and the veins supplying the varices can be embolized.

A wide range of materials have been used and they include blood clot, gel foam sponge, human dura, plastic microspheres, balloons, ethyl alcohol, quick-setting plastics and mechanical devices made of stainless steel coils and wool. Therapeutic embolisation is usually carried out under local anaesthesia and has a low morbidity. This is particularly useful for patients with advanced malignant disease where palliation is the aim of the procedure.
Caisson and decompression disease
These similar conditions may affect divers and those who work in compressed air chambers or who ascend in unpressurised aircraft to above 8000 m. If decompression is too rapid, bubbles of nitrogen are set free in the tissues and bloodstream, and occlude small vessels. Symptoms include pain in the muscles or joints, which may be excruciating (the ‘bends’), and neurological disturbances; if the spinal cord is affected the patient suffers from weakness of the legs and sphincters. In severe cases, the lungs may be affected, and the patient complains of tightness of the chest and a dry cough (the ‘chokes’). Caisson disease requires recompression followed by gradual decompression. The high-altitude flyer is relieved by gradual descent. Inhalation of oxygen assists the excretion of nitrogen. If the spinal cord is not permanently damaged the prognosis is good, but hypertrophic changes may persist in the ends of long bones.

Acute arterial occlusion due to trauma
Arteries (like all tubes) can be occluded as a result of changes:
• in the lumen, e.g. thrombosis;
• in the wall, e.g. subintimal haematoma;
• in the surrounding tissues, e.g. compartment syndrome.

The history of trauma should alert the clinician to check the pulses in the affected limb. There may be obvious injury, for example ‘butcher’s thigh’, when the boning knife slips and enters the groin, but sometimes in blunt injury the lack of surface changes may be misleading. Absent pulses with rest pain, or skin colour and temperature change, suggest arterial occlusion. In many Western nations, the commonest cause of arterial trauma is iatrogenic. In this group, the commonest event is femoral or brachial artery damage at cardiac catheterisation; the latter vessel is much more prone to iatrogenic complications and should be avoided if possible by those using catheter techniques.

Preoperative assessment
Preoperative assessment including arteriography is valuable. It is also useful to recognise pre-existing atherosclerotic disease.

Operative procedure
On exposing a damaged artery, an obvious laceration may be found —remember to look for a puncture wound in the back of an artery in a stabbing. If this is very small, e.g. from a needle puncture, a single suture may suffice to repair a leak. If damage is more widespread and if thrombosis forms part of the picture, it may be necessary to resect a damaged segment (Fig. 15.32). If the resection is very limited, it may be possible to reconstitute the vessel by direct anastomosis of the cut ends. In general, however, a short interposition graft (vein is best) is to be preferred. The vein should not be taken from the damaged limb because concomitant deep venous trauma may be present and superficial veins may be required to return blood centrally.

It should first be appreciated that occlusion due to trauma should never be casually ascribed to arterial spasm; ischaemia after trauma demands urgent action. Second, the results of operating on traumatised arteries are, in general, good. The outflow is not compromised by atheromatous disease in most cases. If the return of blood supply to the limb after arterial declamping is not very obvious, preoperative angiography is mandatory. Not only may there be a problem with the local arterial reconstruction but also thrombosis (from stasis) or embolism at a distal site may be present and may require separate attention.

Fractures of bone occur frequently alongside arterial injuries and require stabilisation, both in their own right and to protect the vascular repair. Stabilisation may be carried out before or after the vascular reconstruction (depending on how acute is the ischaemia) and fixation (often external) is greatly to be preferred to traction, for obvious reasons.

Compartment syndrome (Chapter 21)
It must also be remembered that in the lower limb the additional problem of compression of the main artery due to haematoma or oedema in the fixed fascial compartments of the calf, especially the anterior tibial compartment, can cause distal ischaemia (and crush syndrome renal effects). The treatment is urgent fasciotomy to release the external compression on the artery.
Gangrene

Gangrene implies death with putrefaction of macroscopic portions of tissue. It is commonly seen affecting the distal part of a limb, the appendix or a loop of small intestine, and sometimes organs such as the gallbladder, the pancreas or the testes. Note that the term necrosis applies mainly to the death of groups of cells, although it is extended to include bone, i.e. a sequestrum. A slough is a piece of dead, soft tissue, e.g. skin, fascia or tendon.

Types of gangrene according to causes

Secondary to arterial obstruction from disease, for example:

- thrombosis of an atherosclerotic artery;
- arterial shutdown in Raynaud’s disease or ergotism;
- embolus from the heart in atrial fibrillation or after coronary thrombosis;
- indirect, such as crushes, pressure sores and the constriction groove of strangulated bowel; or indirect, due to injury of vessels at some distance from the site of gangrene, e.g. pressure on the popliteal artery by the lower end of a fractured femur.

Phlegmonous, bacterial, chemical, irradiation and electrically induced.

Vonous gangrene: see Chapter 16.

Clinical features of gangrene (Fig 15.4 and Fig 15.5)

A gangrenous part lacks arterial pulsation, venous return, capillary response to pressure (colour return), sensation, warmth and function. The colour of the part changes through a variety of shades according to circumscription (pallor, dusky grey, mottled, purple) until finally taking on the characteristic dark brown, greenish black or black appearance, which is due to the disintegration of haemoglobin and the formation of iron sulphide.

Clinical types

Dry gangrene occurs when the tissues are desiccated by gradual slowing of the bloodstream; it is typically the result of atherosclerosis. The affected part becomes dry and wrinkled, discoloured from disintegration of haemoglobin and greasy to the touch. Infection and putrefaction are always present, the affected part becomes swollen and discoloured, and the epidermis may be raised in blisters. Crepitus may be palpated, owing to infection by gas-forming organisms. Moist gangrene is manifest also in such conditions as acute appendicitis and strangulated bowel.

Separation of gangrene

Separation by demarcation

A zone of demarcation between the truly viable and the dead or dying tissue appears first. It is indicated on the surface by a band of hyperaemia and hyperaesthesia. Separation is achieved by the development of a layer of granulation tissue which forms between the dead and the living parts. These granulations extend into the dead tissues and penetrate further until the pressure on the intact tissues can no longer be borne and adequate nourishment. Necrosis follows and thus a final line of demarcation (separation) forms which separates the gangrenous mass from healthy tissue.

In dry gangrene, if the blood supply of the proximal tissues is adequate, the final line of demarcation appears in a matter of days and separation begins to take place neatly and with the minimum of infection (so-called separation by aseptic ulceration). Where the separation by completion takes longer than when soft tissues alone are affected, and the stump tends to be conical as the bone has a better blood supply than its coverings.

In moist gangrene, there is more infection and suppuration extends into the neighbouring living tissue, thereby causing the final line of demarcation to be more pronounced than dry gangrene (separation by septic ulceration). This is why dry gangrene must be kept as dry and aseptic as possible, and why every effort should be made to convert moist gangrene into the dry type.

Vague demarcation; spread of gangrene; skipping and die-back. In many cases of gangrene from atherosclerosis and embolism, the line of final demarcation is wavy and dissipated. Unless the arterial supply to the living tissues can be improved forthwith, the gangrene will spread to adjacent tissues or toes, or will suddenly appear as ‘skip’ areas further up the limb. Signs of skipping should always be carefully looked for. Black patches suddenly appear, perhaps on the other side of the foot, on the heel, or on the dorsal of the foot or even in the calf. Infection, another cause of the spread of gangrene, may spread upwards beyond the line of separation along the lymphatic vessels or cellular tissue into healthy parts; extensive inflammatory changes may occur.

Muscular involvement is frequently accompanied by loss of reflexes and deformities. In some cases, the feet are splayed and deformed (neuropathic joints). Thick callosities develop on the sole and are the means whereby infection gains entry, often following amateur chiropody. Infection involving fascia, tendon and bone can spread proximally with speed via subfascial planes.

Clinical examination and investigations include those on the urine and blood for diabetes. Palpable dorsalis pedis and posterior tibial pulses, and the absence of rest pain and intermittent claudication, imply that there is no associated major arterial disease. A bacteriological examination is made of any pus. A radiograph may help to reveal the extent of any osteomyelitis.

Local treatment

Care of the affected part includes keeping it fully dry. Exposure and the use of a fan may assist in the desiccation and may relieve pain. The limb must not be heavily bandaged. Omission of local pressure areas, e.g. the skin of the heel or the malleolus, is required otherwise fresh patches of gangrene are likely to occur in these places. A bed-cradle, padded rings, foam blocks and air beds are useful preventive aids. Careful observations are of utmost importance. A gangrenous part will show whether the lifting of a crust, or the removal of hard or desiccated skin, will assist in demarcation, the release of pus and the relief of pain.

Varieties of gangrene

Diabetic gangrene

Diabetic gangrene is due to three factors. These are:

- trophic changes resulting from peripheral neuropathy;
- infection resulting in sepsis;
- excess of sugar in the tissues which lowers their resistance to infection (Fig. 15.33).

The neuropathic factor impairs sensation and thus favours the neglect of minor injuries and infections, so that inflammation and damage to tissues are ignored.

Muscular involve-ment is frequently accompanied by loss of reflexes and deformities. In some cases, the feet are splayed and deformed (neuropathic joints). Thick callosities develop on the sole and are the means whereby infection gains entry, often following amateur chiropody. Infection involving fascia, tendon and bone can spread proximally with speed via subfascial planes.

Clinical examination and investigations include those on the urine and blood for diabetes. Palpable dorsalis pedis and posterior tibial pulses, and the absence of rest pain and intermittent claudication, imply that there is no associated major arterial disease. A bacteriological examination is made of any pus. A radiograph may help to reveal the extent of any osteomyelitis.

Treatment. The diabetes must be brought under control by diet and appropriate drugs. The gangrene is treated along the lines already described, the accent being on conservatism if there is no major arterial obstruction. A rapid spread of infection requires drainage of the area by incision and the removal of any obviously dead tissue. Adequate surgical drainage of pus and the control of infection due to bacteria and necrosis must then be followed by rapid healing. After healing, protection of the affected part is essential.

Direct traumatic gangrene

Direct traumatic gangrene is due to local injury and may arise as a result of crushes, pressure (as in the case of splints or plasters) or bedsores. Gangrene following severe injury, e.g. a street accident in which the victim passes over a live electric fence, may be due to the effects of an excessive reduction in arterial blood supply to the damaged part, which leaves the most useful limb.

Indirect traumatic gangrene

Indirect traumatic gangrene occurs when the arteries are occluded as a sequel to the injury. In this case, the local arterial injury is usually of minor importance, as the main cause of the gangrene is the reduction in arterial blood supply to the area due to the injury. A thorough inspection of the area is essential to determine the cause of the gangrene.

Medical treatment

Antiseptic dressings and hot, moist fomentations will help to dry the area and to promote healing. Vaso-active drugs, such as ergotamine, will help to improve the blood supply to the area. If the gangrene is due to arterial injury, surgical treatment may be necessary to repair the damaged artery. In cases of diabetic gangrene, the diabetic state must be kept under control.

Prophylaxis

Prophylactic measures include the avoidance of pressure over the bony prominences, regular turning of patients and nursing on specially designed beds, which reduces the pressure to the skin. These beds include the high air loss Clinitron bed, low air loss Mediscus bed and the very low air loss OSA 1000. There are advantages in not blowing large quantities of air around the ward, and also advantages in being able to articulate the patient, yet removing the increased pressure over bony prominences. These beds include the high air loss Clinitron bed, low air loss Mediscus bed and the very low air loss OSA 1000. There are advantages in not blowing large quantities of air around the ward, and also advantages in being able to articulate the patient, yet removing the increased pressure over bony prominences.

Bedsores

Bedsores (syn. decubitus ulcers) are predisposed to by five factors — pressure, injury, anaemia, malnutrition and moisture. They can appear and extend with alarming rapidity in patients with disease or injury of the spinal cord and other patients with debilitating illness. It is important to recognise patients at risk and take adequate prophylactic measures. These measures include the avoidance of pressure over the bony prominences, regular turning of patients and nursing on specially designed beds, which reduces the pressure to the skin. These beds include the high air loss Clinitron bed, low air loss Mediscus bed and the very low air loss OSA 1000. There are advantages in not blowing large quantities of air around the ward, and also advantages in being able to articulate the patient, yet removing the increased pressure over bony prominences. These beds include the high air loss Clinitron bed, low air loss Mediscus bed and the very low air loss OSA 1000. There are advantages in not blowing large quantities of air around the ward, and also advantages in being able to articulate the patient, yet removing the increased pressure over bony prominences.

A bedsore is to be expected if erythema appears which does not change colour on pressure. The part must be kept dry. An aerosol silicone spray may be used.

Clinical types

Moist and phlegmonous.

Moist bedsore

A moist bedsore occurs when the tissues are desiccated by gradual slowing of the bloodstream; it is typically the result of atherosclerosis. The affected part becomes dry and wrinkled, discoloured from disintegration of haemoglobin and greasy to the touch. Infection and putrefaction are always present, the affected part becomes swollen and discoloured, and the epidermis may be raised in blisters.

Diabetic bedsore

Diabetic bedsore occurs when venous as well as arterial obstruction is present, when the artery is suddenly occluded, as by a ligature or embolus, and in diabetes. Infection and putrefaction are always present, the affected part becomes swollen and discoloured, and the epidermis may be raised in blisters. Crepitus may be palpated, owing to infection by gas-forming organisms. Moist diabetic gangrene is manifest also in such conditions as acute appendicitis and strangulated bowel.

Phlegmonous bedsore

Phlegmonous bedsore is due to the pressure of a piles sac or thrombosed varicose vein. There is usually a history of increased pressure and a recent trauma. The part becomes hard, tender and swollen, and the overlying skin is usually marked with a spreading weal, which often ulcerates. There is usually an offensive smell.
Indirect traumatic gangrene is due to interference with blood vessels:
- from pressure by a fractured bone in a limb or by strangulation (Fig. 15.35) (stranulated hernia, Chapter 62);
- thrombosis of a large artery following injury;
- ligation of the main artery of a limb, as after division by injury;
- poor technique for local digital anaesthesia. The combination of a tourniquet and an adrenaline-containing local anaesthetic solution can lead to permanent occlusion of all the arteries (Chapter 30).

The likelihood of gangrene depends upon the sufficiency of the collateral circulation. **Treatment**
- directed to the cause, e.g. closed or open reduction of a fracture together with direct arterial surgery for the damaged vessel, will usually prevent the onset of gangrene. The limb must be kept cool, so as to reduce metabolism to the minimum. When gangrene is slow to develop, a line of demarcation will indicate the level of viability. If moist gangrene occurs and spreads rapidly, amputation may be needed to save the patient’s life.

**Ergot**
Ergot, a cause of gangrene among dwellers on the shores of the Mediterranean Sea and the Russian steppes who eat rye bread infected with *Claviceps purpurea*, also occurs in migraine sufferers who, for prophylactic reasons, unwittingly take ergot preparations over a long period. The fingers, nose and ears may be affected (Fig. 15.36).

**Physical and chemical causes of gangrene**

**Frostbite** is due to exposure to cold, especially if accompanied by wind or high altitude (e.g. climbers and explorers). It is also encountered in the elderly or the vagrant during cold spells (Fig. 15.37). Pathologically, there is damage to the vessel walls, which is followed by transudation and oedema. The sufferer notices severe burning pain in the affected part, after which it assumes a waxy appearance and is painless. Blistering and then gangrene follow.

**Treatment**
- Frostbitten parts must be warmed very gradually. Any temperature higher than that of the body is detrimental. The part should be wrapped in cottonwool and kept at rest. Friction, e.g. rubbing with snow, may damage the already devitalised tissues. Warm drinks and clothing are provided and powerful analgesics are required to relieve the pain which heralds the return of circulation. Paravertebral injection of the sympathetic chain may be helpful in relieving associated vasospasm. Amputations should be conservative. Hyperbaric oxygen (Chapter 4) may help.

**Trench foot** is due to cold, damp and muscular inactivity; it is predisposed to by tight clothing, such as garters, puttees and ill-fitting boots. Prophylaxis is of paramount importance. Numbness is followed by pain, which is excruciating when boots are removed. The skin is mottled like marble and, in severe cases, blisters containing blood-stained serum develop; moist gangrene follows. The pathology is similar to that of frostbite and the treatment is essentially the same.

**Inadvertent intra-arterial injection of thiopentone** can happen when a high division of the brachial artery results in one of its two terminal branches, usually the ulnar, passing superficially downwards in the antecubital fossa. The appreciation by palpation of pulsation of the vessel and of the withdrawal of bright red blood prior to injection should prevent this calamity. Injection causes immediate and severe burning pain, with blanching of the hand. The needle should be left in position, and 5 ml of 1 per cent procaine and/or 2 per cent papaverine sulphate injected to reduce vascular spasm. Dilute heparin solution may also be given intra-arterially if the needle is in position. Intra-arterial thrombolysis and intravenous low molecular weight dextran may be employed. Brachial block should also be performed and repeated as necessary. Even so, gangrene of one or more fingers may occur.

**Drug abuse.** Inadvertent arterial injection of drugs is becoming common in many countries with significant numbers of drug addicts. usually the femoral artery in the groin is involved, and presentation is with pain and mottling distally in the leg. Often all pulses down to ankle level are retained. If pulses have been lost, angiography and intra arterial thrombolysis may be considered (possibly with dextran and heparin in addition). If pulses are retained, dextran and heparin may be given but there is no firm evidence of any efficacy in this condition. Many cases are self-limiting and resolve spontaneously. It should be remembered that many of these patients carry the human immunodeficiency virus (HIV) or have frank acquired immunodeficiency syndrome (AIDS).

**Chemical gangrene.** Carbolic acid (phenol) is the most dangerous, as anaesthesia masks the pain which occurs before the onset of gangrene. Carbolic compresses should never be used, for fingers have been lost by application of compresses even as dilute as 1:80. The gangrene is due to local arterial spasm. In addition, there is danger of severe systemic effects from absorption of phenol. Local bicarbonate soaks should be applied. Later, excision of the slough and skin grafting are necessary. **Ainhum** (Fig. 15.38), a disease of unknown aetiology, usually affects black males (but some females) who have run barefoot in childhood. Besides Central Africa, there are reports from Central America and the East. A fissure appears at the level of the interphalangeal joint of a toe, usually the fifth. This fissure becomes a fibrous band, which encircles the digit and causes necrosis. The treatment is either early Z-plasty or, later, amputation.

**Venous gangrene** is discussed in Chapter 16.
Amputation
Amputation should be considered when part of a limb is dead, deadly or a dead loss.

Dead
Arterial occlusion or stenosis, if sufficiently severe, will lead to tissue infarction with putrefaction of macroscopic portions of tissue (gangrene). The occlusion may be in major vessels (atherosclerotic or embolic occlusions) or in small peripheral vessels (diabetes, Buerger’s disease, Raynaud’s disease, inad-vertent intra-arterial injection, ergotism). If the obstruction cannot be reversed and the symptoms are severe, amputation is indicated.

Major amputation
Moebius—Stokes and through-knee amputations are rarely done nowadays. In the Moebius—Stokes type, the section is transcondylar.

Above-knee amputation

Choice of operation (Fig. 15.41)
When distal amputation facilities exist, above- or below-knee amputations are preferable because the best cosmetic and functional results can be obtained by the cone-bearing amputation tamps. (Note the words ‘cone-bearing’.) The term conical stump is reserved for an entirely different pathologi-cal entity — that which occurs when the growing humerus (or tibia), following amputation in a child, stretches the stump tissues and skin into an unsightly cone. (Main growth occurs in the epiphyses located ‘toward the knee and away from the elbow’. If limb-fitting facilities are limited, and bearing amputation may be preferable.) Long posterior flap below-knee amputation (Fig. 15.42). In cases of trauma a tourniquet is applied at the thigh, but not in cases of ischaemia. Anteriorly, the incision is deepened to bone and the lateral and posterior incisions are fashioned to leave the bulk of the gastrocnemius muscle attached to the flap, muscle and flap being sutured back at the same level. The amputation is refashioned at a higher level. Blood vessels are identified and ligated. Nerves are not clamped but pulled down gently and transected as high as possible. Vessels in nerves are ligated. The fibula is divided 2 cm proximal to the level of tibial diaphysis. The skin and muscle ends are brought together at the same level, and bearing amputation may be preferable. (May, Gritti—Stokes) so that simple prostheses (peg leg or simple boot) can be used. Syms’s amputations are not suitable for severely ischaemic atherosclerotic limbs because of the poor healing of the heel flap.

Postoperative care of an amputation
Pain relief
Diamorphine or other opiates should be given regularly (Chapter 6).

Care of the good limb
Attention is fixed on the amputation. but a pressure ulcer on the good foot will delay mobilisation, despite satisfactory healing of the stump. The use of a cradle to keep the weight of bed clothes off the foot and pressure area care are adjuncts to good nursing care.

Exercises and mobilisation
Individual exercises for the preservation of flexion deformity can be achieved by the use of a cloth or plaster over the stump with sand bags on each side to weight it down. Once the drain has been removed, exercises are started to build up muscle power and co-ordination. A stump bandage is applied each day to mould the shape of the stump. Mobility is progressively increased with walking between bars and the use of an inflatable artificial limb which allows weight-bearing to be started before a pylon or temporary artificial limb is read (Fig. 15.43). It is emphasised that the whole episode in the patient’s lifetime should be conducted in an attitude of promotion through the

Physiotherapy
Before the operation enables the patient to get used to the exercises that will prevent muscle wasting and flexion deformity of the hip. Antibiotics should be given with the premedication to prevent clostridial infection (Chapter 6), particularly in above-knee amputations.

Amputees
The stump is maintained up to the time of operation (and see Postoperative care of an amputation in Chapter 6).

Assessment of joints
Flexion contracture or severe arthritis may influence the level of amputation and/or the final degree of mobility.
stages towards full independence. Early assessment of the home (part of the whole programme) allows time for minor alterations, such as the addition of stair rails, movement of furniture to give support near doors, and clearance in confined passages.

**Complications**

*Early* complications include the following: reactionary haemorrhage, which requires return to the theatre for operative haemostasis; a haematoma, which requires evacuation; and infection, usually from a haematoma. Any abscess must be drained. Depending upon the sensitivity reactions of the organisms cultured, the appropriate antibiotics are given. Gas gangrene can occur in a midthigh stump, the organisms coming from contamination by the patient’s faeces. Wound dehiscence and gangrene of the flaps are due to ischaemia; a higher amputation may well be necessary. Amputees are at risk of deep vein thrombosis and pulmonary embolism in the early postoperative period. Prophylaxis with subcutaneous heparin 5000 units twice daily is advised for several weeks after operation.

*Late.* Pain is sometimes a problem due to unresolved infection (sinus, osteitis, sequestrum), a bone spur, a scar adherent to bone, an amputation neuroma from the outgrowth of nerve fibrils which become attached to skin, muscle or fibrous tissue, or a phantom limb. 

**Phantom pain.** Patients frequently remark that they can feel the amputated limb and sometimes that it is painful. The surgeon’s attitude should be one of firm reassurance that this sensation will disappear. Other late complications include ulceration of the stump due to pressure effects of the prosthesis or increased ischaemia. Rarely, an ulcer is artefactual *(Fig. 12.16)*. Some patients are troubled by cold and discoloured stumps, especially during the winter.
Arterial dilatation (aneurysm)

Dilatations of localised segments of the arterial system are called aneurysms. They can either be true aneurysms, containing the three layers of the arterial wall in the aneurysm sac, or false aneurysms, having a single layer of fibrous tissue as the wall of the sac, e.g. aneurysm following trauma (Fig. 15.44). Aneurysms can also be grouped according to their shape [fusiform, saccular (Fig. 15.45), dissecting], or to their aetiology [atherosclerotic, traumatic, syphilitic, collagen disease (Marfan’s syndrome), mycotic]. The term mycotic is a misnomer because, while it indicates infection as a causal element in the formation of the aneurysm, this is hardly ever due to a fungus. In general, mycotic aneurysms are due to bacteria. Aneurysms occur all over the body in major vessels such as the aorta, femoral, popliteal, subclavian and carotid arteries, or in smaller vessels, such as the cerebral, mesenteric, splenic and renal arteries. The majority is true fusiform atherosclerotic aneurysms.

Symptoms

All aneurysms can cause symptoms due to expansion, thrombosis, rupture or the release of emboli. The symptoms relate to the vessel affected, the site supplied or the tissues compressed by the aneurysm. Emboli from an aortic aneurysm can occasionally cause ischaemia of the toes and thrombotic occlusion of a popliteal aneurysm is a well-recognised cause of gangrene of the foot.

Clinical features of an aneurysm

Intrinsic

A swelling exhibiting expansile pulsation is present in the course of an artery. The pulsation diminishes if proximal pressure can be applied; the sac itself is compressible (although large aneurysms are frequently full of mural thrombus and may not be compressible), filling again in two or three beats if proximal pressure is released. A thrill may be palpable and auscultation sometimes reveals a bruit.

Extrinsic

Neighbouring or distal structures are affected. Thus pressure on veins or nerves causes distal oedema or altered sensation. Bones, joints or tubes, such as the trachea or oesophagus, are sometimes affected, but structures which are resilient, such as the intervertebral discs, often withstand prolonged pressure.

Differential diagnosis

Swelling under an artery

An artery may be pushed forwards, e.g. the subclavian by a cervical rib, and thus rendered prominent. Careful palpation distinguishes this condition.

Swelling over an artery

Transmitted pulsation is liable to be mistaken for that caused by expansion. However, posture may diminish pulsation; thus a pancreatic cyst examined in the genupectoral position falls away from the aorta, and consequently pulsation is less definite.

Pulsating tumours

Pulsating tumours include bone sarcoma, osteoclastoma and metastasis, especially from a hypernephroma.

An abscess

Before making an incision into a swelling believed to be an abscess, e.g. of the chest wall (Fig. 15.46), in the groin, in the axilla or in the popliteal fossa, it is essential to make sure that it does not pulsate. This mistake has been made many times.

A serpentine artery

A serpentine artery, e.g. innominate, carotid.
Abdominal aortic aneurysm

Abdominal aortic aneurysm is the commonest type of aortic aneurysm and is found in 2 per cent of the population at autopsy; 95 per cent are due to atherosclerosis and 95 per cent occur below the renal arteries.

Symptomatic aneurysms cause either minor symptoms, such as back pain and abdominal pain, or sudden, severe symptoms when they expand and rupture.

Asymptomatic aneurysms are found incidentally on physical examination, radiography or ultrasound investigation.

Ruptured abdominal aneurysm

Abdominal aortic aneurysms can rupture anteriorly into the peritoneal cavity (20 per cent) or posteriorly into the retroperitoneal space (80 per cent). Less than 50 per cent of patients survive to reach hospital.

Anterior rupture results in free bleeding into the peritoneal cavity. Very few of these patients reach hospital alive. Those who do have had a prolonged period of hypotension and shock, and consequently the results of surgery are poor.

A posterior rupture generally heralds a haemorrhage (Fig. 15.47). There is a brief period in many of these patients when a combination of moderate hypotension and the resistance of the retroperitoneal tissues stops the haemorrhage. The patient remains conscious, but in severe pain. If no operation is performed, the mortality is 100 per cent. Operation results in a better than 50 per cent survival.

Anterior rupture is treated surgically, the clinical scene being made early. The clinical features include sudden, severe back pain, accompanied in some cases by a brief loss of consciousness. The femoral pulses in one or both groins may be diminished or absent. A pulsatile mass is palpable in the abdomen and there are signs of shock. The procedure is as follows.

- Two good intravenous infusion lines and a central venous pressure line must be inserted as soon as the patient arrives in hospital or the diagnosis made on admission.
- Blood is sent for immediate cross-match of 8 units.
- Infusion of saline, or volume-expanding fluids (Chapter 4), is given to raise the systolic blood pressure to approx. 100 mmHg. On no account should the blood pressure be allowed to rise unduly as further uncontrolled haemorrhage may be stimulated.
- A urinary catheter is passed.
- If the patient appears to be unstable, although in pain, the operation may be delayed until cross-matched blood is ready but the patient should still be transferred immediately to the operating room so that surgery may be commenced immediately if haemodynamic problems develop.

Aneurysm without rupture

Patients most commonly present without symptoms although they may have pain, usually felt in the back in the lumbar region and in the upper abdomen. In addition, pain can occur in the thigh and groin due to nerve compression. Gastro-intestinal, urinary and venous symptoms can also be caused by abdominal aneurysm. As a general rule, in the presence of a pulsatile mass if symptoms cannot be reasonably explained by another lesion, they must be assumed to be due to the aneurysm (until proved otherwise) and the aneurysm placed in the symptomatic group.

Investigations

Symptomatic aneurysm

Without surgery, 80 per cent with a symptomatic aneurysm will be dead in a year. With surgery, 80 per cent will be alive in a year. Surgery is indicated, therefore, in patients with symptoms or without symptoms clinically. If the presence of hypertension, haematuria, or the presence of an abdominal mass is found in the clinical history and investigation, the mortality from intervention is acceptably high and the benefits of operation are clear.

Arteriovenous fistula (AVF)

Communication between an artery and a vein (or veins) may be either a congenital malformation, or acquired by the trauma of a penetrating wound or a sharp blow. Arteriovenous fistulas are also created surgically in the arms or legs of patients undergoing renal dialysis (Chapter 64). All arterio-venous communications have complications to prevent amputation, and in asymptomatic cases, to prevent complications. Diagnosis can be difficult and relies on palpation of a pulsatile mass which is raised or sitting above the aneurysm. Treatment is either a bypass-graft with ligation of the aneurysm or an inlay graft.

Aortography, computerised tomography (CT) and/or magnetic resonance imaging are essential (Figs 15.48–15.50 and 15.51).

Aortoduodenal fistula

Aortoduodenal fistula is an uncommon but treatable complication of abdominal aortic replacement surgery. It should be suspected whenever haematemesis or melaena occurs. A combination of moderate hypotension and a pulsatile mass can be detected in the retroperitoneum and the, aorta is palpable. An abdominal aortogram will confirm the diagnosis.

Open surgical procedure (Fig. 15.52 and Fig. 15.53)

The patient is placed in the supine position with the anterior surface of the abdomen accessible. Under general anaesthesia, with the patient lying supine with a urinary catheter and central venous line in place, a full-length midline or upper transverse incision is made. The small bowel is lifted to the patient’s right and the aorta identified. The peritoneum overlying the aorta is opened and the upper limit of the aneurysm is identified. A plane is sought between the aorta and vena cava below the left renal vein. The iliac arteries are then dissected free from surrounding structures, haemostasis is achieved, and clamps are applied above and below the aneurysm. The aneurysm is opened longitudinally to the right of the inferior mesentric artery, and back-bleeding from lumbar and mesenteric vessels controlled by sutures placed within the aneurysm sac. The graft is then sutured end to side into the aneurysm sac (20 or 3/0 Prolene). The upper clamp is released and haemostasis achieved. The lower end is then sutured to the aortic bifurcation in a similar manner. Clamps are released carefully, to one leg at a time, because hypotension and arrhythmias can occur if release is too rapid. The aneurysm sac is then closed round the graft (Fig. 15.54) and the posterior peritoneum closed to exclude the graft and suture lines from the intestine (to reduce the risk of fistula formation).

The abdomen is then closed in layers. Occasionally, when the iliac vessels are also involved with dilatation or severe atheroma, it is necessary to construct an aorto-bi-iliac or aorto-bifemoral bypass, rather than use a simple aorto-iliac tube graft.

Endoluminal stent-graft procedure

Many major vascular surgical centres are now able to offer this minimally invasive treatment for certain aortic aneurysms, generally on an elective or a semi-elective basis. A stent-graft is a tube of Dacron or other material, with the stent providing structural support to prevent kinking of the graft and the resistance. A short length of the tube is placed within the common femoral artery, which are exposed surgically. Under radiological control, a delivery system is guided up into the aorta and a stent-graft placed within the aortic sac; this usually comprises aortic body and one iliac, the opposite iliac being replaced by a separate single iliac stent-graft introduced from the common femoral artery. The stent system must be able to produce a blood-tight seal at the uppermost (infrarenal aortic) level of the graft, and this is achieved at the junction of the aorto-uni-iliac stent-graft and its contralateral iliac partner. The technique has been carried out successfully in almost every patient so far in a few thousand patients world-wide but concerns remain about stent-graft fragmentation with the passage of time, and leakage (endoleak) at the interface of vessel and stent-graft or from patent lumbar arteries.

Postoperative complications

The commonest complications following open repair of abdominal aortic aneurysms are respiratory (lower lobe consolidation, atelectasis and ‘shock lung’). Haemorrhage occurs in relatively few cases provided anticoagulation is not continued beyond the immediate operative period and haemostasis is satisfactory at the end of the procedure. A degree of colonic ischaemia due to lack of collateral blood supply occurs in 10 per cent of all cases; fortunately this severe complication usually resolves spontaneously. Renal failure and infection of the graft are rarely seen following nonurgent procedures, but can complicate procedures for repair of ruptured aneurysm. Other complications are sexual dysfunction, fistula formation and spinal cord ischaemia.

Aneurysm elsewhere

Aneurysms of the thoracic aorta are uncommon but treatable complications of abdominal aortic replacement surgery. It should be suspected whenever haematemesis or melaena occurs in the months or years after surgery. A successful outcome may be achieved by prompt operation, separating aorta from duodenum, closing the holes and interposing some omentum.

Peripheral aneurysm

Popliteal aneurysm accounts for 70 per cent of all peripheral aneurysms. Two-thirds of them are bilateral. Three-quarters develop complications within 5 years if treated conservatively. Careful examination of the abdominal aorta is indicated if a popliteal aneurysm is found because one-third are accompanied by aortic aneurysms, and are obviously at risk due to possibility of embolism following atheroma, or ischaemic ulceration of the toes due to embolism. Surgery, possibly preceded by intra-arterial thrombolysis, is indicated urgently in the presence of complications, in asymptomatic cases, to prevent complications. Diagnosis can be difficult and relies on palpation of a pulsatile mass behind the knee. As a general guide, if the popliteal pulse is easily felt in a patient who is not thin, the presence of an aneurysm should be considered. Ultrasound and CT scan can be helpful in confirming the diagnosis. Treatment is either a bypass-graft with ligation of the aneurysm or an inlay graft.

False aneurysm of the femoral artery is usually due to the atherosclerotic process. Complications occur in less than 3 per cent and so conservative treatment is indicated initially. Look for aneurysm elsewhere: more than half are associated with abdominal or popliteal aneurysms.

False aneurysm of the femoral artery occurs in 2 per cent of patients after arterial surgery at this site. Many are infective in origin and rupture is possible, making surgical treatment indicated. Local repair with reanastomosis at the groin under suitable antibiotic cover may be successful, but bypass, clear of the infected area, with subintimal excision of infected material, is the only way of preventing further problems.

Iliac aneurysm (Fig. 15.55) usually occurs in conjunction with aortic aneurysm and rarely occurs on its own. On its own, it is difficult to diagnose clinically and so 50 per cent present already ruptured. Surgical treatment is indicated, with bypass, and exclusion of the aneurysm by ligation above and below the dilation.

Treatment of aneurysm at the aortic bifurcation may require cardiopulmonary bypass for reconstruction to be undertaken. These, together with dissecting aneurysms of the thoracic aorta and traumatic false aneurysms in that situation, are considered in Chapter 48.

Arteriovenous fistula (AVF)

Infection between an artery and a vein (or veins) may be either a congenital malformation, or acquired by the trau-ma of a penetrating wound or a sharp blow. Arteriovenous fistulas are also created surgically in the arms or legs of patients undergoing renal dialysis (Chapter 64). All arterio-venous communications have a structural and a physiological effect.

Structural effect
The structural effect of arterial blood flow on the veins is characteristic as they become dilated, tortuous and thick walled (arterialised) (Fig. 15.56). It also makes the lesions diffuse and so renders surgical procedures difficult.

**Physiological effect**
The combination of an uncontrolled leak from the high-pressure arterial system and an enhanced venous return and venous pressure results in an increase in pulse rate and cardiac output. The pulse pressure is high if there is a large and persistent shunt. Left ventricular enlargement and, later, cardiac failure occur. A congenital fistula in the young may cause overgrowth of a limb. In the leg, indolent ulcers may result from relative ischaemia below the short circuit.

**Clinical signs**
Clinically, a pulsatile swelling may be present if the lesion is relatively superficial. On palpation, a thrill is detected and auscultation reveals a buzzing continuous bruit. Dilated veins may be seen, in which there is a rapid blood flow. Pressure on the artery proximal to the fistula causes the swelling to diminish in size, the thrill and bruit to cease, the pulse rate to fall [known variously as Nicoladoni’s (1875) or Branham’s (1890) sign] and the pulse pressure to return to normal.

**Arteriography**
Arteriography confirms the lesion, which is noteworthy for the speed with which venous filling occurs. It is often difficult to pinpoint the actual site of the fistula.

**Treatment**
Embolisation by the radiologist or excision is advocated only for severe deformity or recurrent haemorrhage. It is often wise to enlist the aid of a plastic surgeon so that proper ablation and reconstruction can be effected. Ligation of a ‘feeding’ artery is of no lasting value and is likely to be detrimental as it may preclude treatment by embolisation.

The acquired lesions especially tend to be progressive and embolisation or operation is indicated if feasible and safe. At operation the vessels are separated and, if possible, repaired by suture, any intervening sac being excised. Failing this, ligation of the involved artery and vein is required both above and below the lesion (quadruple ligation). Bypass grafts may be required.
Arteritis

Thromboangiitis obliterans (Buerger's disease)

This is a condition characterised by occlusive disease of the small and medium-sized arteries (plantars, tibials, radial, etc.), thrombophlebitis of superficial or deep veins, and Raynaud’s syndrome occurring in male patients in a young age group (usually under the age of 30 years). Usually one or two of the three manifestations are present and occasionally all three. The condition does not occur in women or nonsmokers. It is not, as used to be stated, more common in Russian Jews; cases are seen in different races all over the world. Histologically, localised inflammatory changes occur in the walls of arteries and veins leading to thrombosis. The usual symptoms and signs of arterial occlusive disease are present. Gangrene of the toes and fingers is common and progressive. Arteriography sometimes shows a characteristic ‘corrugation’ of the femoral arteries as well as the distal arterial occlusions and helps to distinguish the condition from presenile atherosclerosis. Other forms of arteritis, e.g. polyarteritis nodosa, must be excluded.

Investigations

A formal vascular assessment should be undertaken, e.g. ESR, autoantibodies, coagulation screening and lipid profile.

Treatment

The treatment is total abstinence from smoking. While this will arrest the disease it will not reverse established arterial occlusions. A mere reduction in smoking is not sufficient to prevent the relentless progression of this devastating condition. Established arterial occlusions may be treated along the usual lines and sympathectomy may be a useful adjunctive procedure. Nevertheless, amputations, conservative if possible, may eventually be required.

(Other types of arteritis)

Other types of arteritis are encountered in rheumatoid arthritis, diffuse lupus erythematosus and polyarteritis. Treatment is similar. Diabetes was discussed earlier.

Temporal, occipital and ophthalmic arteritis

Localised infiltration with inflammatory and giant cells leads to arterial occlusion, ischaemic headache and tender, palpable, pulseless (thrombosed) arteries in the scalp. The major catastrophe of irreversible blindness occurs when the ophthalmic artery is occluded. A raised ESR and a positive temporal artery biopsy call for immediate prednisolone therapy to arrest and reverse the process before the ophthalmic artery is involved. The dose must be reduced as soon as possible, in line with clinical improvement and a fall in the ESR, to a maintenance dose which is controlled under long-term surveillance.

Takayasu’s arteriopathy

Takayasu’s arteriopathy (syn. obliterative arteritis of females, pulseless disease) causes narrowing and obstruction of major arteries. It usually pursues a relentless course (Fig. 15.57).

Cystic myxomatous degeneration

An accumulation of clear jelly (like a synovial ganglion) in the outer layers of a main artery may occasionally be encountered, especially in the popliteal artery. The lesion so stiffens the artery that pulsation disappears and claudication occurs when the limb is flexed (as on walking up stairs). Arteriography shows a smooth narrowing of an otherwise normal artery and a sharp kink or buckling when the knee is flexed. Decompression, by removal of the myxomatous material, is all that is required, but the ganglion may recur and require excision of part of the artery with interposition vein graft repair.
Vasospastic conditions

Raynaud’s syndrome

Raynaud’s syndrome may be primary or secondary. The primary idiopathic form usually occurs in young women and affects the upper extremities more than the lower. The peripheral pulses are normal. The condition is attributable to abnormal sensitivity in the direct response of the arterioles to cold. When cooled, these vessels constrict and, as a result, the part (usually the fingers) becomes blanched and incapable of finer movements. The capillaries then dilate and fill with slowly flowing deoxygenated blood, the digits therefore becoming swollen and dusky. As the attack passes off, the arterioles relax, oxygenated blood returns into the dilated capillaries and the digits become red. Thus the condition is recognised by the characteristic sequence of blanching, dusky cyanosis and red engorgement, often accompanied by pain. In the idiopathic form, superficial necrosis is very uncommon. Early cases must be distinguished from chilblains and vascular disturbances sometimes associated with the costoclavicular syndrome, and from the other causes of secondary Raynaud’s syndrome.

Conservative treatment

Protection from cold and avoidance of pulp and nail-bed infections are part of the conservative regimen that is advised for mild cases. The use of calcium antagonists, such as nifedipine, may also have a role to play and electrically heated gloves can be useful in winter. Sympathectomy has been discredited in this condition.

Secondary Raynauds syndrome

This was previously called Raynaud’s disease (a term to be avoided). Although peripheral vasospasm may be noted in atherosclerosis, thoracic outlet syndrome, carpal tunnel, etc., the term secondary Raynaud’s syndrome is most often used for a peripheral arterial manifestation of the collagen diseases, especially progressive systemic sclerosis (scleroderma) and systemic lupus erythematosus. It may also follow the use of vibrating tools (when it is commonly known as ‘vibration white finger’), e.g. pneumatic road drills, mining boring and chain saws, which vibrate at certain frequencies.

Treatment

Treatment is directed primarily at the underlying condition, although the conservative measures outlined above are often helpful. The syndrome when secondary to the collagenoses leads frequently to necrosis of digits and multiple amputations. Sympathectomy yields disappointing results and is rarely used. Nifedipine, steroids and vasospastic antagonists may all have a place. Patients with vibration white finger should avoid vibrating tools.

Acrocyanosis

Acrocyanosis, crurum puelurarum frigidum^2, may be confused with Raynaud’s disease, but it is painless and is not paroxysmal. Affecting young females, the cyanosis of the fingers and, especially, the legs may be accompanied by paraesthesia and chilblains. In severe cases, sympathectomy may be tried. If merely affecting the calves, a differential diagnosis is Bazin’s disease.

Preganglionic cervicodorsal sympathectomy

Supraclavicular method. Through a supraclavicular incision, the clavicular part of the sternomastoid, the posterior belly of the omohyoid and the scalenus anterior muscles are divided, the phrenic nerve being divided medially. The subclavian artery is exposed and depressed; the subpleural fascia is divided so that the dome of the pleura can be displaced downwards. The stellate ganglion is identified as it lies on the first rib (Fig. 15.55). The sympathetic trunk is traced downwards and divided below the third thoracic ganglion. All rami communicantes associated with the second and third ganglia and the nerve of Kuntz, a grey ramus running upwards from the second thoracic ganglion to the first thoracic nerve, are meticulously divided. Occasionally, the approach is undera high arching subclavian artery.

Transthoracic method. This gives a greater exposure and facilitates the removal of the sympathetic chain from the fifth ganglion up to the lower fringe of the stellate ganglion. It tends to give better results than the supraclavicular method and can be employed when that has failed. In women where cosmetic effects are a consideration, the approach can be made via an axillary incision through the third space (Hedley Atkins). The sympathetic chain is easily seen and after dividing the pleura, it is dissected out, care being taken to avoid damage to the intercostal vessels, which may cause tedious haemorrhage. Care should also be taken, when making and suturing the approach wound, to avoid damage to the nerve to seratus anterior, giving rise to ‘winging’ of the scapula.

Endoscopic method. This seeks to achieve a sympathectomy via the transthoracic route using a suitable endoscope, e.g. a cystoscope or laparoscope. A Verres needle is passed via the axilla to induce a CO₂ pneumothorax. A trochar and cannula are then employed to introduce the endoscope. The sympathetic chain is visualised and a coagulating electrode used to disrupt the ganglia. Some surgeons carry out the procedure without using CD₂, the lung being simply deflated by the anaesthetist using a double-lumen endotracheal tube. The endoscopic method is now the procedure of choice for cervicodorsal sympathectomy.

Lumbar sympathectomy

Operative method. Using a transverse loin incision, an extraperitoneal approach is used in which the colon and peritoneum, to which the ureter clings, are stripped medially so as to expose the inner border of the psoas muscle (Fig. 15.56). The sympathetic trunk lies on the sides of the bodies of the lumbar vertebrae; on the right side it is overlapped by the vena cava. Lumbar veins are apt to cross the trunk superficially. The sympathetic trunk is divided on the side of the body of the fourth lumbar vertebra. It is then traced upwards to be divided above the large second lumbar ganglion, which is easily recognised by the number of white rami which join it. Care should be taken not to mistake small lymph nodes, lymphatics, the genitofemoral nerve or the occasional tendinous strip of the psoas minor for the sympathetic chain. It is possible to perform the operation via an endoscope after the creation of a suitably expanded retroperitoneal tissue plane. Along with a decline in the recognised indications for sympathectomy there has been a move away from the operative approach in favour of the less hazardous chemical (phenol) sympathectomy.

Chemical method. This is contraindicated in patients taking anticoagulants. Under radiographic fluoroscopic control, with the patient in the lateral position, local anaesthetics is injected. A long spinal needle is then inserted (Fig. 15.56) to seek the side of the vertebral body and to pass alongside it to reach the lumbar sympathetic chain. After confirming the needle position by injection of contrast agent, approximately 5 ml of phenol in water (1:16) is injected. This is usually done at two sites: beside the bodies of the second and fourth lumbar vertebrae. Great care is needed to avoid penetrating the aorta, cava or ureter; the plunger of the syringe must always be drawn back before injection to exclude the presence of blood.
Further reading
Introduction

Venous disorders are very common and especially affect the lower limb. Twenty per cent of the population suffer with varicose veins and 2 per cent have skin changes which may precede venous ulceration. At any one time 200 000 people in the UK have active venous ulceration. The provision of wound care and bandaging costs the National Health Service £600 million per annum.
Anatomy of the venous system in the limbs

Arterial blood flows through the main axial arteries to the upper and lower limbs. It returns via the deep and superficial veins. In the upper limb the superficial veins are more important in carrying blood back to the heart. In the lower limb, the superficial veins carry only about 10 per cent of the blood, while the remainder passes via the deep veins. The superficial veins lie superficial to the muscle fascia of the limb. The principal superficial veins in the leg are the long and short saphenous veins (Fig. 16.1). In the arm, the cephalic and basilic veins are the principal superficial veins.

Interestingly, venous diseases occur much more frequently in the lower limb than in the upper limb, and most often in the superficial veins. The deep veins of the lower limb may be the site of life-threatening venous thrombosis or venous valvular incompetence resulting in leg ulceration. Each major axial artery has at least one and often a pair of accompanying veins named after the artery (Fig. 16.2). The superficial and deep veins join at a number of points. The short saphenous vein terminates at the saphenopopliteal junction (SPJ) and the long saphenous vein at the saphenofemoral junction (SFJ) in the groin. Here the flow in the superficial veins joins that in the deep veins. There is, in addition, a number of places in the calf and thigh where flow in the superficial veins may also join that in the deep veins. These is the ankle, calf and thigh communicating or perforating veins (Fig. 16.3). The names of these veins come from their course from the superficial to the deep venous system in which they perforate the deep fascia of the leg. Near the ankle are the Cockett perforating veins, near the knee the Boyd perforators and in the thigh the Hunterian perforating vein. All veins in the upper and lower limbs contain valves every few centimetres which ensure that blood flows towards the heart.
Venous pathophysiology

Blood flows into the leg because it is pumped by the heart along the arteries. By the time it emerges from the capillaries it is at a low pressure (about 20 mmHg), but this is enough for the blood to return to the heart. Blood from the muscles of the leg returns through the deep veins. Blood from the skin and superficial tissues, external to the deep fascia, drains via the long and short saphenous veins — SFJ and SPJ — and communicating veins into the deep veins. Valves prevent the flow of blood from the deep to the superficial system.

The venous pressure in the foot vein on standing is equivalent to the height of a column of blood, extending from the heart to the foot. Depending on the height of the person, this can be 80—100 mmHg. However, the same is true of the arterial system so that on standing the arterial blood pressure at the ankle rises by 80—100 mmHg.

In the venous system there is a sophisticated series of muscle pumps that act as peripheral hearts. The calf and thigh muscles are surrounded by muscle. In addition, there is a foot pump which everts the plantar veins as pressure is placed on the foot during walking. On exercise, the calf and thigh muscles contract, compressing the veins and ejecting blood towards the heart. The direction of venous blood flow is controlled by the venous valves. The pressure within the calf compartment rises to 200—300 mmHg during walking and this is more than enough to propel the blood in the direction of the heart. During the muscle relaxation phase, the pressure within the calf falls to a low level and blood from the superficial veins flows through the perforating veins into the deep veins. The consequence of this is that the pressure in the superficial veins falls during walking. This can be monitored by a cannula placed in a superficial vein of the foot and connected to a pressure transducer. Normally the pressure in the superficial veins of the foot and ankle falls from a resting level of 80—100 mmHg to about 20 mmHg.

This ability to reduce the pressure in the superficial venous system is crucial to the health of the lower limb. Patients with damage to the veins in whom the superficial venous pressure does not fall during exercise may develop varicose eczema, skin damage and, eventually, leg ulceration.
Venous Incompetence - varicose Veins

One of the most common problems with the veins of the leg is failure of their valves. This occurs frequently in the superficial venous system resulting in varicose veins, which affect 10—20 per cent of the adult population in Westernised countries. In developing countries, where a primitive way of life is maintained, there is a very low incidence of varicose veins. The reasons for this difference are unclear but are probably related to differences in diet. A further major factor is inheritance: women in whom neither parent has varicose veins have a 10 per cent risk of developing varices, but when both parents are affected there is an 80 per cent chance. Men are affected less frequently than women.

The mechanisms that cause the superficial vein valves to fail have not been fully established. What appears to happen is that first a small gap appears between the valve cusps at the commisure (where the valve leaflets join the vein wall). This gap widens and more reverse flow (venous reflux) is allowed. The valve cusps degenerate and holes develop in them. Eventually they disappear completely (Fig. 16.7). The vein below the valve responds by dilating. Varicose veins may eventually reach five times their usual size if left to develop for long enough.

In the past it was thought that varicose veins were caused by anatomical abnormalities in the deep vein valves. It is now clear that this is not true. Varicose veins often develop in the calf when the veins above are normal. This seems to be a process where congenital and environmental factors accumulate to cause valve failure.

Varicose veins are thought to develop more often in people who stand during their work. People who sit or walk are at less risk of developing varices. They often develop during pregnancy under the influence of oestrogen and progesterone which cause the smooth muscle in the vein wall to relax.

Clinical features

Varicose veins are very common; they may either give no symptoms or cause aching and discomfort in the legs. Varices are recognised as tortuous dilated veins in the leg, but physiologically speaking a varicose vein is one which permits reverse flow through its faulty valves. Varices of the major tributaries of the saphenous veins or the saphenous veins themselves are large (5—15 mm diameter) and usually start in the calf (Fig. 16.8). Later varices of the long saphenous system may also appear in the thigh. Patients may develop much smaller varices. These range from 0.5-mm diameter vessels in the skin, which are commonly referred to as thread veins or dermal flares, and are usually purple or red in colour. Slightly larger veins (1—3 mm diameter) lying immediately beneath the skin may also present as small varicosities. These are usually referred to as reticular varices. The association of thread veins and reticular varices is frequently seen, and these probably reflect a type of varicose veins which is confined to the smallest size of vein. These tiny veins are associated with superficial venous incompetence in about 30 per cent of cases. They require different treatment from large varices (Fig. 16.9). The combination of small varicosities and much larger truncal and tributary varices is often seen, but each type may occur on its own. The symptoms reported by patients affected by either type of varices are very numerous. Often there are no specific symptoms but the cosmetic appearance is unsatisfactory. Patients may also report aching especially on standing, itching, ‘restless legs’ and ankle swelling. The severity of the symptoms is unrelated to the size of the veins, and is often more severe during the early stages of development of varices.

Complications of varicose veins

Occasionally complications of varicose veins may develop. These include thrombosis, which is referred to as superficial thrombophlebitis. Usually this remains in the superficial veins and may cause considerable discomfort. Sometimes thrombosis extends into the deep venous system to cause deep vein thrombosis, although this is infrequent. Spectacular haemorrhage can occur when large superficial varices are damaged. This is easily controlled by lying the patient down, elevating the leg and applying a compression bandage. The most serious problem is venous ulceration which complicates varicose veins in less than 5 per cent of patients. However, it is a troublesome and painful condition which requires careful management if the ulcer is to heal.
Valvular incompetence of the deep veins may develop in the same way as in the superficial venous system, with the degeneration of the valve cusps resulting in reverse flow in these veins. In other patients it may develop following a deep vein thrombosis. When the deep veins fill with thrombus a new channel appears (recanalisation) after a number of weeks or months. However, the deep vein valves are destroyed by this process and, although the veins carry blood, the valves no longer work and reverse flow is allowed. Some veins are severely scarred by the recanalisation process so that they also become very narrow and ineffective at carrying blood. Occasionally veins fail to recanalise at all. This is sometimes seen following a venous thrombosis in the iliac veins. Under these conditions the blood must find an alternative way round the blockage and collateral veins develop. In the leg the long and short saphenous veins may act as collateral channels and may double in size to accommodate the additional blood flow. In patients with chronic iliac vein occlusion large suprapubic or abdominal varices may be seen carrying the collateral flow.

Clinical features of deep vein incompetence

A number of patients with severe deep vein damage has little to show for their problems. In patients with venous valvular incompetence the calf muscle increases in size, apparently in response to the greater work in returning blood from the leg. There may be some ankle oedema, especially in those patients who have persistent venous obstruction. A proportion of patients develops skin complications. These may range from mild eczema to severe ulceration. An early sign of skin injury is brown pigmentation due to haemosiderin deposition in the skin. This occurs because the high venous pressures which result from damage to the muscle pumping mechanism cause red blood cells to be forced out of capillaries in the skin where their haemoglobin breaks down to form haemosiderin. A later and more serious stage is lipodermatosclerosis in which palpable induration develops in the skin and subcutaneous tissues. This particularly affects the gaiter area of the leg, just above the malleoli, and may be the precursor of leg ulceration. Contraction of the skin and subcutaneous tissues is seen and the ankle becomes narrower. The combination of a narrow ankle and prominent calf is often referred to as a 'champagne bottle leg' (Fig. 16.10). Atrophie blanche may also develop. In this condition the superficial blood vessels are lost from the skin and white patches develop. These indicate that the skin has been severely damaged by the venous valvular incompetence. Venous ulceration may develop in these areas.

Patients may remain untroubled by many of these symptoms and may not seek medical advice until venous ulceration develops. Even then, it is thought that less than half of the patients with venous leg ulcers are known to their general practitioners (Fig. 16.11).

Effects of deep and superficial venous incompetence on the vascular physiology of the leg

When the venous valves fail, the ability of the muscle pumps to reduce the pressure in the leg is decreased. Following muscle contraction blood may return to the leg rapidly by flowing in the reverse direction along deep or superficial veins. Incompetence of the deep veins usually has a more severe effect on the venous physiology than does superficial venous incompetence as the deep veins are much larger than the superficial veins. The effect of reverse flow in the deep or superficial veins is to prevent the superficial venous pressure from falling during exercise. This is referred to as 'ambulatory venous hypertension' and is the main cause of venous leg ulceration. Persistently raised venous pressure tracks back to the microcirculation of the skin and causes skin damage that eventually may result in venous ulceration.

In some patients veins remain permanently blocked following a deep vein thrombosis leading to the blood experiencing difficulty leaving the leg. This usually causes worse symptoms than venous valvular incompetence alone. Swelling of the leg, especially ankle oedema, is often a feature in patients with persistent venous obstruction. In many cases the passage of time allows deep veins to recanalise and the ankle oedema may then become less severe. However, the recanalised veins are likely to be incompetent and the features of venous hypertension may then predominate.

How does ambulatory venous hypertension cause leg ulceration?

The damage caused by venous hypertension in patients with venous disease is confined to the skin and subcutaneous tissues. The main focus of the damage is in the capillaries in the skin. These increase in size and length, and become very convoluted and are described as ‘glomerulus like’ (Fig. 16.12). The amount of capillary endothelium is increased in the skin and many more capillary loops are cut on histo-logical sections of damaged skin. This results in the development of a fibrotic process affecting the skin and subcutaneous fat which comprise the condition of lipodermatosclerosis. Around the capillaries are many inflammatory cells, especially macrophages. The combination of capillary proliferation and inflammation accounts for the appearance of liposclerotic skin, which looks inflamed. A perivascular cuff is present around the capillaries, which is made up of many connective tissue proteins including fibrin, collagen IV and fibronectin. This perivascular cuff is probably the result of chronic inflammation and occurs in many other types of inflammatory processes. It was originally thought that the fibrin cuff acted as a barrier to diffusion preventing nutrient exchange between the capillaries and the tissues. The ‘fibrin cuff’ hypothesis was accepted for many years as the explanation for venous ulceration. Research and theoretical calculations have shown that there is no physical barrier to the diffusion of nutrients to the tissues in this condition.

The factors which cause the inflammatory process have been sought. It has been shown that venous hypertension causes leucocyte sequestration in the microcirculation of the leg. Patients with chronic venous disease resulting in lipodermatosclerosis and venous ulceration trap more leucocytes than do subjects with normal limbs. It has been shown that these ‘trapped’ leucocytes become activated and release the proteolytic enzymes that are normally used in defence against infection. This, in turn, causes injury to the capillary endothelium. It seems likely that inappropriate activation of leucocytes instigates the series of events that results in leg ulceration. The fibrill mechanism is incompletely understood and further investigation of the processes involved may eventually lead to the development of better treatments for venous ulceration. This mechanism is referred to as the ‘white cell trapping hypothesis’ and was first proposed in 1988 (Fig. 16.13).
Investigation of venous disease

A full history should always be taken, enquiring about any injury to the leg or swelling which may suggest a previous episode of deep vein thrombosis. Patients report a wide range of symptoms associated with venous disease. These include tiredness, aching, tingling and ankle swelling which get progressively worse towards the end of the day and are relieved by elevating the leg. Sometimes patients report cramps in the legs, which are usually worse at night. Patients with more severe venous disease may notice the skin changes that occur. Pain in the calf on walking is usually attributable to lower limb arterial disease, referred to as intermittent claudication. Patients with severe deep vein obstruction may also develop bursting pain in the calf on walking, due to the very high venous pressures that may occur under these conditions.

A clinical examination carried out with the patient standing will reveal the extent of any varicose veins and whether they are associated with the long or short saphenous systems. Further information may be gained by using a tourniquet test (Brodie, 1846; Trendelenburg, 1890) to determine the source of varices. The tourniquet is often replaced by the hand of the examiner used to compress the long or short saphenous vein. The patient lies and the leg is elevated to empty the veins. The tourniquet is applied high on the thigh and the patient stands again. The speed with which the varices fill is observed. In the case of varicose veins from the long saphenous vein, filling occurs at a much faster rate than in the short saphenous vein. If filling is not controlled by an above-knee tourniquet, then a tourniquet is applied to compress the short saphenous vein, just below the knee. If the varices now fill slowly then the source of venous reflux is from the SFJ. If the varices continue to fill rapidly some further source must be the cause. The patient may have incompetent deep veins or a calf perforating vein. The success of tourniquet tests lies in the ability of the examiner to assess the varices and their rate of filling. This may be easy in the case of large varices, but can be very difficult with smaller varices. Considerable practice is required for successful application of these tests (Fig. 16.14).

The clinical examination should continue by noting the presence and extent of any skin changes or ulceration at the ankle. An examination of the peripheral pulses should be carried out. Venous and arterial disease of the lower limb often coexist, especially in more elderly patients. An abdominal examination completes the clinical examination in patients presenting with lower limb varices, as these may occasionally be the result of an abdominal neoplasm causing venous obstruction.

More detailed information than can be obtained from clinical examination is useful in the management of patients with primary varicose veins and essential in the management of patients with recurrent varices, a history of lower limb venous thrombosis or venous leg ulcers.

Doppler ultrasound

A Doppler assessment is now the minimum level of investigation required before treating somebody with venous disease. A Doppler probe is placed over a vein, and a bidirectional flow probe used to determine venous reflux. This investigation is carried out with the patient standing. The Doppler probe is first placed over the SFJ and the blood flow assessed to locate the venous flow in the common femoral vein. With one hand the examiner gently squeezes the calf to produce an acceleration of blood flow in the veins. This is heard as a ‘whoosh’ from the loudspeaker of the Doppler machine. The calf compression is released and any reverse flow in the veins sought. With practice it is possible reliably to identify venous reflux in the SFJ. The examination may be repeated with the probe held over the long saphenous vein in the mid-thigh region, to confirm that the venous reflux lies in the superficial vessels. Some surgeons use a tourniquet to occlude the superficial veins, in the same way as when performing a Trendelenburg test. The probe may also be held over the SFJ while the calf is compressed and released to test the competence of veins in this region. In the popliteal fossa it is more difficult to distinguish between deep and superficial venous incompetence (Fig. 16.15).

This method is very useful when examining patients with primary varicose veins, especially those which are thought to result from SFJ incompetence. The popliteal fossa contains many veins and if venous reflux is heard it is difficult to be certain from which veins it arises. However, in patients with primary varicose saphenopopliteal incompetence it is usually readily identified. All surgeons who regularly treat patients with varicose veins should be competent at this type of investigation. Where the source of recurrent varices or a leg ulcer is sought, duplex ultrasonography is usually more reliable.

Photoplethysmography and other plethysmographic techniques

In this investigation a probe is attached to the skin to assess venous filling of the surface venules by measuring light transmission of the skin. The filling of these vessels reflects the pressure in the superficial veins of the leg. The patient sits quietly until the trace stabilises. Then he or she performs a series of 10 dorsiflexions at the ankle. The venous pressure falls in the superficial veins of the leg and the skin venules empty, so the photoplethysmography (PPG) trace falls. The patient then sits and the veins refill. Under normal conditions venous refilling occurs through arterial inflow alone, a slow process taking 20 or 30 seconds when the limb is at rest. In patients with venous incompetence the veins also fill via venous reflux, which speeds the refilling process. Fast refilling times mean that one or more veins in the leg are incompetent. The test can be repeated after the application of a tourniquet above the knee to occlude the superficial veins, and then below the knee to occlude the deep veins. This helps to establish which set of superficial veins are incompetent (Fig. 16.16).

A number of other plethysmographic tests is used to evaluate the venous system physiology including the ai plethysmograph, light reflex rheography and strain gaug plethysmograph. These are usually used by vascular surgeon in vascular laboratories or by specialists in venous diseases All are used to quantify the impairment of venous function caused by obstructed or incompetent venous valves.

Duplex ultrasound imaging

This technique involves the use of high-resolution B-mode ultrasound imaging and Doppler ultrasound to obtain images of veins and simultaneously measure flow in these vessels. It allows direct visualisation of the veins and provides functional, as well as anatomical, information. Modern duplex ultrasound machines represent blood flow as a colour map which is superimposed on the greyscale image of the vessel. This technique is highly reliable in the investigation of arteries and veins, and is the most appropriate investigation to use when detailed analysis of the anatomy and physiology of the venous system is required.

The examination is performed with the patient standing. In this position the veins are filled and easily seen on the ultrasound image. The flow in the veins is assessed in exactly the same way as when using a hand-held Doppler probe. The examiner examines the vein that he or she wishes to study and compresses the calf with his/her hand to produce forward flow. This results in upward flow towards the heart in a normal vein. The patient then sits and the veins refill. Under normal conditions venous refilling occurs through arterial inflow alone, a slow process taking 20 or 30 seconds when the limb is at rest. In patients with venous incompetence the veins also fill via venous reflux, which speeds the refilling process. Fast refilling times mean that one or more veins in the leg are incompetent. The test can be repeated after the application of a tourniquet above the knee to occlude the long saphenous vein, and then below the knee to occlude the short saphenous vein. This helps to establish which set of superficial veins are incompetent (Fig. 16.16).

Venography

This investigation is the X-ray equivalent of duplex ultrasonography. Historically it preceded ultrasonography and has been widely used in the past for the assessment of patients with vein problems. An ascending venogram is performed by cannulating a vein in the foot in order to inject X-ray contrast medium. A narrow tourniquet is applied just above the malleoli to direct blood flow into the deep veins and an injection of nonionic contrast material given to outline the veins. The technique provides excellent anatomical information but gives much less information about the veins where the valves have failed. It is a useful examination for suspected deep vein thrombosis where ultrasonography is not available.

The contrast material is heavier than blood and flows down the limb though incompetent valves. Both ascending and descending phlebography is required to establish suspected deep vein thrombosis where ultrasonography is not available. The contrast medium is injected into the vein that he or she wishes to study and compresses the calf with his/her hand to produce forward flow. This results in upward flow towards the heart in a normal vein. The patient then sits and the veins refill. Under normal conditions venous refilling occurs through arterial inflow alone, a slow process taking 20 or 30 seconds when the limb is at rest. In patients with venous incompetence the veins also fill via venous reflux, which speeds the refilling process. Fast refilling times mean that one or more veins in the leg are incompetent. The test can be repeated after the application of a tourniquet above the knee to occlude the long saphenous vein, and then below the knee to occlude the short saphenous vein. This helps to establish which set of superficial veins are incompetent (Fig. 16.16).

The source of recurrent varicose veins may be identified by a varicogram. Contrast material is injected into one of the varicities and followed to identify its source. Again, duplex ultrasonography has largely replaced this investigation (Fig. 16.20).
Management of patients with varicose veins

A history should be taken from the patient to find out how long the varices have been present and if any event seemed to cause them. A history of previous lower limb deep vein thrombosis should be sought. Venous thrombosis may follow lower limb fractures, so this also should be asked about. Superficial varices which develop after a venous thrombosis may be the only route of venous drainage in the lower limb and should not be removed until the patency of the deep veins of the limb has been shown. Patients may also have received previous surgical or other treatment for their varices. Any previous treatment may greatly alter the surgical management of the patient. When the SFJ has been ligated previously, a further operation here is technically much more demanding for the surgeon and should not be performed unless recurrence at the previous operation site has been conclusively demonstrated. Unfortunately, patients often have only a vague recollection of their previous vein operations and therefore diagnostic ultrasound imaging or venography is essential to establish the anatomy and source of varices in patients with recurrent varicose veins.

Clinical examination should establish the extent and size of varices, as well as the presence of any associated skin changes. Tourniquet tests should be used to decide the location of venous incompetence. All patients considered for surgical treatment of their varices should be examined using a hand-held Doppler ultrasound device to confirm the source of the varices.

Patients with recurrent varices or a history suggestive of previous venous thrombosis and any patient with skin changes should be fully investigated using duplex ultrasonography or venography. The presence of ankle pulses should be confirmed by palpation or, if necessary, by measuring the ankle blood pressure using Doppler ultrasound.

The treatment of varicose veins following a proper assessment may include reassurance, the use of elastic compression stockings, injection sclerotherapy or surgical treatment. The treatment of choice depends on the size of the varices, their extent and the symptoms that they produce.

Compression stockings

The symptoms of varicose veins may be relieved by the use of compression stockings. These are available for the treatment of venous disease in three grades of compression, classes 1—3. Light compression stockings may be helpful in the early stages of varicose veins but do not prevent the development of more varicose veins or result in the disappearance of veins.

Injection sclerotherapy

This treatment is best used in the management of small varices and those where the main long and short saphenous veins, and their major tributaries, are competent. This type of treatment is also effective where the larger varices have been removed surgically and only small varices remain. In the past, sclerotherapy has been used in the management of incompetence of the main saphenous trunks. Evidence suggests that varicose veins managed in this way recur much more rapidly than following surgical treatment.

The basis of sclerotherapy is that a solution which destroys the endothelial lining of the veins is injected. In the UK the most widely employed drug is sodium tetradecyl (STD), which chemically is a soap. To be effective, the sclerosant has to be given into an empty vein that is compressed immediately after the injection has been given to avoid the development of thrombosis within the vein. It is easy to produce thrombo-phlebitis which can recanalise and result in the recurrence of the varices. The aim is to produce sclerosis with the vein being replaced by a fibrous cord, incapable of recanalisation and recurrence (Fig. 16.21).

Technique

The limb is examined with the patient standing and the position of the varices that should be injected marked on the skin. The needle is inserted into the vein with the patient sitting down and the leg in a horizontal position. A 23G or 25G needle is usually used for this. The position of the needle in the vein is confirmed by drawing back on the syringe. Injection of the sclerosant outside the vein causes tissue necrosis and ulceration, and must be avoided. The leg is elevated to empty the veins and a small volume of saline (0.5 ml) is injected into the vein. Compression is immediately applied to the vein being treated with the fingers and a firm bandage applied. Treatment is usually commenced at the ankle so that the bandage can be applied progressively from the ankle to the groin as treatment progresses along the limb. A latex foam pad is put over the sites of the injection and incorporated within the bandage. Skin sensitivity to rubber may lead to allergic reactions if the latex pads come into direct contact with the skin. Immediately after the bandage has been completed, the patient is asked to walk to encourage the blood to circulate reducing the risk of venous thrombosis in the limb and also reducing the venous pressure in the varices of the calf.

Further sessions of sclerotherapy continue at weekly intervals until all lower limb varices have been treated. The patient should wear a compression bandage or stocking for 3—6 weeks after the completion of a course of sclerotherapy This ensures that the veins which have been treated do not suffer thrombosis and are converted into a fibrous cord, achieving sclerosis of the vein.

Complications

The complications of this treatment include skin pigmentation and ulceration if the sclerosant is not injected within a vein. Small regions of thrombophlebitis are often seen during a course of sclerotherapy. Deep vein thrombosis develops only rarely.

Microsclerotherapy

Thread veins and reticular varices may be treated by injection through a very fine needle, a treatment referred to as ‘microsclerotherapy’. Very dilute sclerosing solutions are used. The most frequently employed drugs used for this are STD and polidocanol. A skilled practitioner can insert a 30G needle into dermal flares and successfully eradicate these tiny veins. Compression bandaging is usually applied after this treatment for 1—5 days. Treatment of these veins is normally regarded as a cosmetic procedure.

Surgical treatment of varicose veins

Surgical treatment of varicose veins is widely used and is effective in removing varicose veins of the main saphenous trunks, as well as their tributaries, down to a size of about 3 mm. Veins smaller than this are best treated by sclaro-therapy. Surgical removal of varices is inappropriate where these form a major part of the venous drainage of the limb, for example where a deep vein thrombosis has destroyed the main axial limb veins and the patient relies on the superficial veins. This possibility may be suggested by the patient’s medical history and can be confirmed by duplex ultrasonography or venography.

The main principles of surgical treatment are to ligate the source of the venous reflux (usually the SFJ or the SPJ) and to remove the incompetent saphenous trunks and the associated varices. Sapheno-femoral ligation alone, sometimes referred to as a ‘Trendelenburg
procedure’, is associated with a high rate of recurrence of varices. Recent research has shown that it is necessary to remove the long saphenous vein to ensure that as much venous reflux as possible is eliminated. Similarly, communications between the many deep veins in the popliteal fossa and the short saphenous vein mean that some patients develop recurrences in the short saphenous vein due to the re-establishment of reflux from these veins. This problem may be eliminated by removing the short saphenous vein. Removal of the saphenous veins has the disadvantage that both veins are accompanied by a nerve that may be damaged in the vein stripping operation. To avoid nerve injury the long saphenous vein should not be removed below mid-calf level and great care should be exercised in removing the short saphenous vein.

Venous anatomy is particularly variable, and for some veins preoperative vein localisation is very helpful. The termination of the short saphenous vein may lie from 2 cm below the knee to 15 cm above the knee. Its course and ter-mination can be readily identified by ultrasound imaging and marked on the skin with an indelible pen before the operation, reducing the risk of damage to nerves and arteries in the popliteal fossa. Perforating veins in the calf and thigh, and residual segments of the saphenous veins left after previous venous surgery, can also be localised in this way (Fig. 16.25).

**Technique of saphenofemoral junction ligation**

An oblique incision is made in the groin commencing over the femoral artery and ending 4 cm medially. The long saphenous vein is exposed and the common femoral and superficial femoral veins are identified before dividing the long saphenous vein. Having divided the long saphenous vein, all branches should then be isolated and divided. The SFJ should be tied flush with the femoral vein. Any tributary of the saphenous vein or femoral vein left in this operation may be the source of a future recurrence, so it is important that all are ligated and divided. It is important that the femoral vein is inspected carefully for at least 1 cm above and below the SFJ, and any tributaries ligated and divided.

The conventional way of removing the saphenous vein is with a Babcock stripper. This consists of a flexible wire which is passed down the long saphenous vein. The end is identified in the upper third of the calf and a 2-mm incision is made to retrieve the stripper. An olive about 8 mm in diameter is attached to the upper end and the saphenous vein is removed by firm traction on the wire in the calf.

More recently ‘inverting’ or ‘invaginating’ stripping has become popular. The aim here is to reduce the damage to the tissues around the vein leading to less bleeding and post-operative pain. This may be done in a number of different ways. A rigid metal ‘pin-stripper’ has recently been developed (Fig. 16.23). This is passed down the inside of the saphenous vein and recovered through a small incision in the upper part of the calf. A strong suture is attached to the end of the stripper and firmly ligated to the proximal end of the vein (Fig. 16.24). Pulling gently on the stripper, the long saphenous vein will invert and can be delivered through a 2-mm incision in the mid-calf region (Fig. 16.25). No olive is used and the technique relies on the strength of the vein. Should the vein break, an instrument with a small olive on one end is used to recover the remaining saphenous vein.

**Technique of saphenopopliteal junction ligation**

Accurate preoperative ultrasound localisation of this junction makes the operation easy, as the position of the SPJ is notoriously variable. A skin incision is made over the junction and the deep fascia incised to reveal the short saphenous vein beneath. The vein is followed to the SPJ, where the short saphenous vein enters the side of the popliteal vein. The vein can then be ligated and divided close to the popliteal vein. This operation may not be enough to eliminate venous reflux in the short saphenous vein because communication with the gastrocnemius (muscle) veins in the calf is often present and may lead to further varicosities arising from the short saphenous vein. Many surgeons now routinely strip the short saphenous vein to prevent this problem. This is best done using an inverting technique as the sural nerve lies close to the vein and may be damaged if a large olive is used.

A pin-stripper (Oesch) is passed down the short saphenous vein as described above for the long saphenous vein. This is recovered through a 2-mm incision made at the mid-calf level. A heavy suture is used to attach the vein to the upper end of the stripper and gentle traction applied to the stripper. The inverted vein appears in the calf incision.

**Removing superficial varices**

Varicose veins do not disappear following saphenous vein stripping and should be removed through small incisions. It was standard practice to insert artery forceps through the incision in order to remove varices. However, this necessitates long incisions in the leg which require suturing and are unsightly. European phlebologists have developed instru-ments to minimise the size of incision required for this procedure. The technique is referred to as ‘hook phlebectomy’ and uses small hooks which may be inserted through incisions of only 1—2 mm (Fig. 16.26). The hook is used to capture a small section of a varicosity and bring it to the surface where is may be grasped using a large artery forceps; the remaining vein is then teased through the tiny incision. The aim is to remove all the varicosities through incisions that require no suture. Closure of the incisions is achieved using adhesive strips or dressings. The cosmetic outcome from this procedure is excellent.

The results of varicose vein surgery depend on the care taken with the preoperative assessment, the preoperative marking and the determination of the surgeon to remove all the superficial varicosities. Patients may complain of symptoms of varicose veins, but most remain unsatisfied until they achieve a good cosmetic result following treatment!

**Postoperative management**

Compression bandaging is applied to the limb at the end of the operation to prevent excessive bruising. In fact, some surgeons apply compression to the limb before stripping the long saphenous vein. After 1 or 2 days the bandages may be replaced by a thigh-length high compression stocking (class 2 compression is appropriate). This can usually be removed easily to allow the patient to take a shower and can then be reapplied.

**Complications of varicose vein surgery**

Bruising and discomfort are common following removal of varices, especially where the veins were of very large diameter. However, the pain usually requires only mild analgesics.

Sensory nerve injury is seen occasionally after removal of varicose veins. The saphenous nerve and its branches accompany the long saphenous vein in the calf, the sural nerve accompanies the short saphenous vein. Damage to the main part of these nerves occurs in about 1 per cent of operations, but small areas of anaesthesia may occur more frequently (in up to 10 per cent of patients). The adoption of inverting stripping techniques and avoidance of stripping the long saphenous vein below mid-calf level have reduced the risk of damage to these nerves. All patients should be warned before surgery that they may experience small areas of numbness and tingling after the operation. These changes are usually reversible but can be quite persistent.

Motor nerve injury is an uncommon complication of varicose vein surgery and may occur during exploration of the popliteal fossa if care is not
taken to protect the nerves in this region. Preoperative ultrasound localisation of the short saphenous vein helps in limiting the extent of the dissection in this region and risk to the nerves during dissection. Venous thrombosis is often seen in residual varices following varicose vein surgery and resolves without the need for specific treatment. The risk of this is reduced if all visible varices are removed at the time of surgery. Deep vein thrombosis occurs in about one operation per 1000 following varicose vein surgery. The factors which result in increased risk are described below. Patients who have previously suffered a deep vein thrombosis seem to be particularly at risk and should receive full prophylactic measures, usually low-dose subcutaneous heparin in addition to compression stockings. Patients receiving oestrogen treatment may also be at increased risk of venous thrombosis, and heparin prophylaxis should be considered.

**Venous reconstructive surgery**

Surgery to the deep veins is limited by the absence of suitable prosthetic grafts or any satisfactory way of creating a venous valve. Surgery may be carried out for venous occlusion and for deep venous insufficiency. Patients who might be considered for these procedures include those who have persisting swelling of the lower limb after a previous venous thrombosis, even when a number of years has passed and collateral veins have had the opportunity to develop. The presence of a functional obstruction must be confirmed using direct venous pressure measurements. In the case of suspected iliac vein obstruction, the pressure in the femoral vein is measured with the patient lying supine. If there is a substantial rise in venous pressure during exercise then venous obstruction is confirmed. An alternative method is to measure the venous pressure in the hand and foot veins with the patient lying supine (the Raju test). Normally the foot venous pressure is the same as the hand venous pressure or no more than 5 mmHg greater. If venous obstruction is present the pressure difference is greater, with pressure differences of 10—15 mmHg indicating significant venous obstruction.

**Venous obstruction**

In patients with venous obstruction venous bypass procedures can be performed. Simple bypass with vein or prosthetic material may be used in the larger vessels, such as the iliac veins and vena cava. One problem is to find a vein of large enough calibre to insert in this region. These are sometimes constructed from opened out sections of saphenous vein reconstructed as a spiral graft (Fig. 16.27). Alternatively a Palma operation can be carried out. This involves mobilising the long saphenous vein in the opposite leg, tunneling the distal end of the long saphenous vein across suprapubically and inserting it into the femoral vein below the obstruction. Blood then drains from the affected leg via the long saphenous vein into the femoral vein in the opposite leg (Fig. 16.28).

In patients who have obstruction of the superficial femoral vein, the long saphenous vein may be connected to the popliteal vein in the same limb, allowing blood to flow along the superficial veins more easily (May—Husni procedure). However, in the majority of patients with chronic superficial femoral vein obstruction, the blood flows along the long saphenous vein to reach the groin and therefore this operation is not required.

**Venous incompetence**

The surgical treatment of deep venous insufficiency remains a difficult problem that is dealt with in a few centres. Venous valves in the deep veins may be repaired if their incompetence is a consequence of primary valve failure. Kistner has described two methods of repairing incompetent valves, and successful completion of this operation may lead to long-term maintenance of leg ulcer healing. However, the operations are technically difficult and there is a risk of thrombosis which may destroy the reconstructed valve (Fig. 16.29). In patients who have previously suffered a deep vein thrombosis, transplantation of a segment of axillary vein has been carried out. This is usually attempted in patients who have damage to the deep veins following a previous venous thrombosis. The risk of further episodes of venous thrombosis makes the likely success of such operations as low as 50 percent.
Leg ulcers

The most common cause of leg ulceration in Western countries is venous disease of the lower limb. However, many patients have other causes for their leg ulcer. The most frequent associated cause is peripheral arterial disease, which may be the sole cause for ulceration or may occur with venous disease. Because of this common association with arterial disease, patients presenting with leg ulceration should be investigated for arterial disease as well as for vein problems. In addition, a number of other common conditions may cause leg ulceration. A brief list of the causes of leg ulcers is given in Table 16.1.

Examination and investigation

Clinical examination should be performed carefully. The ulcer itself should be examined to establish its location. Venous ulcers usually lie just proximal to the medial or lateral malleolus, although they may extend to the ankle and dorsum of the foot. Venous ulcers are accompanied by lipodermatosclerosis and haemosiderosis. If these are not present then the ulcer is probably not of venous origin. The presence of obvious varicose veins should be recorded, although these are often not present or not visible in patients with venous ulcers. The peripheral pulses should be palpated to assess the peripheral arteries. The presence of loss of sensatiion in the foot or area of ulceration should be assessed, especially in a diabetic patient. Diabetic leg ulceration usually affects the foot and is almost always associated with peripheral neuropathy.

In patients suspected of suffering lower limb venous or arterial disease as the cause of the ulceration, complete examination of the venous system by duplex ultrasonography combined with measurement of Doppler ankle blood pressures is the most appropriate investigation in the first instance. This investigation is highly effective in establishing the location of incompetent veins and assessing the extent of post-thrombotic vein damage. In those patients with venous ulceration, between 40 and 50 per cent have ulceration due to superficial venous insufficiency alone. Simple noninvasive tests can exclude those patients with arterial occlusion and identify those with deep and superficial venous insufficiency. Patients with pure superficial venous insufficiency, i.e. varicose ulcers — ulcers due entirely to varicose veins, respond well to surgical treatment of their varicose veins (Fig. 16.30). Where severe arterial disease is found it may be necessary to undertake detailed duplex ultrasound or angiographic examination of the arteries. Should the vascular system prove to be normal, blood tests may be done to test for systemic inflammatory disorders [e.g. rheumatoid disease, systemic lupus erythematosus (SLE)]. In addition, a biopsy of the ulcer may be helpful when it is not clearly due to an arterial or venous cause. A small proportion of leg ulcers is of malignant origin and any persistent ulcer, especially in an unusual place, should be biopsied to detect malignancy. Squamous cell carcinoma and basa cell carcinomas are the most frequent cause of leg ulceration due to neoplasms, although occasionally malig-nant melanomas are found. In addition, malignant change may complicate a long-standing venous ulcer (Marjolin’s ulcer). This should be suspected where part of an ulcer shows evidence of proliferation. This type of tumour is usually a squamous cell carcinoma.

Management of venous leg ulcers

In patients who have venous ulceration due to superficial venous incompetence alone, varicose vein surgery is effective in producing ulcer healing in those patients who are fit enough to undergo this treatment. In the authors’ experience it is not necessary to delay surgery until the ulcer has healed. The ulcer is covered by a dressing during surgery and pro-phyllactic antibiotics are given to prevent infection of the surgical wounds with any bacteria present in the ulcer. Ulcers managed in this way usually heal rapidly (within 4 weeks) following surgery.

In those patients with deep venous insufficiency or who are unfit or unwilling to undergo surgery, standard ulcer management should be used. The mainstay of this is local ulcer management combined with the application of compression. The ulcer is cleaned by soaking in tap water (the use of sterile water is unnecessary) and debriding the ulcer to remove any slough. The skin of the leg often becomes very scaly beneath compression dressings and should be treated with emulsifying ointment. No topical application has been shown to speed the healing of a venous leg ulcer, and patients with venous disease of the lower limb are very likely to become allergic to dressing materials. Topical antibiotics are ineffective in healing leg ulcers and are particularly likely to produce skin sensitisation. They should never be used in the management of venous ulceration. Patients who have eczematous reactions around their ulcers may require the use of topical steroids to treat the allergic response. The dressing material should follow standard guidelines — see Chapter 3 on ‘Wounds, tissue repair and scars.

The most important factor in achieving healing is the use of high levels of compression. The use of dressings alone leads to a very slow rate of ulcer healing. It has been found that pressures of 30–45 mmHg applied to the ulcer are much more effective than lower levels of compression. These can be achieved by the use of compression stockings or by bandaging. Class 3 stockings exert about 30 mmHg compression at the ankle but require the patient to have sufficient strength in their hands to apply these. They are useful in younger patients who wish to manage their own ulcer. Frail patients often cannot manage this type of stocking, but may be able to apply two stockings of lower compression to the limb or use a stocking with a zip fastener in the seam. The compression need only be applied to the ulcer region, so patients with venous leg ulcers should wear below the knee stockings. Patients who are unable to manage with stockings are treated using multilayer bandaging regimes. These must be applied by a person trained in the procedure, as the use of lower pressures leads to slow ulcer healing and too high a pressure may cause injury to the leg. The best known of these techniques is the ‘four-layer bandage’ developed at Charing Cross Hospital in London. This method achieves pressures of 45 mmHg at the ankle and has been shown to produce healing of 70 per cent of venous ulcers within 12 weeks. The bandage must be changed once or twice per week (Fig. 16.31). The requirement that, for leg dressings, a nurse must change the dressing leads to a great deal of investment in the provision of community nursing services. Community nurses spend about 30 per cent of their time attending to leg ulcers and this leads to enormous expenditure by the National Health Service on this problem. It has been estimated that in the UK between £600 million and £800 million per annum is spent in the management of leg ulcers.

Prevention of recurrence

Even when healing has been achieved there is a risk that further ulcers may develop. Patients with healed ulcers should be encouraged to wear support stockings and rest with their feet elevated whenever possible. Recurrence rates of 25 per cent per year are accepted as the norm for such patients. In those who have been treated surgically for superficial venous incompetence the risk of reulceration is about 2–3 per cent per year.

Drug treatment for leg ulcers

No drugs have been found which are more effective than compression bandaging in the management of venous leg ulceration. Antibiotics have no effect on ulcer healing but are required if infection develops around an ulcer. This usually takes the form of cellulitis but, surprisingly, only occurs occasionally. A few drugs have been investigated to assess their efficacy in venous ulcer healing. These have included aspirin, oxpentifylline (Trental, Hoechst), prostaglandin El analogue and diosmin (Daflon 500 mg, Servier). All of these have an effect on leg ulcer healing but none is currently in widespread use. Future developments in understanding of the pathology of leg ulcers may lead to improvements in drug treatment for this condition.
Venous thrombosis

Venous thrombosis of the deep veins is a serious life-threatening condition which may lead to sudden death in the short term or to long-term morbidity due to the development of a post-thrombotic limb and venous ulceration. The most frequent location of deep vein thrombosis is in the lower limb. This condition may arise spontaneously or after injury to the limb. In modern medical practice the most common cause of lower limb venous thrombosis is following hospital admission for treatment of medical or surgical conditions. In 10 per cent of patients who die in hospital, the cause of death is pulmonary embolism following a lower limb deep vein thrombosis (Fig. 16.32).

Factors which lead to venous thrombosis

These were originally described by Virchow over a century ago. He suggested that the following factors may lead to clotting in the veins.

1. Changes in the vessel wall with damage to the endothelium due to injury or inflammation. This is known to happen following previous deep vein thrombosis.
2. Diminished rate of blood flow in the veins. In modern medical practice this occurs during and after operations, and in debilitating conditions such as strokes and myocardial infarction.
3. Increased coagulability of the blood. This also occurs following surgery and in the presence of infection or systemic malignancy.

Much more is now understood about the clotting cascade that results in the deposition of thrombus, as well as the fibrinolytic system that removes thrombus. Congenital deficiencies in either of these systems may result in increased susceptibility to thrombosis in that individual (Table 16.2).

Thrombophilia

Severe deficiencies of antithrombin III, protein C or protein S lead to severe or fatal episodes of venous thrombosis at an early age. More mild deficiencies may present as recurrent episodes of venous thrombosis in later life. Activated protein C resistance results in only a modest increase in the risk of venous thrombosis, perhaps presenting as deep vein thrombosis in the lower limb following hospital treatment for some other condition. However, this abnormality is fairly common, occurring in 6—7 per cent of Caucasian people. In any patient presenting with an episode of venous thrombosis a family history of thrombotic episodes should be sought.

Spontaneous venous thrombosis may occur following injury to the leg such as a severely sprained ankle, as the consequence of an infection or following a period of immobility. Long-haul air travel is recognised as the cause for venous thrombosis in a number of people who are obliged to spend long periods in conditions permitting little movement of the legs. Long car journeys may also cause venous thrombosis in the lower limbs in susceptible individuals. In a proportion of patients an underlying malignancy appears to be the precipitating factor. In a patient who develops venous thrombosis in the absence of any identifiable cause clinical examination and special investigations should be arranged to detect common malignancies (e.g., lung, stomach, large bowel).

Patients receiving treatment in hospital are at increased risk of venous thrombosis. This includes patients being treated surgically or for medical conditions. The factors which result in increased risk of venous thrombosis include advancing age and greater complexity of surgical treatment. Orthopaedic operations on the lower limbs (hip and knee replacements) are especially likely to result in venous thrombosis. The risk of venous thrombosis associated with particular surgical procedures is summarised in Table 16.3. However, medical patients are also at risk, particularly those being treated for strokes and other neurological conditions. Any patient with myocardial infarction or any serious illness runs the risk of venous thrombosis of the lower limb. Should this thrombus detach and become a pulmonary embolism, the result may be fatal. A large number of medical conditions, in addition to those mentioned above, may lead to venous thrombosis. These are listed in Table 16.4.

Prevention of deep vein thrombosis

All patients admitted to hospital or being treated for a serious illness should be assessed for the risk of deep vein thrombosis. These patients may be considered at low risk, moderate risk or high risk:

- low risk — young patients, minor illnesses, operations lasting for less than 30 minutes with no additional risk factors;
- moderate risk — patients over the age of 40 years with debilitating illnesses, undergoing major surgery but no additional risk factors;
- high risk — patients over the age of 40 years with serious medical conditions, such as stroke and myocardial infarction, and undergoing major surgery with additional risk factor, such as a past history of venous thromboembolism, extensive malignant disease or obesity.

Both mechanical and pharmacological methods are effective in preventing deep vein thrombosis. Graduated compression stockings (TED stockings) have been shown in clinical trials to reduce the incidence of deep vein thrombosis. Sequential pneumatic compression devices have also been shown to reduce the incidence of deep vein thrombosis in patients (Fig. 16.33). Their efficacy is enhanced if graduated compression stockings are worn as well.

Pharmacological methods evaluated include: low-dose heparin, low-molecular-weight heparin, dextran and adjusted dose warfarin. There is now good scientific evidence that low-dose heparin is effective in reducing the incidence of deep vein thrombosis and pulmonary embolism. Most studies suggest that the use of 5000 units of heparin, given subcutaneously two or three times a day, is effective. This should be continued for at least 5 days. The risk of developing a deep vein thrombosis following hospital discharge has now been recognised, and deep vein thrombosis prophylaxis probably ought to be extended into the postdischarge period. Low-molecular-weight heparin is effective in reducing the incidence of deep vein thrombosis. It has been shown to be more effective than low-dose heparin in orthopaedic patients and as effective in patients undergoing general surgical procedures. The advantages of low-molecular-weight heparin over standard heparin include once a day administration and a lower risk of bleeding complications, making it more suitable for out of hospital use.

Pulmonary embolism

Pulmonary embolism is a potentially fatal complication of lower limb deep vein thrombosis. A clot from the lower limb veins becomes detached from its site of formation and passes via the inferior vena cava and right heart to the pulmonary arteries. Here it may totally occlude the perfusion to part or all of one or both lungs. This leads to collapse or sudden death in some patients and is a medical emergency. Treatment includes full, immediate anticoagulation with intravenous heparin combined with standard methods of resuscitation. Large emboli may be treated by infusion of fibrinolytic drugs into the pulmonary arteries via catheters inserted via arm or leg veins.
Diagnosis of deep vein thrombosis

The symptoms and clinical features of a lower limb deep vein thrombosis are listed in Table 16.5. The most significant findings are tenderness in the calf and oedema at the ankle. However, these may also be attributable to other conditions. Pain in the calf on dorsiflexion of the ankle (Homari’s sign) has been described in many textbooks. However, this is a very misleading clinical sign and provides no useful information about the presence or otherwise of a lower limb venous thrombosis. It should no longer be used. Some patients with deep vein thrombosis of the lower limb may have no symptoms in the leg, but present with severe dyspnoea due to pulmonary embolism.

Signs and symptoms of deep vein thrombosis

The clinical features a lower limb deep vein thrombosis are given in Table 16.5.

Objective diagnosis of deep vein thrombosis

The only reliable way to detect venous thrombosis is using an imaging investigation. The test of choice is duplex ultrasonography because it is a noninvasive, hazard-free method of investigation. If this is not available, then ascending phlebography should be undertaken. For diagnosis of pulmonary embolism, enhanced helical computerised tomography (CT) scanning is considered the standard test and is replacing isotope imaging studies. Treatment with anticoagulants is potentially hazardous and should not be commenced until a definite diagnosis has been made.

Treatment of deep vein thrombosis

In treating an established deep vein thrombosis it is important to make the correct diagnosis. Twenty per cent of patients with clinical signs and symptoms of a deep vein thrombosis have normal deep veins. The differential diagnosis includes ruptured Baker’s cyst, superficial thrombophlebitis, calf muscle haematoma and a ruptured plantaris tendon. All of these diagnoses can be demonstrated on ultrasonography, which has the advantage of allowing the examination of the soft tissues, something which venography is unable to do.

Having made the diagnosis of a deep vein thrombosis and confirmed it by duplex ultrasound imaging or venography, treatment should be instituted. Standard treatment involves intravenous heparin with the dose adjusted according to the weight of the patient and controlled by the activated partial thromboplastin time (APTT). The duration of heparin treatment should be at least 5 days. The aim is to minimise the risk of pulmonary embolism and encourage the thrombus to resolve. At the same time, the patient should be commenced on warfarin. The aim here is to reduce the risk of a further recurrence of venous thrombosis. Warfarin does not remove the clot from blocked veins and the duration of treatment (usually 3—6 months) is selected to prevent further episodes of venous thrombosis. Warfarin dosage is controlled by monitoring the international normalised ratio (INR) by regular blood tests. The INR should be prolonged to between 2.5 and 3.5 times the control value. Patients with recurrent venous thromboembolic problems should be anticoagulated for life.

Venous thrombectomy

Occasionally massive venous thrombosis in the lower limb leads to severe impairment in the blood supply to the limb, leading to ischaemia and, eventually, gangrene. This is a surgical emergency and requires rapid relief of the venous obstruction. This can be achieved surgically by opening the femoral vein via an incision in the groin and removing all clot from the deep veins of the leg and pelvis. This operation used to be more widely performed on the assumption that it would reduce the severity of post-thrombotic vein damage following a deep vein thrombosis. However, very few surgeons now perform this operation. The more modern treatment of thrombolyis, achieved by passing a catheter into the affected vein and infusing a fibrinolytic drug such as streptokinase or tissue plasminogen activator (TPA), is reducing the need for this operation (Fig. 16.34).

Prevention of pulmonary embolism

In some patients the risk of pulmonary embolism is very great, e.g. a large venous thrombosis in the lower limb where anticoagulation is contraindicated (e.g. following a haemorrhagic stroke). In others, pulmonary embolism occurs despite full anticoagulation with warfarin. Pulmonary embolism may be prevented by the insertion of an inferior vena cava filter which traps large thrombi in its wires and prevents them from occluding the pulmonary arteries. These filters are usu-ally placed by a radiologist via the femoral or jugular vein under X-ray control without the need for an open surgical procedure (Fig. 16.35).

Superficial vein thrombosis

Venous thrombosis (thrombophlebitis) often occurs in superficial veins. This is a frequent complication of varicose veins and may follow cannulation of a vein for an intravenous infusion. Spontaneous superficial thrombo-phlebitis may occur in the presence of polycythaemia, polyarthritis and Buerger’s disease and may also herald the presence of a visceral cancer. This condition does not carry the severe risks of deep venous thrombosis and is normally treated symptomatically. Patients benefit from simple analgesics and anti-inflammatory drugs. Occasionally deep vein thrombosis may complicate superficial venous thrombosis and should be investigated where there is a clinical suspicion that thrombosis may have reached the deep veins. Patients with varicose veins should be advised to undergo surgical treatment for their varices as further episodes are likely in these patients.

Axillary vein thrombosis

Thrombosis of the axillary vein may occur following excessive exercise or as a complication of thoracic outlet syndrome. It is occasionally associated with a cervical rib. The arm becomes swollen and the superficial veins are distended. Early treatment with anticoagulants may result in rapid resolution. In severe cases the use of fibrinolytic therapy, streptokinase or TPA may be considered. Definitive treat-ment of the thoracic outlet syndrome by surgical decompres-sion of the subclavian vein may be needed, for example by resection of the first rib (Fig. 16.36).
Introduction

The lymphatic system was first described by Erasistratus in Alexandria more than 2000 years ago. However, the anatomy was not described in detail until the seventeenth century and William Hunter, in the late eighteenth century, was the first to describe the function of the lymphatic system as we now understand it. Starling’s pioneering work on the hydrostatic and haemodynamic forces controlling the movement of fluid across the capillary provided further insights into the function of the lymphatics. In the past two decades this knowledge has been further refined through the application of advanced in vivo microscopic techniques and the advances in molecular biology. Nevertheless, there is much about the lymphatic system that is not yet understood and debate continues over the precise aetiology of the commonest abnormality of the system; namely, lymphoedema.
Anatomy and physiology of the lymphatic system

Functions

1. Removes water, electrolytes, low-molecular-weight moieties (polypeptides, cytokines, growth factors) and macromolecules (fibrinogen, albumen, globulins, coagulation and fibrinolytic factors) from the interstitial space and returns them to the circulation.

2. Permits the circulation of lymphocytes and other immune cells.

3. Intestinal lymph (chyle) transports cholesterol, long-chain fatty acids, triglycerides and the fat soluble vitamins (A, D, E and K) directly to the circulation, bypassing the liver.

Development and macroanatomy

In the embryo, the lymphatic system develops from four cystic spaces, located one on either side of the neck and one in each groin. These cisterns enlarge and develop communications (lymphatic vessels) that permit lymph from the lower limbs and abdomen to drain via the cisterna chyli, lying between the aorta and azygos vein, into the thoracic duct. This duct is a major lymph channel which passes cephalad on the left of the bodies of the thoracic vertebrae to enter the left side of the neck, where it drains into the left internal jugular vein at its confluence with the left subclavian vein. Lymph from the head and right arm drains via a separate lymphatic trunk, the right lymphatic duct, into the right internal jugular vein. Lymph nodes develop as condensations along the course of these lymphatic highways.

Lymphatics accompany veins everywhere in the body except in the cortical bony skeleton and central nervous system, although the brain and retina possess analogous systems (cerebrospinal fluid and aqueous humour, respectively). The lymphatic system comprises lymphatic channels, lymphoid organs (lymph nodes, spleen, Peyer’s patches, thymus, tonsils) and circulating elements (lymphocytes and other mononuclear immune cells).

Microanatomy and physiology

Lymphatic capillaries

Lymphatics originate within the interstitial space either from specialised endothelialised capillaries (initial lymphatics) or from nonendothelialised precapillary channels such as in the liver (spaces of Disse). Initial lymphatics capillaries are unlike arteriovenous capillaries in that they:

- are blind-ended;
- are much larger (50 micron);
- allow the entry of molecules up to 1000 kDa in size because the basement membrane is fenestrated, tenuous or even absent and the endothelium itself possesses intra and intercellular pores.

- The abluminal surface of the endothelium is intimately related to the interstitial matrix through anchoring collagen and elastic filaments. In the resting state initial lymphatic capillaries are collapsed. When interstitial fluid volume and pressure increase, the space expands and the lymphatic capillaries and their pores are held open by these filaments to facilitate increased lymphatic drainage.

Terminal lymphatics

Lymphatic capillaries drain into terminal (collecting) lymphatics which possess bicuspid valves and endothelial cells rich in the contractile protein actin. Larger collecting lymphatics are innervated and surrounded by smooth muscle. Valves partition the lymphatic into segments termed lymphangions which are believed to contract sequentially in order to propel lymph into the lymph trunks. The area of skin drained by a single terminal lymphatic is termed an areola. Although there is some overlap between adjacent areolata, there are lymphatic watersheds and there is limited capacity for bypass flow when a main collecting duct or lymph trunk is blocked.

Lymph trunks

Terminal lymphatics lead to lymph trunks which have a structure that is similar to veins: a single layer of endothelial cells, lying on a basement membrane overlying a media comprised of smooth muscle cells that are innervated with sympathetic, parasympathetic and sensory nerve endings. About 10 per cent of lymph arising from a limb is transported in deep lymphatic ducts that accompany the main neurovascular bundles. The majority of lymph, however, is conducted, in epifascial lymph ducts, against venous flow from the core of the limb to the surface. Superficial ducts form lymph bundles of various sizes which are located within strips of adipose tissue and tend to follow the course of the major superficial veins.

The distribution of fluid and protein between the vascular and interstitial spaces depends on the balance of hydrostatic and oncotic pressures between the two compartments (Starling’s forces), together with the relative impermeability of the blood capillary membrane to molecules over 70 kDa. In health there is net capillary filtration into the interstitial space of 2—4 litres per 24 hours which is removed by the lymphatic system. Disease processes which disturb Starling’s forces lead primarily to oedema that is low in protein, whereas diseases which primarily impair lymphatic drainage lead to high-protein oedema (lymphoedema).

Transport of particles

Particles enter the initial lymphatics through interendothelial openings and vesicular transport through intraendothelial pores. In contradistinction to arteriovenous capillaries, the larger the particles the greater the lymphatic uptake. Large particles are actively phagocytosed by macrophages and transported through the lymphatic system intracellularly.

Mechanisms of lymph transport

Whereas resting pressures in the interstitial fluid compartments of the skin and subcutaneous tissues are negative (—2 to —6 mmH₂O) pressures within lymphatics are positive, indicating that lymph flows against a small pressure gradient. It is believed that prograde lymphatic flow depends on two mechanisms:

- transient increases in interstitial pressure secondary to muscular contraction and external compression;
- the generation of alternating suction and propulsive forces through the sequential contraction and relaxation of lymphangions separated by valves that prevent retrograde flow.

Lymphangions respond to increased lymph flow in much the same way as the heart responds to increased venous return, in that they increase their contractility and stroke volume. Contractility is also enhanced by noradrenaline, serotonin, certain prostaglandins and thromboxanes, and endothelin-1. Pressures of up to 30—50 mmHg have been recorded in normal lymph trunks and up to 200 mmHg in severe lymphoedema. Lymphatics modulate their own contractility through the production of nitric oxide. Contractility appears to be inhibited by haemoglobin, haem-containing proteins and oxygen-derived free radicals.

Transport in the thoracic and right lymph ducts is also dependent on the changes in intrathoracic pressure that occur with respiration, as well as changes in central venous pressures through the cardiac cycle. Cardiac and respiratory disease may, therefore, have an adverse effect on lymphatic function.

Lymphovenous communications were first observed on lymphangiography and were thought to act as safety valves that would allow decompression of a hypertensive lymphatic system. While lymphscintigraphy may reveal lymphovenous communications in normal limbs, they have been reported to be absent in some cases of lymphoedema, for example post-mastectomy. The pathophysiological importance of this observation remains uncertain.

In summary, in the normal limb, lymph flow is largely due to intrinsic lymphatic contractility, although exercise, limb movement and external compression do increase lymphatic return. However, in lymphoedema, where the lymphatics are constantly distended with lymph, these forces assume a much more important functional role and this explains the success of physical therapy.
Acute inflammation of the lymphatics

Acute lymphangitis occurs when a deep or superficial infection, often due to *Streptococcus pyogenes* or *Staphylococcus aureus*, spreads to the draining lymphatics and lymph nodes (lymphadenitis) where an abscess may form. Eventually this may progress to bacteraemia or septicaemia. The normal signs of infection (rubor, calor, dolor) are present and a red streak is seen in the skin along the line of the inflamed lymphatic ([Fig. 17.1](#)). The part should be rested to reduce lymphatic drainage, elevated to reduce swelling and the patient treated with intravenous antibiotics based upon actual or suspected sensitivities. Failure to improve within 48 hours suggests inappropriate antibiotic therapy, the presence of undrained pus either in the lymph nodes or at the site of primary infection, or the presence of an underlying systemic disorder (malignancy, immunodeficiency). The lymphatic damage caused by acute lymphangitis may lead to recurrent attacks of infection and lymphoedema.
Lymphoedema

Definition

Oedema is due primarily to defective lymphatic drainage in the presence of (near) normal net capillary filtration.

Fig. 17.1 Acute lymphangitis of the arm. Erythematous streaks extend from the site of primary infection on the volar aspect of the forearm to epicondylar nodes at the elbow and thence to enlarged and tender axillary lymph nodes.

Pathophysiology

Lymphoedema is the end result of insufficient lymphatic out-flow due to aplasia, hypoplasia, primary decreased lymphatic contractility (with or without valvular insufficiency) or inflammatory obliteration. Lymphatic hypertension occurs and leads to distension with secondary impairment of contractility and valvular competence. Lymphostasis leads to the accumulation of fluid, proteins, growth factors and other active peptide moieties, glycosaminoglycans and particulate matter, including bacteria. As a consequence, there is increased collagen production by fibroblasts, an accumulation of inflammatory cells (predominantly macrophages and lymphocytes) and activation of keratinocytes. The end result is protein-rich oedema fluid, increased deposition of ground substance, subdermal fibrosis, and dermal thickening and proliferation.

Cross-sectional imaging of the affected limb by means of computerised tomography (CT) or magnetic resonance imaging clearly indicates that lymphoedema, unlike all other causes of oedema, is confined to the epifascial space comprising the skin and subcutaneous tissues. Although muscle compartments may be hypertrophied as a result of the increased work involved in limb movement, they are characteristically free of oedema.

Classification

Lymphoedema was originally classified by Allen in 1934 who subdivided it into primary lymphoedema, in which the cause is unknown (or at least unproved), and secondary lymphoedema, in which there is a clear aetiology (Table 17.1). Primary lymphoedema is usually further subdivided on the basis of age of onset and the presence of a family history. Lymphoedema may also be classified on the basis of lymphangiographic findings (see below) and clinical severity regardless of the underlying cause (Table 17.2).

History

The age of onset of painless swelling, together with the presence or absence of a family history or coexistent pathology, will allow differentiation of primary from secondary lymphoedema to be made in most cases. It is important to remember that in developed countries lymphoedema is a relatively uncommon cause of limb swelling (Table 17.3).

Signs

Unlike other types of oedema, lymphoedema characteristically involves the foot (Fig. 17.2). The contour of the ankle is lost through infilling of the submalleolar depressions, a ‘buffalo hump’ forms on the dorsum of the foot, the toes appear ‘square’ owing to confinement of footwear and the skin on the dorsum of the toes cannot be pinched because of subcutaneous fibrosis (Stemmer’s sign). Lymphoedema usually spreads proximally to knee level and less commonly affects the whole leg (Fig. 17.3). Lymphoedema will pit easily at first but, with time, fibrosis and dermal thickening prevent pitting except following prolonged pressure. Chronic eczema, fungal infection of the skin (dermatophytosis) and nails (onychomycosis), fissuring, verrucae and papillae are frequently seen in advanced conditions. Frank ulceration is rare except in the presence of chronic venous insufficiency, but the two conditions not infrequently coexist and chronic venous insufficiency may actually lead to lymphatic insufficiency (Fig. 17.4). Ulceration can also develop after minor trauma and be slow to heal (Fig. 17.5). Protein-losing diarrhoea, chylous ascites, chylothorax, chyluria and discharge of lymph from skin vesicles (lymphorrhoea, chylorrhoea) suggest lymphangectasia (megalymphatics) and chylous reflux, but this is rare. Ulceration, nonhealing bruises and raised purple-red nodules should lead to suspicion of malignancy. Lymphangiosarcoma was originally described arising in postmastectomy oedema (Stewart—Treves syndrome) but can arise in any in long-standing lymphoedema. It is rare, aggressive, usually diagnosed late and frequently leads to loss of limb or life.
Primary Lymphoedema

Pathophysiology

Primary lymphoedema affects only one or two people per 100,000 under 20 years of age. Approximately 10 per cent have a positive family history.

Non familial primary lymphoedema

It has been proposed that all cases of primary lymphoedema are due to an inherited abnormality of the lymphatic system, sometimes termed ‘dysplasia in utero’. However, it is more likely that many sporadic cases occur in the presence of a (near) normal lymphatic system and are, in reality, examples of secondary lymphoedema for which the triggering event has gone unrecognised. In animal models, simple excision of lymph nodes and/or trunks leads to acute lymphoedema that resolves within a few weeks, presumably due to collateralisation. The human condition can only be achieved by inducing extensive lymphatic obliteration and fibrosis, for example by injecting silica particles; even then there may be considerable delay between the injury and the onset of oedema. It is likely that most nonfamilial primary lymphoedema is due to chronic injury over many years due to seemingly trivial (but repeated) bacterial and/or fungal infections, insect bites, barefoot walking (silica), deep venous thrombosis or episodes of superficial thromboflebitis. Primary lymphoedema is much more common in the legs than the arms. This may be due to gravity and a bipedal posture, the fact that the lymphatic system of the leg is less well developed than that of the arm in terms of the volume of tissue drained, or the increased susceptibility of the lower extremity to trauma and/or infection.

Familial primary lymphoedema

In familial cases it is assumed that there must be some, as yet undefined, genetic susceptibility of the lymphatic system to such injury. This may be:

- a structural problem such as aplasia or hypoplasia
- a functional problem such as defective lymphatic contractility;
- an immune deficiency.

However, at the present time, the exact mechanisms causing familial primary lymphoedema remain speculative.

Lymphoedema congenita

Congenital lymphoedema (onset at or within a year of birth) is more common in males, more likely to be bilateral and to involve the whole leg, and accounts for less than 5 per cent of primary lymphoedema. Milroy’s disease describes familial lymphoedema that is present at birth or is noticed shortly thereafter. Congenital lymphoedema is also associated with other disorders, such as yellow nail and Pierre–Robin syndrome (micrognathia).

Lymphoedema praecox

Lymphoedema praecox (onset from 1 to 35 years of age) is three times more common in females than males, has a peak incidence shortly after menarche, is three times more likely to be unilateral than bilateral, usually only extends to the knee and accounts for about 20 per cent of primary lymphoedema. The familial form is referred to as Meige’s disease and represents about one-third of all cases.

Lymphoedema tarda

Lymphoedema tarda develops, by definition, after the age of 35 years but, in practice, is a disease of middle age. It is often associated with obesity and, histologically, lymph nodes are replaced with fatty and fibrous tissue. The cause is unknown. Lymphoedema developing for the first time in later life should prompt a thorough search for underlying malignancy, particularly of the pelvic organs, prostate and external genitalia; such malignancy may be found in up to 10 per cent of patients. It is worth noting that in such patients lymphoedema often commences proximally in the thigh rather than distally (Fig. 17.6).

Lymphangiographic classification

Browse has classified primary lymphoedema on the basis of lymphangiographic findings (Table 17.4, Fig 17.7 and 17.8). These findings are related to the clinical presentations described above.

Megalymphatics

Some patients with lymphatic hyperplasia possess megalymphatics in which lymph or chyle refluxes freely under the effects of gravity against the physiological direction of flow. The megalymphatics usually end in thin-walled vesicles on the skin surface causing excoriation, secondary infection, fluid electrolyte and protein depletion; serous surfaces of peritoneal (chylous ascites) or pleural (hydrothorax, chylothorax) cavities; or mucosal surfaces of the intestine (protein losing enteropathy), kidney or bladder (chyluria) (Figs. 17.9).
Filarisis

This is the commonest cause of lymphoedema worldwide, affecting up to 100 million individuals. It is particularly prevalent in Africa, India and South America where 5–10 per cent of the population may be affected. The viviparous nematode *Wuchereria bancrofti*, whose only host is humans, is responsible for 90 per cent of cases and is spread by the mosquito. The disease is associated with poor sanitation. The parasite enters lymphatics from the blood and lodges in lymph nodes where it causes fibrosis and obstruction, due partly to direct physical damage and partly to the immune response of the host. Proximal lymphatics become grossly dilated with adult parasites. The degree of oedema is often massive, in which case it is termed ‘elephantiasis’ (Fig. 17.10). Immature parasites (*microfilariae*) enter the blood at night and can be identified on a blood smear, a centrifuged specimen of urine or in lymph itself. A complement fixation test is also available and is positive in present or past infection. Eosinophilia is usually present. Diethylcarbamazine destroys the parasites but does not reverse the lymphatic changes; although there may be some regression over time. Once the infection has been cleared treatment is as for primary lymphoedema. Public health measures to reduce mosquito breeding, protective clothing and mosquito netting may be usefully employed to combat the condition.

Malignancy and its treatment

This is the most common cause of lymphoedema in developed countries. Hodgkin’s and non-Hodgkin’s lymphoma may present with lymphoedema, as may malignant melanoma which has metastasised to regional lymph nodes (Fig. 17.11) and malignancy of the pelvic organs (ovary, uterus, bladder), anus, prostate, testes, penis and breast (*peau d’orange*). More often lymphoedema is a result of treatment, either surgical excision of draining lymph nodes and/or radiotherapy. Lymphoedema following treatment for breast carcinoma is the commonest example, but fortunately this is decreasing in incidence as surgery for the condition has become more conservative (Fig. 17.12). Lymphoedema may occur after radical mastectomy (up to 60 per cent), modified radical mastectomy (up to 20 per cent), local excision with either axillary node clearance or radiotherapy (less than 5 per cent), and local excision with axillary node clearance and radiotherapy (up to 40 per cent).

Trauma

This is an unusual cause of lymphoedema but is especially seen after degloving injuries of the extremities.

Acute cellulitis

As described above, acute bacterial lymphangitis is a frequent-ly observed triggering event for secondary lymphoedema.

Other causes

Other rare, but well-documented, causes of secondary lymphoedema include tuberculosis, rheumatoid arthritis (chronic inflammation and lymph node fibrosis), and snake and insect bites. It is likely that deep venous thrombosis, chronic venous insufficiency and superficial thrombophlebitis can lead to lymphoedema. Indeed, lymphatic abnormalities are frequently observed in patients who have the skin changes of chronic venous insufficiency and venous ulceration.

Factitious Lymphoedema

This may be caused by application of a tourniquet (a cut and sharp cut-off is seen on examination) or ‘hysterical’ misuse.

Investigation of lymphoedema

Are investigations necessary? Many clinicians diagnose lymphoedema purely on the basis of history and examination, especially when the swelling is mild and there are no apparent complicating features. Severe swelling, with unusual features, or where there may be more than one pathology contributing to the clinical picture usually warrants further investigation. Not only will this allow the diagnosis to be confirmed, but it may also provide useful prognostic information and guide management decisions.

Investigation techniques

Listed are several procedures used in the investigation of lymphoedema.

‘Routine’ tests. A full blood count, plasma urea and electrolytes, creatinine, liver function tests, chest radiograph and midnight blood

Contrast lymphangiography. Although few centres now perform this technique, it remains the standard by which all other lymphatic imaging is judged and provides precise information about the anatomy of the lymphatic system. It is now generally reserved for preoperative evaluation of patients with megalymphatics who are being considered for bypass or fistula ligation.

Technique (Kinmonth, Browse, Wolfe). The patient is admitted for limb elevation to reduce swelling and facilitate lymphatic cannulation. Originally a vital dye such as patent blue was injected and its ascent in the lymphatics to the regional nodes (in about 5–111 minutes) simply observed with the naked eye (visual lymphangiography). In patients with obliterated lymphatics dermal backflow could be observed soon after injection and the appearance of dye at the groin was delayed. This technique was soon replaced with direct contrast lymphangiography. Under local anaesthesia, a small transverse incision is made in the dorsum of the foot after 1 ml of isosulphan blue has been injected subcutaneously to identify the lymphatics. Lymphatics are dissected out under loupe magnification and a 30G needle used to infuse lipid-soluble contrast at a rate of 1 ml in 8 minutes to a maximum of 7 ml (taking about 1 hour) into each limb. Serial radiographs are taken during injection and at intervals up to 24 hours. As the procedure is uncomfortable and patients are often unable to lie still, it is frequently performed under general anaesthesia. In a normal limb the injection will usually fill between five and is superficial valved medial lymphatic vessels in the thigh as well as most of the inguinal lymph nodes; iliac nodes fill at between 30 and 45 minutes. Deep lymphatics, which are frequently paired and follow the deep vessels, as well as the lateral superficial lymphatics are not usually seen except in disease. Four main anatomic patterns of lymphatic disease are identified by lymphangiography; namely congenital hyperplasia, distal obliteration (hypo/aplasia), proximal obliteration with distal hyperplasia and proximal obliteration with distal obliteration (Table 17.4 and Fig. 17.13).

Isotope lymphoscintigraphy. This has largely replaced contrast lymphangiography and is used in most centres as the primary diagnostic technique.

Technique. The patient lies supine. Radioactive technetium-labelled antimony sulphide colloid particles (10 nm diameter) are injected into the web space between the second and third toes (or fingers) with a 27G needle bilaterally. This is associated with 5–10 seconds of stinging, about which the patient must be warned. The particles are specifically taken up by lymphatics and about 30 per cent of the tracer is absorbed in 3 hours. Immediately after injection a gamma camera is positioned to include the inguinal region in its upper field. During the first hour, 12
5-minute dynamic anterior exposures are taken. The patient is requested to exercise with a foot ergometer (to permit reproducible exercise and tracer clearance) for 5 minutes initially and then for 1 minute out of every subsequent 5 minutes. At 1 and 3 hours, and in selected patients at 6 and 24 hours, 20-minute whole body exposures are taken. Between exposures the patient is ambulant.

**Interpretation.** In a normal leg activity ascends the anteromedial aspect of the limb. Several lymph channels are seen in the calf but in the thigh they cannot usually be distinguished. Normally, radioactivity first appears in the inguinal (axillary) nodes at between 15 and 60 minutes and is symmetrical; individual nodes cannot usually be distinguished. At 60 minutes there is only faint uptake in the liver and bladder. At 3 hours there is intense activity over the liver and good symmetrical uptake in inguinal, pelvic and abdominal lymph nodes; the thoracic duct may also be seen. Most groups interpret lymphoscintigraphy qualitatively as attempts to perform quantitative assessment have produced inconsistent results. It is not possible to distinguish primary from secondary lymphoedema with certainty. However, lymphoscintigraphic patterns can be correlated to some extent with lymphangiographic findings.

- Distal obliteration is also known as aplasia or hypoplasia and is associated with little or no removal of tracer from the injection site, little or no activity in the regional nodes at 1 or 3 hours, and a cutaneous pattern of tracer distribution (dermal backflow). Although the time taken for radioactivity to reach the groin is prolonged, onward passage from there is usually normal.

- Proximal obliteration is associated with normal uptake from the injection site and appearance of tracer in inguinal nodes. However, there is a failure of tracer to progress from the inguinal lymph nodes and collaterals crossing over to other side are present.

- Lymphangectasia is associated with abnormal collections of tracer activity indicating extravasation into the peritoneal or pleural cavities or into viscera. Lymphoceles and dilated lymph channels (mega-lymphatics) are also seen.

Computerised tomography. The main role of CT is to exclude pelvic or abdominal mass lesions. Although lymphoedema itself can be visualised on CT, it is of little diagnostic value in this respect.

Magnetic resonance imaging can provide clear images of lymphatic channels and lymph nodes, and can also distinguish venous and lymphatic disease as the cause of a swollen limb. However, it cannot at present provide the information available from lymphoscintigraphy, and as a cross-sectional imaging technique it appears to have little advantage over CT.

Pathological examination. In cases where malignancy is suspected, samples of lymph nodes may be obtained by fine needle aspiration, needle core biopsy or surgical excision.
Management of lymphoedema

Physical methods

The patient should elevate the foot above the level of the hip when sitting, elevate the foot of the bed when sleeping and avoid prolonged standing. Various forms of massage are effective at reducing oedema. Single- and multiple-chamber intermittent pneumatic compression devices are also useful. In most clinics the mainstay of therapy is correctly fitted graduated compression hosiery. Pressures exceeding 50 mmHg at the ankle may be required to control oedema. Below-knee stockings are usually sufficient. The patient should put the stocking on first thing in the morning when the leg is at its least swollen. General advice regarding exercise and weight reduction, if necessary, is sensible.

Drugs

Diuretics are of no value in pure lymphoedema. Their use is associated with side effects including electrolyte disturbance. The hydroxyureas are reported to be beneficial, as are the coumadins, but there are no scientifically robust data to support their use. Antibiotics should be prescribed promptly for cellulitis; penicillin V 500 mg four times daily for staphylococcal infection and fluocoxacin 250 mg four times daily for staphylococcal infection are suitable. In severe cases there should be no hesitation in admitting the patient to hospital, elevating the limb and administering antibiotics intravenously. Antibiotics should be continued for at least 7 days or until all signs and symptoms have abated. Erythromycin is a reasonable alternative for those who are allergic to penicillin. In patients who suffer recurrent spontaneous episodes of cellulitis, long-term prophylactic antibiotic therapy may be indicated. Fungal infection (tinea pedis) must be treated aggressively; topical clotrimazole 1 per cent or miconazole 2 per cent used regu-larly is sufficient in most cases, but in refractory situations systemic griseofulvin 250—1000 mg daily may be required. The feet must be dried after washing and the skin kept clean and supple with water-based emollients to prevent entry of bacteria.

Surgery

Only a small minority of patients with lymphoedema benefits from surgery. Operations fall into two categories: bypass procedures and reduction procedures.

Bypass procedures

In less than 2 per cent of patients with primary lymphoedema, lymphangiography will demonstrate proximal lymphatic obstruction in the ilio-inguinal region with essentially normal distal lymphatic channels. In theory at least, such patients might benefit from lymphatic bypass. A number of methods has been described, including the omental pedicle, the skin bridge (Gillies), anastomosing lymph nodes to veins (Neibulowitz), the ileal mucosal patch (Kinmonth) and, more recently, direct lymphovenous anastomosis with the aid of the operating microscope. Although the last two techniques do appear to lead to significant improvement in about 50 per cent of patients, it is not possible to predict which patients will benefit. The procedures are technically demanding, not without morbidity and there is no controlled evidence to suggest that these procedures produce a superior outcome to best medical management alone.

Limb reduction procedures

These are indicated when a limb is so swollen that it interferes with mobility and livelihood. These operations are not ‘cosmetic’ in the sense that they do not create a normally shaped leg and are usually associated with significant scarring. Four operations have been described.

Sistrunk. A wedge of skin and subcutaneous tissue is excised and the wound closed primarily. This is most commonly employed to reduce the girth of the thigh.

Homan. Skin flaps are elevated and subcutaneous tissue is excised from beneath the flaps, which are then trimmed to size to accommodate the reduced girth of the limb and closed primarily. This is the most satisfactory operation for the calf (Figs 17.14 and Fig. 17.15). The main complication is skin flap necrosis. There must be at least 6 months between operations on the medial and lateral sides of the limb and the flaps must not pass the midline. This procedure has also been used on the upper limb but is contraindicated in the presence of venous obstruction or active malignancy.

Thompson. One denuded skin flap is sutured to the deep fascia and buried beneath the second skin flap (the so-called buried dermal flap) (Fig. 17.16). This procedure has become less popular as pilonidal sinus formation is common, the cosmetic result is no better than that obtained with Homan’s procedure and there is no evidence that the buried flap establishes any new lymphatic connection with the deep tissues.

Charles. This operation was initially designed for filariasis and involved excision of all the skin and subcutaneous tissues down to deep fascia with coverage using split skin grafts (Fig. 17.17). This leaves a very unsatisfactory cosmetic result and graft failure is not uncommon. However, it does enable the surgeon to reduce greatly the girth of a massively swollen limb.

Other excisional surgery

Scrotal, penile and labial lymphoedema may be highly symp-tomatic causing embarrassment, preventing intercourse and impeding micturition. Minor swelling may be treated with support hosiery but severe swelling is best treated with excisional surgery. Lymphoedema of the eyelid may be treated by lid reduction.

Chylous ascites and chylothorax

The diagnosis may be obvious if accompanied by lymphoedema of an extremity, especially if the latter is associated with vesicles. However, some patients develop chylous ascites and/or chylothorax in isolation, in which case the diagnosis can be confirmed by aspiration and the identification of chylomicrons in the aspirate. Cytology for malignant cells should also be carried out. CT scan may show enlarged lymph nodes, and CT with guided biopsy, laparoscopy or even laparotomy and biopsy may be necessary to exclude lymphoma or other malignancy. Lymphangiography may indicate the site of a lymphatic fistula which can be surgically ligated. Even if no localised lesion is identified, it may be possible to control leakage at laparotomy or even remove a segment of affected bowel. If the problem is too diffuse to be corrected surgically, a peritoneal venous shunt may be inserted, although occlusion and infection are important complications. Medical treatment comprising the avoidance of fat in the diet and the prescription of medium chain triglycerides (which are absorbed directly into the blood rather than via the lymphatics) may reduce swelling. Chylothorax is best treated by pleurodesis with either bleomycin, talc, pleural stripping or tetracycline. In some cases this leads to death from lymph-logged lungs as the excess lymph has nowhere to drain.

Chyluria

Filarisis is the most common cause, with chyluria occurring in 1—2 per cent of cases 10—20 years after initial infestation. It usually presents...
as painless passage of milky white urine, particularly after a fatty meal. The chyle may clot leading to renal colic and hypoproteinaemia may result. A clot forms in the urine on standing which does not dissolve on shaking with an equal amount of ether. The urine contains chylomicrons, and oral ingestion of fat with Sudan Red turns the urine pink. Chyluria may also be caused by ascariasis, malaria, tumour and tuberculosis, and the differential diagnosis includes gross pyuria, phosphaturia and caseous material from tuberculosis. Intravenous urography and/or lymphangiography will often demonstrate the lymphourinary fistula. Treatment includes a low-fat and high-protein diet, increased oral fluids to prevent clot colic, and laparotomy and ligation of the dilated lymphatics. Attempts have also been made to sclerose the lymphatics either directly or via instrumentation of the bladder, ureter and renal pelvis.
Lymphangiomas

Lymphangioma circumscriptum

This involves superficial proliferation of capillary sized lymphatic vessels which comprise fluid-filled vesicles on the surface and larger cisternae in the subcutaneous tissues and even adjacent muscles. These clear or slightly haemorrhagic skin vesicles have been considered either as hamartomas or as a localised deficiency in skin lymphatic drainage. Affected skin and a generous amount of subcutaneous tissue containing the vessels may be excised if they cause symptoms, but even with generous margins recurrence is common.

Cystic hygroma

Cystic hygroma is an abnormal lymph-filled, often multilocular, space which usually presents in childhood as a soft, brilliantly transluminable swelling in the base of the neck. It is also found in the head and inguinal regions as they develop from primitive lymph cisterns. It behaves like a benign tumour and grows gradually in size, leading to cosmetic problems and compression of surrounding structures. Recurrence is common after simple aspiration and injection of sclerosant. Excision is technically challenging due to the large number of vital structures in the vicinity.

Mesenteric lymph cysts

These cysts present as well-defined mobile lumps within the abdomen, the nature of which can be confirmed by either ultrasound or CT. They may be resected together with the overlying segment of small bowel if they cause symptoms.

Introduction and epidemiology

Injury is the leading cause of death and disability in the first four decades of life and is the third most common cause of death overall. This holds true even in acquired immunodeficiency syndrome (AIDS)-prevalent areas of the world. Yet, the National Academy of Science in the United States has labelled injury as the ‘neglected disease of modern society’. A similar view prevails in the UK, where a leading emergency surgeon has referred to ‘trauma as the neglected stepchild of modern medicine’. Public health officials world-wide concede that there is a global epidemic of violence with an increasing trend towards penetrating injury caused by knives, guns and terrorist devices. This has led to injury as a subject of study undergoing a renaissance over the last 10 years.

In the UK accidental and deliberate injury results in more than 18,000 deaths annually, with 60,000 hospital admissions costing £2.2 billion, which represents 1 per cent of gross national product (GNP). For every injury-related death there are 10 other survivors with serious injury, two of whom will have permanent disabilities. A staggering 120,000 people die from trauma each year in the USA. Ballistic trauma accounts for more than 30,000 of these, most of them in the prime of life. The cost to the USA is between $75 and $100 billion — more than the cost of the Gulf war in 1990.
Mechanisms of injury

By convention, injury is classified into several categories — these are listed below.

Types of injury
• Penetrating
• Nonpenetrating blunt
• Blast overpressure
• Thermal
• Chemical
• Other, including crush and barotrauma

In this chapter discussion centres on blunt, penetrating and blast injury only.

Impact between the body and an external object may result in tissue compression, stretching, tearing and other deformation ranging in severity from trivial to tissue injury beyond recoverable limits. The severity of damage is related to many factors, the most important of which are the amount of energy transferred and the nature and extent of the tissues over which it is applied.

In penetrating injury of low velocity and low available energy, tissue damage is focused over a small area, for example injuries caused by low-energy handguns, knives, sharp instruments, spikes of glass, wood or metal. Injury severity and outcome is related to the tissues involved. While low-velocity and low-energy injury to the soft tissue in the forearm will be slight, a similar injury involving the mediastinum might be lethal. In this case debates concerning velocity and energy transfer become academic. In high-velocity injury, associated with the potential for high-energy transfer, damage to structures may extend over a wide area remote from the wound track (see later).

In blunt injuries mechanisms may be multiple and tissue damage of complex aetiology. Mechanisms are listed below.

Mechanisms of blunt injuries
• Acceleration
• Deceleration
• Rotational
• Stretch and shear

Victims of motor vehicle accidents may be injured either by rapid deceleration or by deformation with intrusion of vehicle components into the interior of the vehicle. In a crash, as deceleration occurs, the occupant’s body is thrown against the interior of the vehicle, often referred to as the ‘second collision’. There is also a ‘third collision’ between soft tissues and skeletal structures. All may contribute to injury, the extent of which will depend on the body region involved, degree of restraint and severity of the impact. Deformation and intrusion may result in blunt, penetrating or crush injury. Prolonged entrapment may exacerbate matters. Ejection of an occupant may occur, in which case rapid deceleration of the body occurs when it strikes the ground or another vehicle. Ejection is associated with increased likelihood of serious injury and death. When a pedestrian is struck by a moving vehicle there is often an acceleration injury in addition to the direct trauma at the sites of impact (Fig. 18.1). In an adult, injury is commonly due to bumper (fender) impact to the limbs; in children, such an impact is over a wider area often involving the chest and abdomen, and is associated with multiple injuries and high mortality.

Patterns of injuries in road traffic accidents

Although the variety of injuries that may occur in a road traffic accident is vast, consistent patterns of injury are observed. The following are typical combinations:
• head, face and cervical spine injuries;
• cervical whiplash and sternal injuries;
• sternal fracture and dorsal spine injury;
• lower rib fractures with injury to kidneys, liver or spleen;
• intra-abdominal and diaphragmatic injuries;
• pelvic fracture with lower urinary tract injury;
• lower limb fracture with hip dislocation or spinal fracture.

Seat-belt injuries

While the wearing of automobile seat belts has undoubtedly saved many lives and has also reduced the incidence and severity of injuries to passengers, there are instances in which significant injury may be produced by their use. These lesions are secondary to restraint caused by the seat belt, whereby the occupant is forced by inertia against the straps as the vehicle rapidly decelerates. Injury may also be attributed to incorrect seat belt usage resulting in ‘submarining’ below the lap section of the belt on impact. While injuries to the head, face, lung, heart, aorta and liver/spleen are rarer since the introduction of seat belts, an increased incidence of injuries to stomach, duodenum, pancreas, small bowel and mesentery has been noted. Major intra-abdominal vessels may also be traumatised and fractures of the lumbar spine can occur.

Airbags

There is considerable interest in the use of airbags for drivers and front seat passengers. Evidence of their effectiveness and safety is gradually emerging with increased use. While they have saved lives, deaths, particularly in front-seat child passengers, have been reported. These were related to inadvertent inflation in slow-speed impacts with inflation velocity sufficient in some cases to decapitate. More evidence is required.

Death following injury
Dr Donald Trunkey has pointed out that deaths following injury fall broadly into three groups giving a distinct trimodal pattern (Fig. 18.2).

Immediate deaths (50 per cent) — those occurring immediately or within the first few minutes of injury and usually due to widespread damage to the brain or upper spinal cord, the heart or major vessels, or multiple injuries. This first peak is due to injuries which are generally lethal so that little can be done in their management that is likely to affect outcome. Reduction of this peak can only be achieved by preventive measures such as wearing of appropriate seat belts in automobiles, head protection on bicycles and motorcycles, road safety legislation and education for pedestrians.

• Early deaths (30 per cent) — those occurring within the first few hours after injury [called by some the ‘golden hour(s)’ of trauma]. These deaths are deemed preventable and are due to facial injuries with developing airway obstruction, lethal disruption of the breathing mechanism, massive blood loss into body cavities or from multiple long bone fractures leading to collapse of the circulation, and dysfunction of the central nervous system due to space-occupying collections of blood within the skull. This became the basis of the ABCDE approach to initial assessment of the severely injured (see later).

• Late deaths (20 per cent) — those occurring days or weeks after injury, generally due to sepsis and multiple organ failure. Organ failure may involve the heart, kidney, liver, lung, brain and haemopoietic systems.

it is among those cases represented by the second and third peaks that potentially preventable deaths occur.
Modern management of the injured

Before turning to retrieval, hospital reception and care of the injured it is necessary to outline the fundamental changes in the management of the injured that have taken place in recent decades. The 1988 Royal College of Surgeons of England report on the management of the multiply injured highlighted that at least one in five, and possibly as many as one in three, trauma deaths in hospital were avoidable. They further concluded that death in such cases was due to medical mismanagement at every level and throughout all specialties. Later that year the Advanced Trauma Life Support Course (ATLS®) was introduced, followed by the Advanced Trauma Nursing Course (ATNC). More recently the Pre-Hospital Trauma Life Support Course (PHTLS) was introduced for those working in the prehospital setting. These training courses have radically altered the way in which the injured patient is perceived and managed throughout the chain of care from point of injury onwards. In this chapter concern is focused on management by surgeons in hospital. Nevertheless, readers must be aware that recovery following injury is dependent upon a collaborative approach involving health professionals throughout the chain of care. A break in the chain at any point is likely to affect outcome adversely. ATLS and its derived variants such as ATNC and PHTLS provide a framework and a common language throughout the chain.
The Advanced Trauma life Support approach

Following the death of his wife and serious injury to his three children in an air crash in the 1970s, an American orthopaedic surgeon, Dr James Styner, introduced a structured trauma management training programme which was soon adopted by the American College of Surgeons and developed into the ATLS educational package now in widespread use in the UK and in 23 other countries. To date, over 200 000 doctors have been trained and the approach is now regarded as the gold standard in early trauma initial assessment and resuscitation.

The philosophy

ATLS management is based on a ‘treat lethal injury first, then reassess and treat again’ strategy. The steps in management are given below.

ATLS component steps

• Primary survey — identify what is killing the patient

• Resuscitation — treat what is killing the patient

•Secondary survey — proceed to identify all other injuries

• Definitive care — develop a definitive management plan

NB. Primary survey and resuscitation must be concurrent.

The philosophy is based on the urgency and crisis surrounding early management of a multiply injured patient whose life is in danger. Underpinning this approach is the quite recent realisation that death following injury is a function of time and occurs in a predictable and measurable way.

Dr Donald Trunkey’s demonstration of the trimodal distribution of death has already been alluded to in Fig. 18.2. The ATLS approach focuses on the second or early death group where death is preventable. Within this so-called preventable group, death will follow if treatment is withheld or delayed and will do so in a predictable way. Early and effective treatment during the period when the second group of deaths occurs also reduces the number of deaths during the third phase of the trimodal distribution.

An obstructed airway in a victim with head injury will kill in 3—4 minutes, well before death might occur from the effects of injury to the brain. Equally, a life-threatening injury within the thorax will kill before a life-threatening bleed within the abdomen. Finally, major haemorrhage in the limbs, chest or abdomen will kill before a life-threatening space-occupying lesion. While these are generalisations and exceptions do occur, they support the ‘primary survey and resuscitation’ management doctrine. The elements of this ABCDE approach are listed below and will be explained in more detail later.

Elements of the primary survey

• Airway with cervical spine control

• Breathing and ventilation

• Circulation with control of haemorrhage

• Dysfunction of the central nervous system

• Exposure in a controlled environment
Prehospital retrieval and management

The aim should be for rapid and smooth transfer of patients from the scene of the accident to a hospital that is well equipped and adequately staffed, with trained personnel to deal quickly and efficiently with all of the injuries encountered.

A ‘scoop and run’ policy is best where transfer time to hospital is short. A ‘stay and play’ policy may be required in the face of entrapment but prehospital personnel must be properly trained and equipped (to PHTLS standards, for example). In all cases, attention is first paid to securing an adequate airway. Gloves are worn and a two-finger ‘sweep’ is used to clear solid material from the mouth and pharynx combined with good suction under direct vision to remove fluid and debris. Airway patency is then maintained by chin lift or jaw thrust maneuvers, lifting the mandible forwards and, if appropriate, inserting an airway device (oropharyngeal/nasopharyngeal or endotracheal according to clinical judgement and expertise available). If unable to open the airway by the above, a surgical cricothyroidotomy may be performed in patients over the age of 12 years by inserting a 6-mm paediatric cuffed tracheostomy tube through the cricothyroid membrane (Fig. 18.3). Under the age of 12 years the cricoid membrane is very narrow and the cricoid cartilage is the only complete ring preventing airway collapse. Under these circumstances, a needle crico-thyroidotomy may buy some time (20 minutes) provided that a means of jet-insufflating oxygen through the needle is available. Proprietary mini-tracheostomy sets should not to be used. These have a very narrow internal diameter and do not allow spontaneous ventilation. They are indicated only in critical care environments for bronchial toilet. Finally, access to the trachea should not be attempted under these conditions — tracheostomy is time-consuming and fraught with danger.

Meanwhile, attention is paid to protecting the cervical spine by the use of a well-fitting semirigid neck brace, sandbags and forehead strapping. Modern spine boards incorporate neck restraint pads and straps, and may be used in lieu of sandbags and forehead strapping (Fig. 18.4).

Other measures include ensuring adequate ventilation and oxygenation, covering and sealing open ‘sucking’ chest wounds, controlling external bleeding by direct pressure and monitoring the neurological status. The ‘AVPU’ method is recommended in the prehospital setting.

Prehospital mini-neurological examination

• A-Alert
• V — Responds to Voice
• P — Responds to Pain
• U — Unresponsive
• Pupils — Size and reaction

If there is any obvious long bone fracture of an extremity with gross deformity, the limb should be gently drawn into alignment and a traction splint applied. Controversy exists regarding the prehospital role in resus-citation by intravenous fluid infusion. Vascular access in a cold, shocked injury victim is often difficult and time-consuming, and there is emerging evidence that a degree of hypotension (systolic blood pressure 80—85 mmHg) may be safely tolerated (see later). If circumstances dictate that transfer time will be prolonged, or when entrapment and difficulty in extrication is encountered, then more sophisticated and advanced life-support measures may be instituted with the caveat made at the beginning of this section.
Management in hospital

Reception in hospital

Planning and preparation

Accident departments dealing with the injured must have purpose-built and well-equipped resuscitation rooms. Medical staff should ideally be trained in a trauma system — ATLS provides an ideal framework within which to work and certification will soon be compulsory in the UK. Certification is already compulsory in North America. Nursing and other professional staff should also be trained within the system. Another advantage of a structured approach relates to equipment and layout. Working within a system removes debate concerning intravenous fluid type and amounts, techniques and investigations to be performed, and the summoning of appropriate specialists. Agreement in these areas is laid down in advance and allows medical teams to work within a common language and sequence.

The trauma team

While a suitably trained doctor can successfully assess and resuscitate an injured patient while working to a system, it is obvious that a team approach is more efficient and is quicker. This is the vertical (alone) versus the horizontal (team) argument. Dr Peter Driscoll in Salford has shown clearly the benefits of a team in improving outcome. The team should initially comprise four doctors, five nurses and a radiographer. Roles should be paired and tasks allocated on a pre-agreed basis. To avoid chaos, there should be no more than six people physically attending to the patient at any one time. Others should stand back until called to perform specific tasks such as vascular access, radiographic assessment or assisting in log rolling. The team should have a leader responsible for co-ordination and at least one member should be a trained general surgeon. Injury is a surgical disease and surgical consultation is required throughout.

Controversy once surrounded the mobilisation of the trauma team, with accusations of inappropriate call-out resulting in time wasted from clinics and operating lists. This has now been resolved by widespread acceptance of traumateteam call-out criteria. Agreed factors indicating high risk of multiple injuries and justifying trauma team mobilisation are (after Champion):

- penetrating injury to the chest, abdomen, head, neck or groin;
- two or more proximal long bone fractures;
- flail chest and pulmonary contusion;
- evidence of high-energy impact:
  - falls of 2 m (6 feet) or more;
  - changes in velocity in an road traffic accident of 32 km/hour (20 miles/hour) or more estimated from outward deformity of car;
  - rearward displacement of front axle;
  - sideward intrusion of 35 cm or more on the patient’s side of the car;
  - ejection of the patient;
  - rollover;
  - death of another person in the same car;
  - pedestrian hit at more than 32 km/hour.

Initial assessment and resuscitation

The objectives in this phase are to seek and manage immediately life-threatening conditions. In ATLS language this is the ‘primary survey and resuscitation’, following an ABCDE sequence in every circumstance. The description that follows holds good for vertical (alone) or horizontal (team) management. The only radiographs permitted during this phase are:

- cross-table lateral cervical spine;
- antero-posterior supine chest X-ray;
- antero-posterior plain pelvic film.

A — Airway management and cervical spine control

Injury to the cervical spine is assumed in the presence of injury above the clavicle, loss or alteration of conscious level, involvement in high-speed collisions or where there is a history of neck pain. Airway assessment and management is performed with the cervical spine immobilised in the neutral position by manual in-line immobilisation or by a well-fitting neck brace, sandbags and forehead tape. Many injured patients arrive in the accident department with neck protection already in situ. In a conscious patient, speaking in a normal voice, the airway is patent and the brain is being adequately perfused. If the patient does not reply to a simple question, the airway is opened and dealt with as described for prehospital personnel. If there is any doubt concerning the integrity of the airway, skilled anaesthetic help should be summoned if not already present as part of an attending trauma team. All injured patients require supplemental oxygen at 15 litres/minute via a mask with a rebreathing bag.

B — Breathing and ventilation

The neck and chest are exposed. Examination involves inspection, palpation, percussion and auscultation. The examination starts in the neck with inspection for wounds, condition of neck veins, wounds and evidence of tracheal injury. The respiratory rate is counted and recorded, with
the time noted. Chest symmetry and respiratory effort are assessed. Wounds and bruising are noted. Palpation, particularly to include the sides and back (without spinal movement), is performed gently followed by percussion and auscultation. A dull percussion note and absent breath sounds over a hemithorax in the presence of shock are indicative of massive haemothorax (see Box 18.6). The objective is to hunt out and treat the six life threatening thoracic conditions listed below

Immediately life-threatening thoracic conditions

• Airway obstruction (dealt with under ‘A)
• Tension pneumothorax
• Massive pneumothorax (> 1500 ml blood in a hemithorax)
• Open pneumothorax (sucking wound’)
• Flail segment with pulmonary contusion
• Cardiac tamponade (almost always penetrating injury)

Tension pneumothorax requires immediate needle thoracocentesis in the second intercostal space in the midclavicular line on the affected side, followed by tube thoracostomy through the fifth intercostal space just anterior to the midaxillary line. Massive haemothorax is a combined breathing (B) and circulation (C) problem with death likely from hypovolaemic shock and impaired ventilation. Management is therefore by vigorous support of the circulation followed by tube thoracostomy. Open pneumothorax is managed by sealing the wound with a dressing secured on three sides followed by tube thoracostomy. Following insertion of the tube, the dressing is sealed on the fourth side. Flail segment with underlying contusion (always present) requires consultation with anaesthetic colleagues as endotracheal intubation and mechanical ventilation may be required to maintain adequate arterial oxygen saturation. Diagnosis of cardiac tamponade requires a high index of suspicion, particularly if a penetrating wound is noted medial to the nipples anteriorly or medial to the scapulae posteriorly. Needle pericardiocentesis may be life-saving in the short term; thoracotomy and repair are required for definitive management.

C—Circulation and haemorrhage control

This begins with assessment for signs of shock (see Chapter 4). Tachycardia in a cold patient indicates shock. Equally, shock associated with injury is hypovolaemic until ruled out. Causes of shock are listed below.

Causes of shock following injury

• Hypovolaemic — haemorrhagic (most common)
• Cardiogenic or pump failure (cardiac tamponade, tension pneumothorax or myocardial contusion)
• Neurogenic (often combined with hypovolaemic shock and masked)
• Septic (a late event > 24 hours and associated with missed faecal spillage)

An early attempt should be made to assess the degree of blood loss. Table 18.1 lists four classes based on volume loss expressed as actual amounts and percentages (to be used for adults only).

Blood loss may be external and obvious, or internal and covert, or combinations of both. External bleeding sites are dealt with by direct pressure at this stage. A hunt must be undertaken for signs of covert bleeding. Bleeding in the chest will have been noted already. The abdomen and pelvis must be rapidly assessed for signs of injury. A good aide-mémoire is ‘blood on the floor and four more’:

• blood on floor or environment, including clothing.
• blood in the chest (dull percussion note);
• abdomen (wounds, abrasions, tenderness but may be silent);
• pelvis (usually associated with obvious pelvic disruption);
• limbs (should be obvious).

The presence of shock demands the presence of a surgeon, appropriate to the region injured if this is obvious. Whereas intravenous fluid administration has a vital role, the emphasis must be on stopping the bleeding by surgical means. Vascular access for resuscitation is by cannulation of peripheral veins

— if this fails, venous cut-down at the ankle or elbow is recommended. Once a cannula is in position, 20 ml of blood should be withdrawn for group, type or full cross-match depending on the degree of urgency. Central access will be required later for monitoring but is not a good route for initial resuscitation owing to slow flow rates, technical difficulty and uncertainty concerning position of the catheter.

tip. There is revival of interest in interosseous access for adults. It is too early to comment on its utility for general use. Its place is well established for children under the age of 6 years and should be resorted to without hesitation if peripheral access fails on two attempts. Special paediatric interosseous needles are available commercially.

In adults, 1—2 litres of warmed Hartmann’s (Ringer’s) solution is recommended as an initial fluid challenge. The initial volume in children is calculated according to weight and is by convention 20 ml/kg body weight. This bolus may be repeated once.
The patient should now be reassessed. The three responses that may be seen are given below.

Responses to initial fluid challenge

- Immediate and sustained return to normal vital signs
- Transient response with later deterioration
- No improvement

Immediate responders are likely to have less than 20 per cent blood loss and bleeding will have ceased spontaneously or by direct pressure — an open fracture of tibia, for example. Transient responders may have intra-abdominal or thoracic bleeding, and surgical intervention will be required. Non-responders are bleeding actively, usually in a body cavity, or shock is nonhaemorrhagic in nature. Hypovolaemic patients have lost over 40 per cent of their blood volume, demanding immediate surgical intervention. Continuing intravenous fluid administration may actually be detrimental.

D— Dysfunction of the central nervous system

The AVPU and pupillary assessment carried out by pre-hospital personnel is repeated (see Box 18.5). In addition, a rapid assessment of motor and sensory function is performed looking only for gross and obvious signs. A more detailed assessment will be carried out during the secondary survey (see later).

E— Exposure and environment

Any remaining clothing should now be removed. The environment must be considered. If too cold, hypothermia will ensue. Blankets or air heaters should be used if available.

Critical decisions

The response of the injured patient to the primary survey and resuscitation phase will influence decision making. A patient in whom no life-threatening condition was found, or one whose condition responded well and in a sustained way, is now fit for a full secondary assessment which may be carried out in the resuscitation room or in a ward area following admission. Some patients will have failed to respond and require immediate removal to the operating theatre. Exam-pies include disruptive pelvic injury, major liver laceration or injuries to multiple body systems requiring immediate control of blood loss — these are relatively rare. Initial surgery in this instance is part of the primary survey and a secondary survey, although deferred, must not be forgotten. Good note-keeping and records are vital. A significant number of patients will respond transiently and is best taken to a critical care environment where more advanced resuscitation techniques and assessments are possible. Such patients will require surgery but it is usually possible to investigate and plan in advance. Examples include splenic laceration, bowel injury, diaphragmatic disruption, or multiple fractures and soft-tissue wounds. In summary, the patient may be taken to the ward, critical care unit or to theatre.

Secondary survey

This phase comprises a head-to-toe examination of the undressed and stable patient. It is lengthy and includes a detailed history if this is feasible. The examination may be conducted in any order. The description here starts with the head and works distally. At this time check that vital signs monitoring devices are in situ. These should include a pulse oximeter and an oesophageal or a rectal thermometer. During this phase detailed radiographic procedures including computerised tomography (CT) and dye studies may be performed. Patients should be stable and can therefore travel safely for CT, ultrasound or even magnetic resonance imaging (MRI) investigations if these are indicated.

Head and Glasgow Coma Scale (GCS)

A thorough check is undertaken for signs of external injury such as bruising, laceration or bony deformity. Depressed skull fractures may or may not be palpable.

At this stage, the patient’s conscious level is determined by applying the GCS, which measures eye opening, best verbal response and best motor response. The coding for each is given in Table 18.2.

The use of this coding system is detailed fully in Chapter 35 on ‘Cranium and head injury’. Neurological deterioration may indicate a haemorrhagic space-occupying lesion or rising intracranial pressure, or it may be due to hypoxia and hypoperfusion. Hypercarbia and hypoxia are the commonest causes of the preventable ‘second injury’ in head-injured patients. Hypotension in a head-injured adult should lead to a further search for evidence of blood loss elsewhere.

The nostrils and external auditory meatus are examined for rhinorrhoea or otorrhoea. Cerebrospinal fluid from these orifices mixed with blood produces a double ring if dropped on a hospital sheet or pillowcase.

Face

Maxillofacial injuries are discussed in Chapter 38. In summary, the eyes are checked for foreign bodies, perforation, subconjunctival haemorrhage, visual acuity, and pupillary and corneal reflexes. The mandible is checked for fracture and stability. Maxillary stability is also assessed — fractures of the middle third of the face may be displaced with risk to the airway, either immediately or late as a result of expanding haematoma. The mouth is checked again for broken teeth, loose dentures and foreign bodies. Check also for retropharyngeal haematoma. This may be associated with previously undetected cervical spine injury.

Neck

Look for subcutaneous emphysema. Palpate (gently) the cervical spine. A lateral radiograph showing all seven cervical vertebrae and the upper border of the first thoracic is essential in all multisystem injury patients. Particular care should be taken not to miss lesions at C1, C2 and C7 levels — fractures and dislocations at these levels are notoriously unstable. Downward traction on the arms while the film is being taken will enhance the demonstration of the lower cervical and Ti vertebral. In some cases a ‘swimmer’s view may be necessary — see also Chapter 33 on the
Thorax

Start by repeating the steps on thoracic assessment performed in the primary survey. The search is now for potentially life-threatening and less serious injuries. These are listed below. Remember, penetrating and blunt injury below the nipples (male patient) raises the likelihood of injury to intra-abdominal structures, in particular the liver, spleen, stomach and transverse colon. Simple haemothorax and pneumothorax may be picked up on an anteroposterior (AP) supine chest radiograph. Tube thoracostomy will suffice in most instances. Check also for the integrity of diaphragm, particularly on the left.

Secondary survey — potentially life-threatening injuries
- Pulmonary contusion
- Myocardial contusion
- Aortic tear
- Diaphragmatic tear
- Oesophageal tear
- Tracheobronchial tear

Abdomen

The secondary survey is the phase of 'fingers and tubes' in every orifice. This particularly applies to the abdomen. Nasogastric and urinary catheters are inserted for diagnostic and assessment purposes. The abdomen is now fully examined in the usual way. A rectal examination and inspection of the per-ineum is mandatory. At this time please read the relevant sections on specific injuries in Chapters 50—61 inclusive. Wounds should be covered with sterile dressings or towels. Eviscerated bowel should be covered in warm wet packs and must not be returned to the peritoneum at this stage. Assessment of the abdomen in cases of penetrating trauma is relatively easy. In most instances the abdomen will need to be explored. In some large centres, protocols may permit local exploration of stab wounds in stable patients. Difficulty arises in cases of blunt injury, all the more when multiple injuries are present or where the conscious level is altered. Diagnostic peritoneal lavage, ultrasound examination or, in some specialist centres, laparoscopy may be required to detect covert intra-abdominal injury. The retroperitoneum is notoriously silent. All of the foregoing remarks refer to stable patients. Any deterioration should lead to consideration of rapid surgical exploration.

Pelvis

The pelvis is gently compressed and distracted manually to check for pain enhancement and pelvic stability. If not already to hand, an AP radiograph of the pelvic ring should be obtained. Blood at the urinary meatus may indicate urethral injury. If injury is suspected, get expert help. If not available, do not catheterise; instead, place a suprapubic catheter. Please also read the sections on specific injuries in Chapters 63—68 inclusive.

Spinal injuries

Please read the relevant sections in Chapter 33. Tests are made for peripheral sensory and motor defects. In spinal injuries with unstable fractures, further neurological damage can be caused by moving the patient inappropriately. Full examination will require the patient to be log rolled when sufficient personnel are present. At least five people are needed. The team leader should control the neck and co-ordinate. Three others are needed to effect rolling the torso and limbs, and a doctor to examine the back and perineum. A rectal examination is performed if not done before. In large urban centres, severely injured patients may be transported to hospital on a long spine board. Removal from the board on to a hospital trolley requires the same care as for a log roll.

Extremities

The limbs should be fully assessed for evidence of injury. This should include a complete neurovascular examination. Appropriate radiographs may be obtained at this stage. Readers are also referred to Chapters 21—23 for more detailed discussions on specific injuries.

Drug administration

As part of the early management of the injured patient, consideration should be given to administration of analgesics. Opiates are best, given in small intravenous increments. Anti-biotics and tetanus prophylaxis may also be appropriate.

Definitive care plan

A position should now have been reached where a daily management and definitive plan is initiated. Patients with multiple injuries may require the attention of a number of specialists. A decision on 'ownership' must be made but with arrangements for all involved to have access. The patient should not 'fall between two stools', without anyone in overall charge. The most appropriate person to take primary responsibility in such cases is usually the general or orthopaedic surgeon.
Emerging concepts and techniques Permissive hypotension

Also called hypotensive resuscitation, this concept is of increasing interest to trauma surgeons faced with intra-abdominal or intrathoracic haemorrhage. The important question is whether the systolic blood pressure needs to be returned to premorbid levels utilising fluid resuscitation. In nontrauma patients, vascular patients for example, controlled preoperative hypotension is well established in certain situations. Further, recent research in the USA seems to deprecate the use of rapid infusion systems (RIS), with evidence emerging that large volume fluid resuscitation to achieve normal systolic blood pressures is associated with increased mortality compared with injured patients resuscitated with small fluid volumes prior to surgery. An increasingly accepted view holds that moderate hypotension — systolic blood pressure of 85–90 mmHg — is sufficient to maintain vital organ perfusion and avoids a hypertensive overshoot with the risk of precipitating further haemorrhage. The concept is still new in the care of the injured and further trials on optimal fluids, levels of permissive hypotension and the effects of delay before surgery are needed before it can be safely assimilated. The most important message to retain is that the best treatment for ongoing haemorrhage is to turn off the tap and not to continue infusion of fluids, including blood products.

Damage control — staged or abbreviated laparotomy

The concept of staged operative procedures for the severely injured patient is not new. The earliest uses of the approach concerned perihepatic packing for extensive liver injury. While the commonest indication remains catastrophic intra-abdominal haemorrhage, the technique now has wider application. The technique should usually be considered as part of the primary survey and resuscitation phases in patients who fail to respond to nonoperative resuscitation methods. The indications suggested by Dr Gene Moore and his colleagues in Denver are listed in Table 18.3.

The technical aspects of the procedure are dictated by the pattern of injuries. The objectives are listed below.

Objectives of staged or abbreviated laparotomy

- Arrest haemorrhage
- Control or limit coagulopathy
- Limit cavity contamination
- Protect viscera and limit fluid/protein loss

Having achieved the objectives, the patient is returned to a critical care environment for continuing monitoring, resuscitation and in-depth investigation prior to a second definitive procedure. Moore terms this 'physiological restoration in a surgical intensive care unit'. Timing for the definitive procedure varies but is usually within 24 hours of the damage-control procedure.

Focused abdominal sonogram for trauma (FAST)

Portable, hand-held ultrasound is now being used by trauma surgeons in the USA in the evaluation of patients with blunt thoracoabdominal trauma, and is the preferred initial technological assessment of the patient. It belongs early on in the secondary survey, although some centres advocate its use during the ‘C’ component of the primary survey to localise intra-abdominal haemorrhage and to rule out cardiac tamponade in overtly shocked patients where no haemorrhage source is evident. The technique is rapid, with only four areas being scanned at the initial investigation (Fig. 18.5). One of the greatest challenges will be to train trauma surgeons in the use of the technology.
Multiple and mass casualties

In both major civil disasters and war, patient numbers may for a time exceed the capacity of medical teams to render normal care. Under these circumstances, it is necessary to sort casualties on the basis of need so that available resources and personnel can render the ‘most for the most’, to quote an American military surgeon. This is 'triage' and it is outlined below. Triage assessments and categorisation should be delegated to a senior, experienced and trained doctor. Failure to perform correct triage will disrupt optimal management for those most at need and divert scarce resources, often to those who can wait. Triage is a dynamic process and needs to be repeated at each level of care from point of injury until arrival in hospital. In general, field triage is for evacuation to hospital. Once in hospital, triage is for access to resuscitation and to operating rooms. The concept is at the heart of major incident planning and is outlined below.

Triage

Triage (from the French ‘trier’) means to sift or to sort and refers to the allocation of injured patients into certain categories for action by emergency teams. A common scheme of assessment is presented below.

• **Triage sieve** — a quick survey is made to separate the dead and the walking from the injured.

• **Triage sort** — remaining casualties are now assessed and allocated to three or four groups according to local protocols:
  — category 1 — critical and cannot wait. Airway obstruction and catastrophic haemorrhage are examples;
  — category 2 — urgent. Serious injury but can wait a short time, 30 minutes in most systems;
  — category 3 — less serious injuries. Not endangered by delay;
  — category 4 — expectant. Severe multisystem injury. Survival not likely;
  — (optional) — heavy manpower demands.

The system outlined above is only one of many. Readers should familiarise themselves with local custom and policy. The ABCDE of ATLS is now used increasingly as a means of assessment for grading.
Audit and quality assurance

Injury severity scoring systems

Statistical analysis of injury severity and the most effective means of managing injured patients is relatively recent and is slowly replacing anecdote and unfounded assumptions. An example is the GCS, to which reference has already been made. The most widely applied is the Revised Trauma Score (RTS). Data combined from vital signs and level of consciousness are mathematically combined into a single variable that correlates with outcome (Table 18.4). There is a myriad of others. Readers are referred to Professor Yates’ paper in the publication ABC of Major Trauma.

Major trauma outcome study (MTOS)

First developed in the USA, MTOS is an ongoing audit of the effectiveness of injury management and is now in widespread use in the UK. Utilising the TRISS (combination of the RTS and Injury Severity Score weighted for age and premorbidity) method with additional input on prehospital events, initial management including time to resuscitative interventions and the grading of medical staff, MTOS is applied to patients with severe injury and to those who die or are transferred to specialist units. The benefits are summarised in Box 18.11.

Box 18.11 Benefits of MTOS

- Measures injury severity
- Records management and outcome
- Provides a database for audit
- Allows comparison of performance

Introduction and epidemiology

Penetrating missile wounds, injuries from blast phenomena and burns are the typical features of modern conventional war. This chapter is concerned only with missile wounds and blast injury. Burn injury is covered in Chapter 14. Missile wounds are caused by bullets or by fragments from exploding shells, mines or bombs. Exposure to blast phenomena may result in unique and complex injury patterns, and these will be described.

There is a wealth of data on the cause and distribution of wounds in wars over the last 30 years. Care is needed in interpretation as the number of wounded varies greatly in each series. For example, Vietnam data cover over 17,000 casualties. In contrast, Gulf war data are restricted to 63 casualties. Inclusion criteria are also very variable and many fail to record multiple injuries to different body systems in single casualties — the hallmark of modern war injury. Tables 19.1, 19.2 and 19.3 summarise the available data.

While care is needed in interpreting the available data, some broad statements concerning war injury can be made. The most common wounding agent in surviving casualties is a fragment wound, not a bullet wound as many erroneously believe. Limb injuries predominate, pointing to the high lethality of hits to the trunk and head. The most startling revelation is the emerging incidence of multiple hits to multiple body regions in survivors. This is a deliberate policy — the aim in modern war is to incapacitate, not kill. The reason is clear; large numbers of surviving casualties are a major financial and logistic burden on a nation engaged in total war.

In conclusion, the factors that govern the nature, severity and outcome of a war wound are many and include the weapon systems deployed, the environment in which the weapon systems are deployed, and the quality and timing of medical management. In short, there is no single entity that merits the description 'the war wound'.

**Wound ballistics and mechanisms of Injury**

As a missile traverses the body it causes injury by transferring some or all of its available energy, and this is manifested by lacerating and crushing tissues in its path and, in some cases, injury remote from the missile path (see below). The amount of energy transferred may be expressed by the formula:

\[ \text{K.E} = \frac{1}{2} M (v_1^2 - v_2^2) \]

where \( \text{K.E} \) is the available energy, \( M \) is the mass, and \( V_1 \) and \( V_2 \) are the velocities at entry and at exit, respectively. In general, bullets fired from handguns and most modern fragment munitions are propelled at low velocity, have low available energy (100—500 J) and result in low-energy transfer wounds. Missiles with high available energy (2000—3000 J) include high-velocity assault rifle bullets (> 900 m/second) and some large fragments, and have potential to cause high-energy transfer wounds (Figs 19.1 and 19.2). Some modern high-performance handguns are now capable of firing high-velocity bullets with high available energy.

By convention, missile wounds are now described in terms of energy transfer, not velocity as was the custom, recognising that velocity is merely one factor determining energy available and its transfer to tissues. Low-energy transfer wounds are characterised by injury confined to the wound track. High-energy transfer wounds also cause local laceration and crush injury but have, in addition, the potential to cause injury remote from the wound track associated with a phenomenon known as temporary cavitation (Fig. 19.3).

The extent of cavitation depends upon the density and elasticity of the target organ or structure, and in certain circumstances is associated with injury many centimetres away from the missile wound track.

Cavitation within solid organs such as the liver, spleen and kidney results in shattering with high morbidity and mortality. The extent of injury to bowel is variable. In general, the small bowel fares better than the colon, particularly if the latter is loaded with faeces. A similar event in an elastic tissue such as the lung may result in quite modest injury. In the limb the position is more complex and controversial. While voluntary muscle may merely stretch if injured in isolation, bone fares badly. As a rule, bone involvement results in severe injury due to high-energy transfer with disruption of the missile and involved bone, with generation of secondary missiles. Extensive devitalisation of muscle is a typical finding. Devitalised muscle in the depths of a missile wound provides the perfect culture medium for the growth of pathogenic bacteria, a fact recognised by military surgeons for centuries. Nerves and blood vessels respond unpredictably with injury, ranging from minimal bruising to complete disruption.

Within the closed skull there is, in addition, a rapid, high-pressure shock wave causing widespread disruption and injury at a distance. Thus, vital centres at the base of the brain may be injured by a wound of the cranium.
Management of missile Injuries

Missile wounds of soft tissue

Management of the soft tissue wound is a formal procedure consisting of clearly defined stages. This is the part of early management most frequently neglected by surgeons with limited or no experience of war surgery. The entrance and exit wounds do not indicate the considerable damage that may have occurred to deeper structures (Fig. 19.4).

This can only be detected by full exploration. In limb wounds, exploration is followed by thorough wound excision, after which, with very few exceptions, the wound should be left open. Delayed primary closure should follow within 4—7 days after injury. Having followed the Advanced Trauma Life Support (ATLS®) guidelines, the patient will have been completely undressed prior to surgery, but it is wise to retain any pressure dressings over a wound until the operation is due to begin. The operation should consist of the following stages.

1. After photographing the wound and cleaning it with an antiseptic, generous longitudinal incisions are made through the skin to allow visualisation and access to the deeper structures and to facilitate subsequent extension of the exposure, should this be required. A minimal amount of skin edge (i.e. only that which has been contaminated) should be excised around the entrance and exit wounds. Skin is remarkably resistant to injury — scrubbing with a nail brush will remove most contaminants and indriven debris, allowing skin excision to be kept to a minimum.

2. The deep fascia is exposed over the length of the skin incisions, and must be incised in a longitudinal direction to allow full inspection of the area damaged by the wounding missile and to decompress the underlying muscle which will swell subsequently. This is the true meaning of the much misused term débridement (Fig. 19.5).

3. Neovascular bundles in the wound track must be identified and examined, but nerves should not be dissected out at the initial exploration. Nerves considered to be injured and warranting later exploration may have their position marked with a nonabsorbable suture marker to ease subsequent identification. It is important to examine the patient for nerve injury before the operation if this is possible and to record in the operation notes the nature of the nerve injury. The majority of nerve injuries is neuropraxias which do recover.

'Débridement (unbridling or unleashing). The term was introduced by Baron Dominique Jean Larrey, 1766—1842, Surgeon to Napoleon's Imperial Guard. He used it to describe the process of laying a wound open to facilitate removal of bullets, bits of loose cloth, detached pieces of bone and soft tissue. He and his contemporaries did not excise tissue in the modern sense and his procedure was much less extensive than the formal wound excision practised today.

4. Foreign matter should be removed from the wound. Pieces of clothing are especially sought, both in the missile track and in the tissue planes on either side. It is not necessary to remove every piece of metal seen on a radiograph. Multiple, very small metal fragments from modern munitions may, in any case, be very difficult to locate and remove.

5. Dead muscle that does not bleed or contract, is mushy in consistency or has an unhealthy colour must be excised. These criteria comprise is the ‘4 Cs’ for muscle excision

The 4 Cs:

• Colour
• Contractility
• Consistency
• Capillary bleeding

6. Tendon repair should not be performed at this initial procedure. Tattered ends should be trimmed.

7. Major artery and vein damage must be noted. Where possible, the ends should be trimmed and sutured. If any tension is likely to develop, a reversed vein graft may be inserted to bridge the gap and the repair covered by healthy muscle. The rest of the wound should be left open for delayed primary closure. Synthetic grafts must not be used. A plastic shunt inserted into an injured artery can be used to revitalise tissue distal to the site of injury prior to definitive repair. In combined arterial and venous injury, concomitant shunting of both vessels may be undertaken. Temporary shunting has a vital role where major vascular damage is associated with fractures of long bones. In this instance, blood flow is established via the shunt(s), and the fracture is reduced and immobilised using an external fixator, after which definitive vascular repair is undertaken.

8. Bone shattered by high-energy transfer will in many instances still have attachment to periosteum or muscle. Such fragments must not be discarded. Loss of bone may result in malunion (e.g. shortening) or nonunion. Contaminated bone may be cleaned by using that useful instrument of military surgery, the Volkmann’s spoon or curette.

9. Injured joints need thorough inspection and cleaning by copious irrigation with saline to remove organic matter. Any exposed articular cartilage should be covered by at least one layer of healthy tissue, preferably synovium, otherwise muscle or skin should be used.

10. At the end of the operation the wound should be irrigated thoroughly with saline to remove any remaining debris. Haemostasis should be secured with the aid of hot packs and the wound left open without closure of either fascial layer or skin, even in the presence of exposed bone. A lightly fluffed gauze dressing should be placed over the wound to allow free drainage. Packing must be avoided.

11. Immobilisation in a well-padded splint allows the soft tissues to recover, a principle expounded by Hugh Owen Thomas at the turn of the century. Split plaster of Paris splints are ideal even in the absence of a fracture. Femoral shaft fractures should be immobilised in a traction splint.

12. Antibiotic cover is advised for all wounds; third-genera-tion cephalosporins or agents with an equivalent spectrum being ideal. In all abdominal, pelvic and perineal wounds, metronidazole is given in addition (see Chapter 7).

Delayed primary closure
All wounds treated by wound excision and left open should be inspected about 4—6 days after injury. Provided the wound looks healthy, delayed primary closure is indicated. This should be by interrupted suture, split skin graft or a combination of both.

**Traumatic amputations**

Traumatic amputations should be surgically tidied, completed at the lowest level possible and the skin left open for delayed primary closure. If there is much skin loss or if a limb is very swollen, split skin grafting may be used to effect wound closure in order to avoid skin tension. If, at the time of delayed primary closure, dead muscle is found, which is not uncommon in traumatic amputation due to antipersonnel mines, the muscle is excised and the wound left open for a further period before closure.

**Missile wounds of the abdomen**

Every penetrating and perforating missile wound of the abdomen should be explored by laparotomy. Before surgery, a nasogastric tube should be passed into the stomach and a urinary catheter into the bladder. Bladder catheterisation must be preceded by a digital rectal examination. Timing of exploration will vary. In some cases, operation will be undertaken as part of resuscitation leaving little or no time for planning (see the section on ‘Damage control’ in Chapter 18). In others, preoperative stabilisation is possible and time is available for investigation, including haematology, biochemistry and radiology. In all cases blood in realistic quantities must be available.

A full midline incision from xiphisternum to pubis is recommended. It has the advantage of facilitating rapid access and extension laterally or into the chest where required. The commonest source of bleeding in survivors is from the small bowel mesentery, but major haemorrhage may come from the solid organs, such as liver or spleen, or from the major vessels. Haemorrhage must be controlled and careful examination is then made of all the abdominal contents.

In all wounds of the stomach, the lesser sac must be opened to inspect the posterior gastric wall. Retroperitoneal haematoma in the region of the duodenum requires inspection of its posterior wall by Kocher’s method (Chapter 51). Haematoma surrounding the retroperitoneal parts of the ascending and descending colon may also necessitate exploration, but nonexpanding retroperitoneal haematomas over the kidneys are best left undisturbed.

Small intestinal perforations are either excised and closed transversely, or the damaged section is resected if there are multiple holes in a short length (Fig. 19.6) Mesenteric tears may also require bowel resection (see Chapter 56).

**Colon and rectal wounds (see also Chapter 57)**

For most injuries of the right side of the colon, primary repair or primary resection is satisfactory. Occasionally, where severe wounding with extensive contamination has occurred, a vented ileotransverse anastomosis is warranted. Rarely, the two ends are brought to the surface as proximal ileostomy and distal mucous fistula, respectively.

On the left side a one-stage procedure may be undertaken if favourable circumstances pertain, i.e. minimal peritoneal contamination, limited blood loss, and a time interval between injury and operation of less than 8 hours. However, if injury is associated with high-risk factors, the injured colon is resected and the proximal end brought out as a colostomy and the distal end as a mucous fistula. If the distal end cannot be brought to the surface, as in low sigmoid or rectal injuries, it may be closed off as in a Hartmann procedure (Chapter 60). Subsequent restoration of bowel continuity will be required.

Extraperitoneal rectal injuries are repaired if feasible and defunctioned by establishing a sigmoid end colostomy. Good dependent drainage is best achieved by a presacral, retrorectal drain brought out between the tip of the coccyx and the anus. The control of haemorrhage in pelvic injuries can be difficult and may require ligation of the internal iliac artery.

**Rectal injury**

Renal injury is best treated conservatively if this is possible. Fortunately, immediate nephrectomy is rarely indicated. A divided ureter may be brought to the surface or may be repaired over a ‘pigtail’ stent.

**Bladder and urethral injuries**

Bladder and urethral injuries are treated by suprapubic cystostomy with placement of a suprapubic drain after wound excision.

**Liver injuries**

In 50 per cent of cases of hepatic injury surviving to reach a surgical centre, bleeding has stopped and is not a problem at laparotomy, a reassuring statistic for the youthful surgeons usually faced with such cases. Where bleeding is still occurring, damage control techniques are particularly appropriate in a warfare setting (see section on ‘Damage control’ in Chapter 18). Manual compression and perihepatic packing are recommended, and may allow a patient to survive to reach a more sophisticated surgical facility in the rear of the fighting area. If these simple measures do not work, and pre-vided that the operator is experienced, finger fracture with exposure of bleeding points followed by individual ligation, or more formal resection procedures, will be needed (see also Chapter 52). These are rare eventualities. In all cases, gen-erous drainage of the spaces surrounding the liver is important.

**Damage to the spleen and pancreas**

Damage to the spleen and tail of pancreas may require resection, although in some cases splenorrhaphy may be feasible. Missile injury of the head of the pancreas is seldom seen in the operating room because injury to it and surrounding structures is usually fatal. In a very few cases it may be possible to apply a Roux loop of jejunum to create an internal fistula.

**Peritoneal toilet**

Using warm saline, it is important to assist the removal of all spilled bowel contents and blood clot.

**Closure**

The laparotomy wound is closed using the mass closure technique. The missile entrance and exit wounds should be excised as described earlier and left open initially with a view to delayed primary closure at 4—6 days.
Missile wounds of the chest

(See also Chapter 47.) Penetrating missile wounds of the chest are common in war and are associated with a high mortality if simple life-saving measures are neglected. It is important to secure an airtight seal of open wounds of the chest to prevent a potentially fatal open pneumothorax. This is immediately followed by tube thoracostomy. Failure to do so will result in collapse of the lung on the affected side with alteration of the ventilation/perfusion ratio and, in addition, will progressively decrease the quantity and quality of air entering the affected lung. As dyspnoea increases due to anoxia, the mediastinum shifts on respiration and decreases venous return to the heart — the clinical picture in the later stages is identical to a tension pneumothorax.

All penetrating wounds of the chest require adequate venting of the pleura by formal tube thoracostomy. This simple procedure will prevent the accumulation of blood or air under tension. The position of the tube should be confirmed by chest radiography. Once pulmonary function has been stabilised, missile entry and exit wounds are excised. During the excision of a large chest wall wound, the pleural cavity is often entered; this need not cause concern. The opportunity should be taken to remove any retained foreign material, arrest haemorrhage (usually from an intercostal or internal mammary vessel) and to oversew or staple holes in the adjacent lung. On completion the pleural opening must be sealed either by direct pleural closure (often difficult) or by utilising overlying healthy soft tissue, and the wound(s) left open for subsequent delayed primary closure.

These simple measures will suffice for more than 80 per cent of chest wounds. The remainder will require formal thoracotomy, often urgently. The usual indications are listed below.

**Indications for formal thoracotomy**

- More than 1.5 litres initial blood loss
- Continuing loss of > 200 ml/hour
- Cardiac tamponade
- Other mediastinal injuries
- Persistent air leak
- Retained foreign bodies > 1.5 cm in diameter

Even in cases where thoracotomy is indicated, considerable delay can often be tolerated provided adequate resuscitation is initiated quickly. Thoracotomy for retained foreign bodies is often a late and planned procedure.

In thoracoabdominal injuries, the thoracic component is treated by tube thoracostomy and the abdominal component by laparotomy through a midline incision. Formal thoraco-abdominal incisions risk contamination of the chest cavity by faeces and should be avoided.

**Missile wounds of the head**

The penetrating high-energy transfer missile wound of the head is usually lethal. The management of penetrating low-energy transfer and tangential wounds depends initially on measures described in the primary survey and resuscitation phases (see Chapter 18). These will ensure a protected airway, adequate ventilation, and maintenance of blood pressure and perfusion pressure to permit oxygenation of the brain. Good radiographs are mandatory to localise foreign bodies and bone fragments. Computerised tomography (CT) images are invaluable in planning surgical exploration. Wound excision should be carried out using gentle irrigation and suction to remove devitalised brain and bony fragments. Every effort, including the use of temporalis fascia or fascia lata, should be made to close overlying dura. The skin overlying the head and face is an exception to the delayed primary closure rule. Blood supply is excellent, allowing primary closure which also serves to control blood loss from the scalp.

Intermittent positive pressure ventilation (IPPV) assists in the reduction of intracranial pressure by reducing brain swelling. Intracranial pressure transducers inserted through burr holes may be employed to monitor intracranial pressure in the postoperative phase.

**Shotgun injuries**

Accidents from large-bore shotguns are common and often lethal when injury is sustained at close range. It is never possible to retrieve all the shot and, indeed, to do so would result in unacceptable damage to uninjured soft tissues. Wound excision should be carried out on the major wound, particularly looking for indriven wadding and plugs of clothing. Laparotomy is essential if it is thought that any of the shot has traversed an abdominal viscus. The retention of lead shot in the body can result in a dangerously high lead concentration, which should be monitored. After a time, this concentration will fall as a result of encapsulation of the lead pellets by fibrous tissue.

**Summary: dos and don’ts of missile injuries**

Do:
- incise skin generously;
- incise fascia widely;
- identify neurovascular bundles; excise all devitalised tissue;
- remove all indriven clothing;
- leave wound open at end of surgery;
- dress wounds with fluffed gauze;
- record all injuries in the notes.
Don't:

• excise too much skin;
• practise keyhole surgery; repair tendons or nerves;
• remove attached pieces of bone; close the deep fascia;
• insert synthetic prostheses;
• pack the wound;
• close the skin.
Blast injuries

Mechanism of explosive blast injury

The explosive pressure that accompanies the bursting of bombs or shells ruptures their casing and imparts a high velocity to the resulting fragments. These fragments have the potential to cause even more devastating injury to the tissues than bullets. They are unstable in flight and may tear through tissue at high speed in a tumbling fashion. These statements are particularly true of old artillery shells and terrorist bombs where the casing fragments naturally into pieces of variable size. However, the trend in conventional war is towards carefully engineered weapons which carry preformed munitions, such as notched wire or ball bearings, or have their casing etched to allow predictable fragmentation patterns resulting in a multitude of small, relatively low-energy fragments (Fig. 19.2). The aim is to incapacitate, not kill, by inflicting multiple low-energy transfer wounds to two or more body systems.

In addition, all explosives are accompanied by a complex blast wave. The two main components of this wave are a blast pressure wave (known as dynamic overpressure), with a positive and negative phase, and the mass movement of air (known as blast wind) (Fig. 19.7).

The positive pressure phase of the blast wave lasts for only a few milliseconds, but close to an explosion it may rise to over 7000 kN/m². As the healthy tympanic membrane ruptures at around 150 kN/m², it is evident that the effects on the human body of such an explosion can be devastating, especially in confined areas. Like sound waves, the blast pressure waves flow over and around an obstruction and affect anyone sheltering behind a wall or in a trench. The pressure affecting such a person is known as the incident pressure (defined as the pressure level at 900 to the direction of travel of the blast shock front). Also, any person standing in front of a wall or other vertical surface facing an explosion is subjected to the added effect of a reflected pressure. The negative effect of a pressure wave is of low amplitude, lasts longer than the positive wave and is of doubtful clinical significance.

A mass movement of air or dynamic pressure results from the rapidly expanding gases at the centre of the explosion which displaces air at supersonic (greater than the speed of sound in air) speed. This has been described by an eminent blast scientist as 'fresh air moving very fast'. The mass movement of air results in what is colloquially known as blast wind and disrupts the environment, hurling debris and people. This phenomenon results in injury patterns ranging from traumatic amputation to total body disruption. The mass movement of air may disrupt buildings, causing entrapment and crush injuries.

Blast pressure waves travel at the speed of sound in the medium being traversed. In water, velocity and distance are greater and injuries tend to be more complex and severe. For example, blast pressure waves in air rarely affect the gastro-intestinal tract to any clinically significant extent in survivors; however, in water, the blast wave exerts a 'water hammer' effect with significant rates of gastrointestinal perforation.

When the body is impacted by a blast pressure wave, it couples into the body and sets up a series of stress waves which are capable of injury, particularly at air—fluid interfaces. Thus, injury to the ear, lungs, heart and, to a lesser extent, the gastrointestinal tract (see above) is notable. The exact mechanisms of injury at each specific tissue are still the subject of controversy but need not unduly worry readers as this topic is debated well by Cripps and Guy in Trauma and by Ryan et al. in Ballistic Trauma, as listed in the ‘Further reading’ section of this chapter.

General management of blast injuries

The structures injured by the primary blast wave, in order of prevalence, are the middle ear, the lungs and the bowel. However, the most common urgent clinical problem in survivors is usually penetrating injury caused by blast-energised debris and fragments from the casing of the exploding device (see below). Much of those exposed will have blunt, blast and thermal injuries in addition to more obvious penetrating wounds (the clinical picture is usually referred to as combined injury). The deafness of the victims of blast, due to disruption of the tympanic membrane, makes communication with them difficult and may complicate early assessment and management. Here, the primary survey and resuscitation phases of a system such as ATLS are particularly apt. The management of penetrating wounds differs little from that of missile wounds particularly at air—fluid interfaces they may result in considerable disruption. This is particularly notable at the alveoli—capillary membrane and leads to capillary leakage resulting in a spreading haemorrhagic alveolar contamination (Fig. 19.9).

It may not always be practical to explore every wound at first surgery. The larger and deeper wounds should have priority of management due to the more serious consequences of infection. In many blast injuries one cannot be sure of complete wound excision and, therefore, it is imperative that all blast wounds should be left open at the end of the initial opera-tion and delayed primary closure performed 4—6 days later.

Regional management of blast injuries

Here one is particularly concerned with identifying specific injuries caused by the primary blast wave.

Auditory system

Blast damages the hearing in three ways. There may be rupture of the tympanic membrane, dislocation of the ossicles or widespread disruption of the inner ear. The latter is sometimes accompanied by permanent deafness. It should be remembered that the likelihood of ear damage depends on the angle between the incident blast wave and the external auditory meatus. Although deafness is a certain indicator of exposure to significant blast loading, its absence does not imply the absence of blast injury to other systems.

Respiratory system

Injury to the lung parenchyma is complex and the exact mechanisms are still the subject of debate. Undoubtedly, the impacting primary blast wave may cause a rapid inward movement of the chest wall and result in underlying pulmonary contusion, but this is not the principal mechanism in the severe and progressive acute lung injury picture seen in small numbers of survivors. In these casualties it is probable that the initial blast wave couples into the chest resulting in stress waves which spread out, reflect and reinforce at tissue interfaces. At air—fluid interfaces they may result in considerable disruption. This is particularly notable at the alveoli—capillary membrane and leads to capillary leakage resulting in a spreading haemorrhagic alveolar contamination (Fig. 19.9).

An inflammatory cascade now ensues resulting in a post-blast respiratory insufficiency (PBRI), which is virtually indistinguishable from adult respiratory distress syndrome (ARDS) following generalised sepsis or fat embolism syndrome (FES), and posing a difficult clinical problem in criti-cal care units. PBRI varies from a mild and localised area of pulmonary contusion injury to a fulminating and rapidly fatal condition involving both lungs. This rapid and progressive condition is relatively rare, as casualties sufficiently close to suffer extreme blast loading to the chest wall are usually killed by multiple low-energy transfer wounds or are dismembered by blast winds. In severe cases, respiratory insufficiency may be further precipitated by overtransfusion with electrolyte solutions. The clinical picture is typical — patients develop a cough with frothy
blood-stained sputum, dyspnoea and a feeling of apprehension, bordering on a foreboding of impending doom — they are often right. A pulse oximeter will show a resistant low saturation, with values well below 90 per cent. Blood gas analysis confirms arterial hypoxia and a raised carbon dioxide partial pressure (PCO₂). Chest radiographs in the initial stages may show localised contusion injury but, as the inflammatory cascade builds, radiographic evidence becomes generalised with bilateral fluffy infiltrates spreading out from the hilum of both lungs (Fig. 19.10).

Specific clinical management of an established case remains controversial. There is still little hard evidence to guide clinicians. However, most agree with the guidelines listed in below:

Postblast respiratory insufficiency (PBRI) — clinical guidelines
• Work within the ABCDE system of the ATLS system
• Avoid overhydration while maintaining vital organ perfusion
• Administer high-flow oxygen (12 litres/minute) with mask and rebreathing bag
• Carry out arterial blood analysis to assess need for further measures
• Resort to mechanical ventilation early to ensure adequate oxygenation
• Use positive end-expiratory pressure (PEEP) carefully while avoiding excessive peak and plateau pressures
• Corticosteroids should be avoided

Gastrointestinal tract
Injury to gas-filled viscera is more common in underwater explosions than air blasts. Perforation of the stomach, small intestine and caecum is most common. The clinical presentation is one of increasing abdominal pain accompanied by signs of peritonism and often gas under the diaphragm. In the presence of clear physical signs urgent laparotomy is indicated. In cases where signs are few but the risks are high, ultrasonography, CT, diagnostic peritoneal lavage and laparoscopy should be considered. There is no single modality agreed by all. Serological assessment of gut-associated enzymes is still an experimental tool and no reliable serum marker of intestinal injury is available.

The eye
The eye should be examined in both the primary and secondary surveys, yet injury is easily missed. Conjunctival haemorrhage following blast exposure may herald a more serious underlying problem of penetration of the globe by blast-energised debris or fragments. The pupil must be carefully examined and any abnormality, distortion of the iris or the presence of a hyphema, for example, should be investigated by an ophthalmologist.

Other factors
Factors that increase the morbidity and mortality following bomb blast injuries are associated chemical and thermal burns, and the inhalation of toxic gases and smoke.

The History

Learning objectives

1. To understand the three key types of history, their function and the different way in which they are obtained.

2. To understand the three zones of abnormality that a history should address.

Introduction

The importance of taking a history in musculoskeletal disorders is threefold (Table 20.1).

- Its first function is to allow the patient to list the problems that they are experiencing and to define what it is that they are hoping to gain from this consultation. This part of the history should be used to ‘set the agenda’ for the consultation.

- The second task is to draw out from the patient a full description of those symptoms which confirm one diagnosis, or which exclude others. This is the ‘diagnostic phase’.

- The final phase is only needed if surgery is a possible option. The questions here are directed at determining the patient’s ‘fitness for surgery’.

Setting the agenda

In this phase the patient should be encouraged with open questions to do most of the talking. As they talk it should be possible to divide the patient’s problems into three main areas: pain, dysfunction and deformity (Table 20.2).

Pain

Patients should be asked to define in what way the pain troubles them, as the answer may give the clue to how this can best be managed if it cannot be cured. For example, if it is pain at night stopping sleep, then a combination of pain killers and sleeping tablets might offer the best solution if no other is available. If, however, the pain occurs in a joint on weight-bearing a splint might stabilise the joint and make the pain manageable.

Dysfunction

A patient may complain of loss of function as a result of pain, stiffness, weakness, instability or even locking. In the first instance the patient should be allowed to describe in their own words what it is they can no longer do. This may be something like inability to reach up to hang clothes on the washing line. This problem will later be translated into a clinical diagnosis, but at this stage should be reported in the patient’s own words.

Deformity

This may be much more of a concern to the patient than might seem reasonable to you. Patients may want bunions corrected not because they are painful (although they may initially claim this), but because they are unsightly. It is crucial to be clear about the patient’s real reasons for seeking treatment, and what it is they hope you will be able to do about it before embarking on the next stage of the interview.

Summary

This part of the interview should be summarised and recorded as the patient’s problems and expectations.

History for diagnosis

The ‘history for diagnosis’ leads directly on from taking a ‘history for agenda’ but the structure of the interview changes. Instead of open questions aimed at getting the patient to talk about how they see their problems, each question is now carefully designed to confirm or exclude a differential diagnosis derived from the initial part of the interview. The same categories are used as before — pain, dysfunction and deformity — but this time the characteristics of each are explored in detail, searching for clues to causation, association and alleviating factors. The main areas to be covered are as follows.

Onset

A careful history of how the problem was first noticed is diagnostically useful. In sports medicine it is usual to divide onset into three categories: acute extrinsic, acute intrinsic and chronic (Table 20.3).

- Acute extrinsic. This is associated with external trauma. A limb which is deformed, after being hit with a stick, is likely to be broken. If it is painful but not deformed then it is likely to be bruised.

- Acute intrinsic. This occurs when the human body is under load and fails. In young people this may be a ligament (e.g. anterior cruciate ligament in a footballer, who twists at speed on a fixed foot). In older people it might be a broken bone (e.g. a fractured neck of femur in an elderly osteoporotic patient who tripped).

- Chronic. These problems are those where the onset is not clearly associated with any traumatic event, but just gradually appears. An example is osteoarthritis of the shoulder.

Association

The human brain is programmed to seek patterns, and may do so even when there is no pattern to see. Just because a patient feels that there is an association between an event and onset of an illness does not mean that this is correct. Conversely, you may need to seek associations which had not occurred to the patient.

Development
The natural history of the problem may also give clues to diagnosis causation and even treatment. If the condition spontaneously resolves, then returns, the cause for recurrence needs to be sought. For example, being compelled to sit for a long period in one place may exacerbate pain from a prolapsed intervertebral disc.

**Nature**

The type of pain in particular may give you a clue as to the origin.

Throbbing pain associated with sweats and chills may be an infection.

Deep boring pain, which wakes the patient from sleep, may be caused by a tumour.

Similarly, dysfunction needs to be explored carefully to see whether it is caused by weakness, pain, instability, locking or even lack of confidence.

**History for surgery**

If surgery is a possibility you need to know whether it would be safe before you offer it as a treatment option. This can be divided into two sections. The first is identification of conditions, which increase the risk of anaesthesia and of surgery morbidity. The second involves determining whether those conditions have been brought into the best possible control to minimise the risk. Orthopaedic surgery is rarely life-saving, but can be very useful for improving quality of life. It is quite acceptable to take a known risk and operate on a high-risk patient provided that you and the patient are aware of what you are doing. It is quite unacceptable to operate on a patient when either you and/or the patient are not aware of the increased risk, or when the condition has not been brought under the best control possible, and so the patient is being exposed to an unnecessary risk (Table 20.4).

Factors in the history which point to high-risk patients are:

- patients who have had problems with previous anaesthetics;
- a history of cardiac or circulatory problems — previous myocardial infarcts, angina, cardiac arrhythmias, high blood pressure, peripheral vascular disease, previous strokes or transient ischaemic attacks;
- breathing problems — chronic breathing problems such as asthma or chronic bronchitis. Acute problems such as chest infection;
- metabolic problems — diabetes and steroid treatment;
- urinary tract problems — benign prostatic hypertrophy which has not been treated.
Musculoskeletal examination

Learning objectives

1. To understand a simple system for examining the musculoskeletal system.

2. To learn the specific features to be sought in each area of the body. Musculoskeletal examination works on a simple system originally designed by Apley. It consists of four-letter words divided into threes.

   The first stem is:
   • look;
   • feel;
   • move.

   The second stem branching off from each of these first two stems is:
   • skin;
   • soft (tissue);
   • bone.

   Finally, ‘move’ is divided into:
   • active;
   • passive;
   • stability.

   Look

   You cannot look with your hands. Once you let your hands on to the patient, your ability to notice things with your eyes seems to be lost. While looking, it may be better to put your hands behind your back to remind you to look first, and to show the examiner what you are doing.

   Make sure that you can see enough of the patient’s body. This means exposing at least one joint above and one below the area in question. It also means exposing the opposite side. It is said by some that the human body was made bilaterally symmetrical to help orthopaedic surgeons distinguish abnormal from normal. Do not spurn such ready-made help.

   It is not always necessary to lay the patient down for an orthopaedic examination. It may be easier if the patient remains standing, provided that they are comfortable to do this. In this position it is easier to look at the patient’s back as well as their front. It is important to inspect all sides of the patient to make sure that no lesion is missed.

   Skin

   Look once at the skin for:
   • bruising and wounds — evidence of recent injury;
   • redness — signs of inflammation;
   • scars — the archaeology of injury;
   • sweating — loss of sweating may indicate nerve damage.

   Soft tissues

   Look a second time at the soft tissues. Now you are looking for:
   • swelling — a cardinal sign of injury and inflammation;
   • wasting — signs of disuse and nerve damage, the archaeology of injury.

   Bones

   Look a third time at the bones (shape of the skeleton). Look for:
   • deformity — unusual angles or joints held in unusual positions.

   Summarise

   You have now looked at three zones. Summarise these in your mind and make a record of what you have found.

   Feel

   Once again you will test in three zones: skin, soft tissue and bone.

   Skin (temperature, sensation)

   • Temperature — stroke the patient’s limbs with the back of your hand. It is more sensitive than the front. Use the patient’s other side for comparison. Warmth may indicate inflammation. A cold limb may indicate nerve or vascular damage.

   • Sensation — if you ask the patient to shut their eyes and then test whether their feeling is normal, you are in danger of missing nerve damage. Patients do not always close their eyes when asked (especially if they are drunk). The question ‘Is that normal?’ is a closed question which invites the answer ‘Yes’. A better system is to leave the patient with their eyes open and then stroke first the normal limb then the other limb lightly. Ask if the touch on the two limbs feels the same. By comparing the two sides the patient should be able to detect any change in sensation, however slight.

   Soft tissue (tenderness, lumps and circulation)

   When you feel the soft tissues, you must be very careful to avoid hurting the patient. The best way to do this is to place your hands on the area under examination, then look up and watch the patient’s face as you palpate. This way you will be certain to spot immediately that you are
causing discomfort or even pain. You will then be able to stop what you are doing immediately to prevent further suffering. If you fail to do this in an examination and then cause pain to a patient, the examiner will regard this as a serious transgression.

Feel for:

• tenderness — as you press with your fingers try to describe to yourself the actual anatomical structure that you are palpating: subcutaneous fat, bursae, muscle bodies, tendons, nerves, arteries and ligaments;

• lumps and effusions — each time you feel an abnormality under the skin you should be able to run through a checklist of features of a lump. A simple system is shown in Table 20.5.

• distal circulation — feel for peripheral pulses and check capillary filling. When checking pulses, take the patient’s pulse elsewhere at the same time. This should ensure that it is the patient’s pulse you are feeling, not your own.

For capillary filling, simply press in on the tip of a digit and say under your breath ‘capillary filling’. If the blanching has not disappeared by then, there is diminished capillary filling. Before diagnosing local vascular damage, check whether the circulation is reduced generally (as it might be in shock).

**Bone (bone outlines and joint margins)**

Watch the patient’s face, feel the bone and joint margins gently for areas of tenderness, steps and lumps. Again, try to work out what anatomical structure your fingers are touching as you palpate.

**Summary**

Review your findings. Try to decide what structures are tender, what structures are swollen, wasted or displaced, and whether the circulation and sensation to the distal limb is normal. If not, where is the likely damage?

**Move**

Once again there are three phases of the examination, but this time they are active, passive and stability.

**Active**

The patient should move their own joints within the limits of pain. Use simple language to explain what you want them to do, and if necessary demonstrate the movement.

**Passive**

Don’t take the range of movement beyond the active range without watching the patient’s face.

**Stability**

There are two types of stability: dynamic and static. Dynamic stability is provided by muscle power; static stability by ligaments and intact joint surfaces.

Dynamic stability. Measure the force that the patient can develop by showing them the movement, then asking them to repeat it while you try to stop them. For each movement, try to work out which muscles are the drivers of that movement, which nerves supply them and the nerve root values.

Static stability. Static stability tests the integrity of the ligaments and the joint surface. The joint should be gently stressed in each direction controlled by a ligament, while watching the patient’s face to make sure that you don’t hurt the patient. You do not need to use any force. Indeed, the tests will not work if you do, as the patient’s muscles will go into spasm and hide the underlying static instability.
**General principles of lower limb examination**

Before you put the patient on the couch, ask them to walk up and down and look at their gait. See if they are limping.

**Types of limp**

The limp caused by any specific diagnosis is usually a complex mixture of several pathological processes, which can be divided simply into the following groups to produce an easily remembered (if ill-spelt) mnemonic:

- Long;
- Incoordinated;
- Muscle weakness;
- Pain;
- Stiff.

Long. If one limb is short then the other is long in relation to it. The patient bobs up and down when walking, when looked at from the front. However, the cadence (rhythm) of the gait is normal. There is equal time spent on each limb.

Incoordinated. The uncoordinated gait — walking has been described as controlled falling (McNeil, Alexander). In patients with neuro-muscular disorders the falling is less controlled and so the patient’s limp is similar to a normal person who has tripped or who is drunk. The arms are swung around to act as counterbalances. The legs frequently scissor across each other and the gait has no rhythm to it.

Muscle weakness. *Hip (Trendelenberg gait).* The patient’s body sways sideways to and fro when looked at from the front. The patient uses the trunk muscles to lift the pelvis high enough to swing the leg through, as they cannot lift the pelvis alone.

Knee. Patients with weak quadriceps (often seen after polio) use a trick manoeuvre to lock the knee as they take weight on the leg. As they swing the leg forward, they flick the lower leg forward so that the knee extends fully well before the heel strikes the ground. They then hold the knee locked straight by keeping their hand in their pocket and pushing back on the front of the thigh as the foot comes down to heel strike. If they do not do this then the knee may buckle into flexion as they start to take weight on the leg.

Ankle. With a weak ankle the patient lifts the foot very high in order to swing the leg through without catching their toes. The foot also lands with a slap on the ground because there is no control over it.

The painful limp (antalgic gait). The patient spends less time on the painful limb than the painless one. They also bob up and down when looked at from the front, dropping down as they take weight on the bad limb, and rising back up again as they take weight on the good limb. This gait can be confused with the ‘long’ leg gait, but there is a major difference. The cadence is abnormal. The gait is dot—dash—dot—dash because so much less time is spent on the painful limb than on the painless one.

The stiff limp. *Hip.* The patient tends to sway forwards and backwards when looked at from the side. They also hoist the pelvis up as they bring the hip through to stop it dragging on the ground.

Knee. Patients with a stiff knee often swing the leg out to the side as they walk. This is because you need to be able to lift the knee to avoid catching your toe on the ground as you bring the leg forward for the next stride.

Ankle. Patients with a stiff ankle walk with a foot that rocks forward from heel to toe in a very pronounced way.
The foot and ankle

In this chapter the examination starts with the foot and ankle. On a live patient the examination should first be directed to the part of the body with the problem (see the section on ‘The history’ in this chapter).

Look

Watch the patient walking, both with their shoes on and barefooted.

Look at the shoes for signs of abnormal wear.

The wear on the shoe tells you about rubbing and pressure. The normal wear pattern is for a corner to be worn off the posterolateral side of the heel (the normal point for heel strike). There may then be a circular wear pattern under the ball of the big toe (where toe off occurs as the foot provides its final drive and then lifts off). These two areas of wear may be linked in a very old shoe by a line of wear along the lateral side of the sole where most of the weight is taken during the stance phase of the stride.

Skin

Look for calluses, corns, bunions and scars, particularly in the following.

- At the base of the big toe for a bunion.

A bunion is a red swelling on the medial side of the metatarsophalangeal joint consisting of inflamed skin, a subcutaneous bursa and an osteophyte on the joint margin of the medial side of the metatarsal head (Fig. 20.1). In gout the whole metatarsal phalangeal joint will be red and swollen.

- Under the metatarsal heads.

In rheumatoid arthritis the fat pad under the metatarsal heads thins, and the heads become prominent and tender immediately beneath the skin of the sole of the foot. The patient complains of pain in the sole of the foot when walking as if walking barefoot on pebbles. Areas of thickened callous skin form over the metatarsal heads.

- Over the dorsum of interphalangeal joints and over the tips of the toes in patients with claw toes.

Feet do not fit easily into most shoes, even when they are normal. If the toes have started to claw then the pulp of the toe will be driven into the floor of the shoe, while the dorsum of the interphalangeal joints will be driven into the top of the shoe (a sort of contra-coup injury) (Fig. 20.2).

- Over the base of the fifth metatarsal if the patient is walking on the outside of the foot.

A bunion can form on the outside of the foot at the base of the fifth metatarsal. This is sometimes called a bunionette.

The counter of shoes (the part that wraps around the heel) can rub on the calcaneum producing a bunion on the insertion of the achilles tendon into the bone.

- Check also for scars, cuts and redness everywhere on the foot including the sole of the foot.

Soft tissues (swelling and wasting)

Swelling in the foot is commonly seen on the dorsum only. In the ankle joint it is commonly seen at the front of the ankle.

Wasting is seen in neurological conditions, and there may be wasting in the clefts between the metatarsals. Wasting may be associated with clawing of the toes (see Fig. 20.2).

Bone

With the patient standing, the heel should be in very slight valgus. The medial side of the foot (the arch) does not normally quite touch the ground, but is not raised so high that you can put a finger between it and the ground. The heel pad, the lateral side of the foot, all the metatarsal heads and the pulps of all the toes are on the ground when the patient is standing erect and relaxed. The toes should be relatively straight, not clawed (flexed at the interphalangeal joints and extended at the metatarsal phalangeal joint) or hammered (extended at the distal interphalangeal, and metatarsal phalangeal joint, flexed at the proximal interphalangeal joint) (Fig. 20.3).

Feel

Skin

Inflammation. Feel for heat. Sensation. In neuropathies, such as that caused by diabetes, the distal sensation may be lost, and the toes may be numb. In nerve compression in the spine (e.g. prolapsed intervertebral disc) it should only be necessary to compare the two sides by testing the sole, the medial side and lateral side, each of which is supplied by a different nerve root.

Soft tissue

Pulses. The easiest foot pulses to feel are the posterior tibial behind the medial malleolus, and the dorsal pedis between the proximal ends of the first and second metatarsals (Fig. 20.4). The toes should also be tested for capillary fillings.

Swelling. Feel the ankle joint for an effusion. It may even be possible to feel cross-fluctuation if there is a tense effusion in the ankle joint.

Wasting and gaps. Feel the tendoachilles passing up from the heel into the calf muscle. If it is ruptured it may be possible to feel a gap in the tendon.

However, an acute rupture is usually so bruised and tender that the gap is not as easy to feel as it should be. The site of tenderness will give you a clue as to whether the rupture is mid-substance or is at the musculo-tendinous junction (much higher in the calf). It is important to
To distinguish between these two as the management and prognosis are very different.

**Tenderness.** The extensor tendons of the toes in the dot-sum of the foot and up the front of the tibia will be very tender and may even produce crepitus if there is tenosynovitis. If they are tender, ask the patient to move the tendons and you may feel crepitus under your fingers.

**Bone**

Tenderness. In injuries around the ankle, start feeling at the proximal fibula head, just below the knee. The Maisonneuve fracture is a sprain of the ankle with a spiral fracture of the fibula proximally. Palpate for tenderness down the length of the fibula to its tip (the lateral malleolus), and then over the lateral collateral ligament as it passes from there to the calcaneum. Then palpate down the medial side of the leg, down the tibia, to the tip of the medial malleolus and on to the medial deltoid ligament. Feel the talus and navicular, on the dorsomedial side of the foot. Feel the fifth metatarsal head on the lateral side of the midfoot (a common site for a fracture after an inversion injury).

After a fall from a height check for tenderness in the calcaneum, as this may be fractured. If the forefoot has been trap-ped (frequently behind the pedals of a car in a head-on crash) then check for tenderness in the bones of the forefoot. These may be both fractured and dislocated if the forefoot is twisted.

**Move**

**Active**

Ask the patient to walk towards you then away from you. Look for limps.

The Windlass test. Make the patient stand on their toes while you look from in front and from behind. Some patients' feet look very flat when at rest. This can simply be a physiological flat foot. As soon as these patients stand on their toes, the arch forms (Fig. 20.5). In pathological flat foot the arch does not form.

Other movements. You should also ask them to move their toes, and move the ankle through a full range of movement (flexion, extension, inversion and eversion).

**Passive**

The Apley test. If you hold the heel in one hand and the fore-foot in the other, the ankle, subtalar and metatarsal mobility can be tested one after the other without moving your hands. Rocking the ankle by moving your hands in opposite directions, like a see-saw, tests ankle mobility. Tilting the foot out-wards and inwards using both hands together tests subtalar movement. Twisting the forefoot while holding the hindfoot still tests midtarsal mobility (Fig. 20.6).

Hallux rigidus and claw toes. The metatarsal phalangeal joint of the big toe is stiff in hallux rigidus.

In claw toes the metatarsophalangeal joint is commonly dislocated with the phalanx riding dorsally over the metatarsal head (Fig. 20.2). Check for passive correction of the metatarsal phalangeal joint and proximal phalangeal joints.

**Stability**

Stability of the ankle and foot joints is not easy to test, especially after acute trauma.

If the ankle is dislocated the talus will be visible pressing hard against the skin anterior and lateral to the foot. It should be reduced at once both to save the skin (which may otherwise become necrotic) and to make the patient more comfortable.

**Resisted**

Test for power of extensor hallucis longus (Fig. 20.7). Remember, this muscle is specifically served only by the L5 nerve root, and is a key test for damage to this nerve in a prolapsed intervertebral disc.

In polio and other neurological disorders, each muscle will need to be tested in turn. One way to do this is to put the tips of your fingers over the muscle body, or its tendon, while holding the limb still with the other hand. The patient is asked to try to move the limb against the resistance that you have created. Your fingertips will detect whether there is any activity in the muscle, as the movement itself might be produced by alternative muscles, the so called 'trick manoeuvres'. The power of each muscle can be graded using the Medical Research Council (MRC) power scale (Table 20.6).

Simmonds' test. The patient lies face down, feet over the end of the bed. Squeeze the calf and the foot should passively dorsiflex (Fig. 20.8). If it does not, the tendoachillles is likely to be ruptured.
The knee

General

Watch a patient walking first before starting examination of the lower limb.

Look also from in front or behind to see whether the knees are aligned in the sagittal plane. Varus knees (or bow legs) have clear space visible between the knees when the ankles are together. It is not uncommon to see slight varus in males, a normal variant. Severe varus is commonly seen in osteo-arthritis which commonly attacks the medial compartment of the knee first, as the arthritis destroys the joint which then collapses.

Varus knees have clear space visible between the knees when the ankles are together. It is not uncommon to see slight varus in males, a normal variant. Severe varus is commonly seen in osteo-arthritis which commonly attacks the medial compartment of the knee first, as the arthritis destroys the joint which then collapses.

Valgus knees tend to brush together as the patient walks even though the ankles may be wide apart. This deformity is commonly seen in rheumatoid arthritis, which attacks the lateral side of the knee first and leads to collapse there.

Look

Expose the legs fully including thighs (rolled up trousers is not enough).

Skin

Check for redness, scars and lacerations. (Do not forget the back of the knee.)

Soft tissue

Swelling. Look for an effusion in the knee. The dimple on the medial side of the knee will be lost compared with the other side if there is an effusion.

Wasting. Vastus medialis can be clearly seen if the patient is asked to force their knees into hyperextension. This muscle wastes within days of a knee injury, and will fail to bulge when contracted, compared with the other side.

Bone

Check for knock-knee, bow legs, fixed flexion and for the position of patella (Fig. 20.9).

Fixed flexion is the position of comfort in the knee and tends to develop secondary to any acute infection or inflammation.

The patella almost always dislocates laterally (Fig. 20.10). If not reduced it may remain jammed outside the lateral femoral condyle.

Feel

Skin

Temperature. Inflammation of the knee will produce a knee hot to the touch compared with the other side.

Sensation. Damage to nerves at or around the knee will produce disturbance of sensation distally. The same examination as described in the section on ‘The foot and ankle’ should therefore be performed.

Soft tissue

Swelling. Check for a knee effusion, using either a patella tap, cross fluctuation or a stroke test.

Stroke test. With the patient lying supine, empty the medial side of the knee joint by stroking any fluid up into the suprapatella pouch. Then watching the medial side of the knee carefully, stroke down the front of the thigh squeezing any fluid lying in the suprapatella pouch back into the medial side of the knee. As the fluid returns the dimple on the medial side of the knee pops out (Fig. 20.11).

The margin of the synovium can most easily be felt on the medial side above the patella. It can be rolled under your fingers, but is only palpable if the synovium is thickened.

Baker’s cyst. This is an outpouching of the synovium through a defect in the capsule posteriorly. It can be difficult to feel. As soon as the knee is flexed the cyst disappears, but reappears in full extension. It is associated with osteoarthritis of the knee. The patient will guide your fingers to the lump if you are having difficulty finding it.

Wasting. Atrophy of the vastus medialis is more easily seen than felt.

Circulation. The distal pulses and capillary filling should be checked in the same way as examination of the foot.

Bone

The margins of the patella, the femoral condyles and the margins of the tibial plateau are all easy to feel as they are subcutaneous. The underside of the patella may be tender if there is synovitis of the knee when the inflamed synovium is compressed against the bone.

The inferior pole of the patella is tender if there is tendonitis of the patella tendon origin (jumper’s knee).

The fat pad beneath the patella tendon is tender in Hoffa’s syndrome, an inflammation commonly brought on by sudden forced hyperextension of the knee.

The tibial tubercle is enlarged and tender when the insertion of the patella tendon is inflamed (Osgood—Schlatter’s syndrome), a common condition in athletic adolescents.

A tear in the meniscus may produce tenderness at the joint line margin over the area of the tear. The medial collateral ligament extends from two finger’s breadth above the knee joint to four fingers breadth below the joint. Tenderness over the ligament may indicate traumatic damage
Swollen and very painful. However, patients who dislocate a patella have frequently previously dislocated the other patella and the patella history of an anterior cruciate rupture. The knee swells at once (with blood) and the patient is unable to walk on it. If the patella stays out the commonly occurs during a twisting manoeuvre on a flexed knee and if the knee cap relocates immediately the injury can closely mimic the History. Patients who have lax ligaments (are double-jointed) are much more susceptible to dislocation of the patella. The dislocation Patella apprehension.

The posterior cruciate has a completely different mechanism of injury. It can occur either as a result of a hyperextension injury, or if the tibia is driven backwards with the knee in flexion (the dashboard injury).

There are several tests for cruciate disruption but one simple method is as follows. The patient lies supine with both knees bent up to a right angle and the feet resting on the bed. The examiner looks from the side to see whether one tibial tunnel is lying further back than the other. If the tunnel on the injured side is lying further back then the knee has a posterior sag (suggestive of a posterior cruciate ligament injury). The examiner then grasps the uninjured knee with fingers meeting in the popliteal fossa and thumbs side by side over the tibial tunnel. Sit on the patient’s foot to keep it still and then rock the upper tibia gently backwards and forwards against the femur, feeling for the amount of laxity in the joint. Now repeat the manoeuvre with the injured limb, comparing the amount of ‘play’ in the injured knee with the normal one. If there is more play and the injured knee had a posterior sag then the posterior cruciate is ruptured. If there was no sag then the problem is rupture of the anterior cruciate (Fig. 20.14).

The pivot shift test. This test relies on the fact that an anterior cruciate deficient knee frequently has some rotatory instability in extension. In this position the femoral condyles rolling on the tibia do not control rotation well. With the patient lying supine and the examiner sitting at the patient’s foot facing up the bed, one hand is used to lift the leg off the bed by the ankle and to rotate the tibia inwards on the femur. The examiner’s other hand presses against the lateral side of the knee pushing it into valgus, so that the lateral femoral condyle is engaged firmly with the tibial plateau. This hand now gently pushes the knee into flexion (Fig. 20.15). If there is anterior cruciate instability the knee starts to bend under the guidance of the examiner’s hand, but then jams at about 100 of flexion. The tibia has rotated so much on the femur (because of the absent anterior cruciate ligament) that the knee will no longer work as a hinge, but jams as soon as it tries to do so. As the examiner’s hand pushes the knee up into flexion, the knee has to come out of internal rotation so that the jammed joint can continue to flex. The jolt as the tibia derotates under the examiner’s hand is clearly palpable to the examiner and to the patient. It is even easier to feel if the examiner’s thumb lies tucked behind the fibula head. It is then forced smartly back when the derotation occurs. This test should be done very gently. If it is not the patient will be hurt and the test will be inconclusive because muscle spasm will mask the pivot shift.

Patella apprehension.

History. Patients who have lax ligaments (are double-jointed) are much more susceptible to dislocation of the patella. The dislocation commonly occurs during a twisting manoeuvre on a flexed knee and if the knee cap relocates immediately the injury can closely mimic the history of an anterior cruciate rupture. The knee swells at once (with blood) and the patient is unable to walk on it. If the patella stays out the patient may claim that they saw a lump on the medial side of the knee. This is in fact the medial femoral condyle (the patient assumes that the patella indicates the position of the knee). Examination of a knee which has recently had a dislocated patella is very difficult as the knee is stiff, swollen and very painful. However, patients who dislocate a patella have frequently previously dislocated the other patella and the patella
Apprehension test can be performed on the opposite knee.

The test. If patients have ever dislocated their patella they will be anxious about dislocating it again. If the knee is placed in extension and the patella pushed laterally, flexing the knee will encourage the patella to dislocate over the lateral femoral condyle (Fig. 20.16). As soon as this starts to happen the patient will become very apprehensive. Do not continue — just note the apprehension; you do not want to actually dislocate the patella.
The hip

The hip is rarely involved in extrinsic trauma but is commonly affected by intrinsic trauma (fractured neck of femur) and by chronic conditions (osteoarthritis). The examination of the joint is made more difficult by the fact that it is covered by muscles. It is also likely to present with pain referred to the knee, and can be the site of pain referred from the spine.

Look

Limp

Watch the patient walk, and look for a limp. The limp of a stiff hip is difficult to spot as the patient rocks their pelvis with the femur on the affected side, but fixed flexion deformity is common and leads to the patient walking with a characteristic stooped gait.

Skin

The scars from surgery on the hip are usually on the lateral side of the hip.

Soft tissue

Gluteal wasting can occur if the superior gluteal nerve was damaged after hip surgery, but beware of confusing gluteal wasting with loss of lumbar lordosis caused by back problems. The tilt of the pelvis may make it look as if there is bilateral gluteal wasting.

Bone

There is little to see because the hip is so deeply buried, but a limp may give a clue to underlying bony deformity.

Feel

Skin

As the joint is so deeply buried the only item that needs checking is distal sensation. Damage to the femoral nerve produces numbness over the front of the thigh. Damage to the sciatic nerve will produce numbness in the lower leg.

Soft tissues

Peripheral pulses can, again, be tested in the foot.

Bone

The hip can be palpated anteriorly in the groin beneath the femoral pulse, but the hip is deep and difficult to feel. Tenderness on the lateral side of the hip arises from the greater trochanter or is referred from the spine. Pain posteriorly is usually the sciatic nerve or, once again, has been referred from the spine.

Leg length discrepancy

Leg length discrepancy can be caused by bones in the two limbs being of unequal length, such as might occur after a fracture. It can also be caused by deformity such as a fixed flexion deformity of the hip. Leg length discrepancy caused solely by short bones is known by convention as 'true' leg length discrepancy. That caused by joint deformity is known as 'apparent' shortening. Most leg length discrepancy is caused by a mixture of the two.

True leg length discrepancy. It is usual to measure the 'true' leg length discrepancy first by putting both legs as straight as possible, and then measuring the leg which cannot be put straight. The other leg is then put into an identical position, so that the deformity has no effect on leg length discrepancy. If the end of the tape measure is held firmly between the pulp of the thumb and the side of the index finger the tip of the thumb can be used to trace the inguinal ligament upwards until it catches in the notch immediately below the anterior superior iliac crest. A similar manoeuvre can be used at the lower end of the leg. The tip of the examiner's other thumb is traced up the calcaneus, until it jams in the notch immediately below the medial malleolus. The measure is repeated on the other limb which is first put in the identical position.

In order to decide which bone(s) are responsible for the shortening, the patient should lie supine and the knees should be bent up to a right angle. The examiner should then look at the knees from the side. If the femur on the short side lies lower then the shortening is below the knee. If the tibia lies further back then the shortening lies above the knee. If the shortening is above the knee then palpation of the greater trochanters will reveal whether the shortening is in the femoral neck or in the femoral shaft. If the shortening is below the knee then palpation of the medial and lateral malleolus will reveal whether the shortening is above or below the ankle.

Apparent leg length discrepancy. Apparent leg discrepancy is that caused by joint deformity and is best calculated from the difference in true leg length, as measured above, and the difference in leg length when both legs are put as straight as possible.

Leg length discrepancy is very difficult to measure accurately using clinical methods, but can be measured very precisely, when necessary, using X-rays with grids superimposed. An alternative method clinically is to give the patient raised blocks to walk over. The height of the blocks is raised under the sole of the shorter leg until the patient feels that the short leg is now too long. Reduction of the height by 5 mm usually produces a measure which can be used as a shoe raise to correct leg length inequality. Discrepancies of 1 cm or less can usually be hidden inside the shoe. Raises of up to 2—3 cm can be put on the heel only, so keeping the shoe light. Raises of more than this usually require a raise of the sole and the heel.

Move

Active and passive

In the hip active and passive movements are measured together in the modified Thomas’s test, which will be described below.
Modified Thomas’s test. The patient bends up both their knees and hips actively, rolling themselves into a ball. The examiner can then carefully (watching the patient’s face) push the hips into further flexion (passive flexion). The flexion of the two hips can now be checked and compared. The patient is now asked to hold the affected hip flexed by hold-ing their shin in their hands. This fixes the pelvis in full flexion. The other leg is now carefully extended as far as comfortable and a note made of the angle that the femur makes to the couch in full extension. The normal leg is now flexed back up again as far as possible, and held there by the patient. The abnormal hip is now allowed to extend (carefully watching the patient’s face) until it too will extend no further (Fig. 20.17). Again, the angle that the femur makes with the couch is noted and compared with the recording made on the other side. Both legs are now lowered on to the bed and a note is made of the range of flexion and extension of both hips, noting that the examination was performed with the pelvis in full flexion.

Abduction. Lay your forearm across the patient’s pelvis with the tips of your fingers resting on one anterior superior iliac spine and your forearm resting on the other one nearer to you. Abduct first one hip and note the angle when you feel the pelvis starting to move under your hands. Return that leg to its original position and repeat the movement with the other leg. Abduction. Still leaving one hip abducted, adduct the other hip across until the pelvis starts to move. Put that hip back in abduction and adduct the other hip, noting the range of movement of abduction and adduction on both sides (Fig. 20.18). Rotation. Rotation of the hip will always be limited in extremes of extension and flexion, as the capsule of the hip is already tight. It is therefore important to test the range of movement of the hip in the mid-range with the thigh flexed at 45°. If the knee is flexed to 90° the tibia can be used as a lever and a protractor. Watch the patient’s face, and test internal and external rotation, comparing the two sides. Note that when the foot comes across the body you are testing external rotation, and when the foot comes out to the side you are testing internal rotation (Fig. 20.19).

Stability

The Trendelenburg test. This is a test of stability of the hip joint or of weakness of the gluteal muscles, such that the patient has great difficulty taking all of their weight on the affected leg. The most sensitive way of performing this test is to ask the patient to stand on both legs facing you, and to place their hands palm downwards on your hands held palm upwards. The patient is asked first to stand on their healthy leg, then repeat the manoeuvre on the affected leg. If the test is positive the examiner will feel a firm push downwards from the patient’s hand on the affected side as the patient tries to transfer their weight on to the affected limb (Fig. 20.20).

Tests for referred pain

Pain in the hip can be referred down from the spine, while pathology in the hip can produce pain in the knee. A simple test which can help distinguish pathology in the hip from pathology elsewhere is the ‘pastry rolling test’. With the patient lying supine on the couch start with the unaffected side. Place the palm of one of your hands on the patient’s shin, and the other on their thigh. Keep your hands flat with the fingers straight, and roll the leg as one to and fro under your hands as if you were rolling pastry. If there is no problem in the hip, the patient will relax completely after a couple of rolls, and their four will flop to and fro at the end of the leg (Fig. 20.21). Repeat the test on the affected side. If there is pain and/or stiffness in the hip joint the patient will not relax, the foot will not flop to and fro, and there will be a distinct resistance to movement at the end of internal and external rotation. Pathology in the knee does not do this because the knee joint is being rolled as one. Similarly, the sciatic nerve is not irritated by internal and external rotation of the hip, so pathology in the spine has no effect on this test.
Lumbar spine

The lumbar spine is another part of the anatomy which can be best examined initially with the patient standing up. Exposure is important and the back must be visible as far down as the natal cleft. The key to the examination of the lumbar spine is a full examination of the lower limbs. Irritation of nerves in the spine can mimic problems in the lower limb. Whenever you see a patient with problems in the lower limb, keep in the back of your mind that this problem could be referred from the spine.

Look

Skin

Look for hairy tufts and dimples at the base of the spine which may indicate an underlying spina bifida.

Soft tissue

Look at the muscles on each side of the spine. If they are very prominent they may be in spasm.

Bone

The lumbar spine should have a smooth concavity (lumbar lordosis). Loss of lordosis and flattening of the buttocks go with muscle spasm (Fig. 20.22). If the spine is curved laterally (scoliosis) then there are three common causes. The legs may be unequal in length (postural scoliosis). This scoliosis will disappear when the patient sits down. Secondly, there may be a fixed scoliosis in the thoracic spine, with a compensatory scoliosis in the lumbar region below it. Thirdly, there may be spasm in the muscles around the lumbar spine caused by pain.

Feel

Skin

Sensation. Test sensation in both legs. Sensory loss is most likely to be detectable distally, so simply compare touch on the lateral and medial side of both feet. If this is abnormal, then continue to a full neurological examination. Test for any loss of sensation in the perineal area if the patient complains of sudden onset of pain and numbness in both legs (cauda equina syndrome).

Soft tissue

Feel the muscles on each side of the spine for spasm.

Bone

Trace the line of the spine with your fingers, checking for scoliosis.

Feel the spine of the L5 and the S1 vertebrae. A step between the two may indicate a spondylolisthesis.

Move

Active

Flexion/extension. Place the tip of your thumb over the T12—L1 junction, and the tip of your index finger of the same hand over the lumbosacral junction. Ask the patient to reach forward to try to touch their toes. Note the distance that your thumb and tip of finger separate as the patient bends forward (Fig. 20.23). This distance is a measure of lumbar flexibility.

Note also how far the tips of the patient's fingers can reach down their legs when they bend forwards. The distance that they can reach is an indication of total spinal flexibility combined with hip flexibility.

Most patients cannot touch their toes, but some hypermobile patients can put the palms of their hands on the floor. Flexibility depends on fitness, age, gender and overall body mobility, and varies enormously between individuals.

Lateral deviation. Ask the patient to slide first one hand and then the other down the side of their thigh, bending laterally. The spine should bend smoothly from top to bottom. Total mobility can be recorded by noting the distance that each hand can move down the side of that thigh (Fig. 20.24).

Rotation. Stand behind the patient and hold their pelvis still with both hands. Ask the patient to twist round and look over their shoulder, first in one direction and then the other. Note the angle that the shoulder girdle can form with the pelvis (Fig. 20.24).

For these last three tests record whether any of the manoeuvres are limited by pain, and if so where.

Passive

The Lasegue or straight leg raise test. This test can be painful and so should only be performed slowly while watching the patient's face at all times. The test should be abandoned if pain becomes severe. It is a test of sciatic nerve irritability and relies on the fact that when the straight leg is flexed fully at the hip the roots of the sciatic nerve move as much as 2 cm through the vertebral foraminae. If the nerve is compressed and/or inflamed this movement will cause pain.

Pick up the leg least affected by the pain and gently bend the hip and the knee until both joints are fully flexed. Note the range of movement of both hip and knee.

Gradually straighten the knee, while allowing the hip to extend only as much as the patient feels is necessary for comfort. All patients will get some discomfort in the back of the thigh during this manoeuvre as the hamstring muscles are put on full stretch. While keeping the knee straight, let the hip drop 100 into extension so that any pain from tight hamstrings is relieved. Then take the foot and dorsiflex the ankle fully. This stretches the sciatic nerve. Pain in the back radiating down the full length of the leg indicates sciatic nerve irritation (Fig. 20.25).

The test should then be repeated with the opposite leg.
Resisted

Extensor hallucis longus is served purely by lumbar nerve root 5 (L5). It can be tested by comparing resisted extension of the tip of the big toes. Stand at the feet of the patient and press down on the big toenails of each patient while asking them to resist this pressure. If one distal phalanx drops into flexion easily compared with the other toe despite the best efforts of the patient, there is likely to be an L5 lesion (Fig. 20.7).

Testing for motor weakness

L5 is the commonest nerve root to be affected by a prolapsed intervertebral disc and is the only nerve root which is completely responsible for serving one muscle (the extensor hallucis longus) and so is easy to test. The simplest test for compromise of L4 motor function is loss of the knee reflex and weakness in the quadriceps (demonstrated in the section on ‘The knee’). The ankle reflex is lost in S1 damage, but beware; it is commonly missing in elderly patients even without nerve root damage.
Thoracic spine

Look

Skin and soft tissues

There are no common lesions in the thoracic spine which can be seen in the skin or soft tissues.

Bone

The thoracic spine is normally convex, and straight in the sagittal plane.

If it is very convex and painful the patient may have Scheuermann’s disease, a condition of unequal growth of the front and back of the spine which presents in adolescence.

Lateral curvature of thoracic spine accompanied by rotation is called scoliosis. As the patient bends forward to touch their toes the associated rib hump increases in size. This is diagnostic of scoliosis.

Feel

Skin, soft tissues and bone

In cases of possible trauma to the thoracic spine the patient should be immobilised on a spine board. A full check of distal neurology should be performed if the patient is alert enough to co-operate. When the time comes to examine the thoracic spine, the patient should be log-rolled using at least three trained staff working as a team. The whole length of the spine should be palpated for tenderness and steps. If any are found the patient should be kept on a spine board until all the necessary investigations have been performed. The spinal cord lies in the thoracic spine so neurological damage may appear as an upper motor neuron lesion in the lower limbs and/or a lower motor neuron lesion in nerve roots originating from the thoracic spine. Any sensory loss may spread progressively (the apparent level of the lesion rises) in the hours after the injury. A very careful examination of perineal sensation should be performed. Preservation of function in these sacral roots (central sparing) is a good prognostic sign that some recovery may occur over the next months.

Move

Active, passive and stability

There are no simple tests for mobility or stability of the thoracic spine and, indeed, if stability is in doubt the thoracic spine should be not be moved. It should be immobilised while investigations are performed to avoid the risk of causing further neurological damage.

A full neurological examination of the lower limbs will be needed if neurological damage in the thoracic spine is possible. Immediately after the injury there may be spinal shock with reduced power and tone. This will mimic a lower motor neuron lesion. Later, the picture of an upper motor-neuron lesion will appear with hyper-reflexia and clonus. Clonus is tested by smartly dorsiflexing the ankle. If the gastrocnemius contracts more than once or twice, then clonus is present.
Cervical spine

The cervical spine can be difficult to see, particularly in women. It is important to get the hair up out of the way, but patients should not use their own arms to do this. A theatre nurse’s cap may be helpful. Just as the key to examination of the lumbar spine is a neurological examination of the lower limb, the key to the examination of the cervical spine is a neurological examination of the upper limbs.

Look

Skin

Look for scars and sinuses, particularly around the cervical lymph node area and over the thyroid. Surgical approach to the neck can be made from the front, the side or the back.

Soft tissue

Look for spasm of the trapezius muscles and the sternomastoid muscles.

Bone

The cervical spine normally has a lordosis like the lumbar spine. If this is lost there is probably muscle spasm caused by pain.

Feel

Skin

Test for sensory loss in hands and feet.

Soft tissue

Feel for spasm in the trapezius muscles.

Bone

Palpate down the contour of the cervical spine feeling for gaps or for tender areas.

Move

Active

Flexion/extension. The patient should be asked to bend their neck forward and put their chin on their chest. Look to see whether the cervical lordosis is lost. They should then extend their neck by looking up at the ceiling. Note the angle that the face makes with the ceiling as a measure of extension.

Lateral rotation. Ask the patient to look over their shoulder on each side keeping their shoulders still. Note the angle that the chin makes with the shoulders on each side.

Lateral deviation. Ask the patient to lay one ear on that shoulder, then the opposite ear on the other shoulder. Note how close they can bring each ear to its shoulder without shrugging the shoulder upwards. Note whether any of these manoeuvres are painful in extreme.

Neurological testing

The neurology of both upper and lower limbs should be tested. Lesions in the lower limbs are likely to be upper motor neuron; those in the upper limb are likely to be lower motor neuron. For testing motor power in the upper limb it is probably only necessary to test grip and the power to spread the fingers apart. Grip tests power of the finger flexors as well as the wrist extensors, so covering most of the middle cervical nerve roots. Abduction of the fingers is supplied by the lower cervical roots including Ti, so testing these two manoeuvres covers most of the motor roots from the cervical spine apart from the uppermost ones.

Passive and stability

These do not contribute much to diagnosis of problems in the cervical spine.
The shoulder

The examination of the shoulder is most easily performed if the patient is standing with their shirt and vest removed. It is not necessary to remove the brassiere.

Look

Look at the patient standing both from in front and from behind.

Skin

Look for scars. Check in the axilla for sinuses.

Soft tissue

Check for wasting of the deltoid (increased angularity of the shoulder) (Fig. 20.26). This is commonly caused by damage to the axillary nerve during an anterior dislocation of the shoulder.

Wasting of the supraspinatus and infraspinatus (hollows above and below the spine of the scapular) occurs with a tear of the rotator cuff. Check for a bulge low in the upper arm which is especially prominent when the patient flexes their elbows. When the long head of the biceps ruptures the body of the muscle retracts back down the arm.

Use the other side of the patient’s body for comparison.

Bone

The commonest deformity is a subluxed acromioclavicular joint, which appears as a prominent lump on the distal end of the clavicle (Fig. 20.27). An anterior dislocation of the shoulder itself is first noticeable because of the loss of the rounded contour of the shoulder. The bulge in front of the shoulder (the humeral head lying anteriorly) is easier to see when you start looking for it. Otherwise, it can easily be masked by the swelling of the acute injury.

Feel

Problems in the shoulder can be referred from the neck or arise from the shoulder complex itself.

The epaulette sign

Before starting the examination, ask the patient to show you where they are feeling pain. If they are able to localise the pain with the tip of one finger then the pathology is probably in the shoulder. If, however, they rub the whole hand over the top of the shoulder then the pain is likely to be referred from a lesion in the neck. The patient rubs their hand over the position of epaulettes on a soldier’s uniform, hence the name of the test.

Localisation in the shoulder

Within the shoulder complex problems commonly arise either from the acromioclavicular joint, from problems in the rotator cuff including the subacromial bursa or from the glenohumeral joint itself. The examination should be designed to distinguish between these possibilities.

Skin

Feel for heat. Test distally for loss of sensation, comparing soft touch on both sides. Test the outer and inner side of the upper and lower arm, then the medial and lateral side of the hand.

Soft tissue

Feel the trapezius muscle for tenderness (common in referred pain from the neck). Tenderness under the margin of the acromion suggests problems with the rotator cuff complex.

Bone

Feel along the clavicle starting at the sternoclavicular joint palpating for tenderness, particularly at the junction of the clavicle with the acromion. Palpate the outlines of the acromion and feel for tenderness immediately beneath the acromion in the subacromial bursa starting anteriorally, moving laterally and finishing posteriorally. Note any tender sites.

Move

Active

Ask the patient to put their hands first behind their head, and then behind their back. These two movements effectively test the functional range of movement in the shoulder. Record how far they can reach towards the back of their heads and up their backs.

Stand behind the patient and ask them to raise both arms from their sides out laterally and 300 forward (in the plane of the scapula) vertically up above their heads. Watch the movement of the scapula in relation to the humerus. There should be a scapulohumeral rhythm. In the first part of abduction the scapula moves very little, perhaps only 10 for every 20 that the humerus moves. In the second part of movement the scapula and humerus tend to move almost together. That is a normal rhythm. Note if there is a catch in this movement, and ask them to point where they experience pain if they get a catch. Pain under the lower margin of the acromion suggests an impingement.

Passive

With their arms at their sides, flex their forearm 900 pointing their hands straight forward. Put one hand on the shoulder joint and use the other hand gently to turn the forearm outwards externally rotating the shoulder. Crepitus in the shoulder suggests arthritis in the glenohumeral joint. Pain and complete stiffness is associated with adhesive cap-sulitis (frozen shoulder).
Stability

Thumb-down test. This test is specific for problems of impingement and inflammation in the subacromial bursa. The patient is asked to flex the shoulder to just under 90° in the plane of the scapula (laterally and 30° forward). With the patient holding their arm straight out in this position, push down gently on the arm so that they have to maintain the position against resistance (Fig. 20.28). If they experience sharp pain in the subacromial area they have an impingement problem.

Apprehension sign. The shoulder commonly dislocates anteriorly when the arm is above the head and externally rotated. If the patient has ever experienced a previous dislocation, putting the patient in that position makes them feel as if the shoulder is about to dislocate (Fig. 20.29). Only do this test gently, and watch the patient’s face. You do not want to dislocate the shoulder.

Sulcus test. In patients who have had a previous dislocation the shoulder joint tends to be lax. Drawing down on the patient’s arm when they are relaxed allows the humerus to drop away from the acromion, producing a sulcus (groove) in the unstable shoulder which is more prominent than on the normal side (Fig. 20.30).
The elbow

The elbow is a subcutaneous joint, which is quite simple to examine. Exposure should include the whole of both arms. It is not sufficient just to roll up the sleeves.

Look

Skin

Look for scars and for redness, especially over the olecranon.

Soft tissue

Swelling can be seen mainly in the dimples either side of the olecranon. Wasting as a result of a lesion around the elbow is commonly the result of an ulna nerve palsy. There will therefore be wasting in the hypothenar eminence and of the intrinsic muscles in the hand.

Bone

Look at the carrying angle of the elbow, the angle that the forearm makes with the upper arm as the arm lies by the patient's side with the hands facing forward (Fig. 20.31). Fixed flexion can be seen in comparison with the other arm if the arms are held out horizontally in front with the palms upwards.

Feel

Skin

If the elbow joint is inflamed it will feel hot as it is a subcutaneous joint.

Sensation. The sensation in the hand should be checked. The ulna nerve is the one most likely to be injured around the elbow. Its sensory distribution is the lateral one and a half fingers of the hand.

Soft tissue

Cross fluctuation in the elbow joint between the postero-medial and posterolateral pouches can be elicited if there is an effusion in the elbow. The ulna nerve can be felt by rolling it under your fingers between the medial epicondyle and the olecranon. If it is tender it is probably inflamed.

Bone

Tenderness over the lateral epicondyle is found in tennis elbow.

The radial head can be felt best by passively pronating and supinating the forearm while feeling for the radial head. It is slightly lumpy and can be felt under the tip of your finger as it rotates. Tenderness indicates a fracture if it is acute, or arthritis if it is chronic.

Move

Active

Flexion/extension. The range of movement of elbows can be compared by moving both elbows together with the shoulders forward flexed 90° (Fig. 20.32). The normal elbow hyperextends slightly, but the variation is large.

Pronation and supination. This is tested with the elbows at a right angle and with the fingers out straight or with a pencil gripped in the fist to act as a protractor (Fig. 20.33).

Passive

Repeat the above movements holding the patient’s wrist in one hand and the elbow clasped between the thumb and index finger on the epicondyles. Watch the patient’s face to avoid causing pain.

Stability

The stability of the elbow can be tested in extension, stressing the collateral ligaments.
The wrist

Look

Skin

Look for scars, particularly over the palmar side of the wrist. The thin scar of a carpal tunnel release may be almost invisible unless carefully looked for.

Soft tissue

Swelling and wasting. Swelling is visible mainly on the dorsal side, or over the radial styloid (De Quervain’s tenosynovitis). Wasting can occur in the thenar or hypothenar eminence. It can also be seen between the metacarpals in the dorsum of the hand. Thenar eminence wasting can best be seen by putting the two hands side by side, thumb upwards, and looking down at the thumbs from above. Any slight difference in shape can then be clearly seen (Fig. 20.34).

Bone

Look for prominence of the ulna styloid and for radial drift of the wrist characteristic of rheumatoid arthritis.

Feel

Skin

Test sensation in the hand by comparing the sides. The median nerve can be tested over the palmar surface of the thumb and the index finger, the ulna nerve over the little finger. The sensory distribution of the radial nerve is a patch over the dorsum of the base of the thumb.

Soft tissue

Feel for the radial pulse and capillary filling at the fingertips. Synovial thickening can be felt in the wrist either dorsally or on the palmar side.

Tinel’s test. This is a test for inflammation in the median nerve. This is usually caused by compression in the carpal tunnel. Lay the patient’s hand on the table, palm upwards, and tap with the tip of your index finger over the median nerve at the wrist crease. Tingling or lightning pains into the fingers suggest that the median nerve is being compressed.

De Quervain’s tenosynovitis. The extensor tendons to the thumb can become inflamed from overuse. The tendon sheath is tender and it is sometimes possible to feel crepitus in the tendon if it is moved gently while palpating over it.

Bone

Scaphoid fracture. The waist of the scaphoid can be felt in the anatomical snuff box and the proximal pole can be felt anteriorly at the front of the base of the thumb.

Carpal instability. Trauma to the wrist can produce tears in the carpal ligaments. Chronic tears can be tender to palpation.

Move

Active

Extension is tested by the patient pushing their two hands together into a ‘prayer’ position but with the elbows raised so that the forearms are in line with each other (Fig. 20.35). If there is loss of extension the palms will not be able to meet together and/or one forearm will tend to be dropped. Palmar flexion is performed in the same way, but with the hands pointing down and the backs of the hands in contact.

Passive

Ulna and radial deviation are tested by taking the patient’s hand in your own and forcing the hand into these positions, comparing the two sides.

Stability and resisted movement

The stability of the wrist is not easy to test, but checking power grip tests the power of the finger flexors, the wrist extensors and the stability of the wrist.
The hand

Look

Skin

Look for tight bands in the palm leading up to the fingers or even thumb (Dupuytren’s contracture) (Fig. 20.36).

Soft tissue

Check for thenar and hypothenar wasting (see previous section on ‘The wrist’) but also check for wasting in the clefts between the fingers dorsally (damage to the ulna nerve or Ti).

Bone

Look for Heberden’s nodes (Fig. 20.37) over the distal inter-phalangeal joints dorsally (associated with osteoarthritis). Look for swan neck and boutonniere (Fig. 20.38) deformities. Swan neck deformities have an extension at the middle interphalangeal joint with flexion at the distal interpha-langeal joint. Boutonniere deformity is extension at the distal interphalangeal joint with flexion at the middle interpha-langeal joint.

Both of these are associated with rheumatoid arthritis. Look also for dropped fingers. If one finger lies lower than the others when the hands are held out, test for rupture of the extensor tendon by asking the patient to extend the finger against resistance. Look for subluxation of the metacarpal phalangeal joints and for ulna drift of the fingers (also associated with rheumatoid arthritis) (Fig. 20.39).

Feel

Skin

Feel for loss of sensation in the tips of the fingers. Review the sensory distribution of the median, ulna and radial nerves. If there is any doubt about the sensation then proceed to test two-point discrimination.

Soft tissues

Check for capillary filling in the fingertips.

Feel for wasting in the first dorsal interosseous on the radial side of the first metacarpal. This muscle is plump and easily palpable. Damage to the ulna nerve or to the Ti nerve root can be detected from wasting in this muscle.

Bone

Feel for swelling and tenderness over the metacarpal phalangeal and interphalangeal joints.

Move

Active

Test roll-up of the fingers from full extension to full flexion. Test flexion of the metacarpal phalangeal joints in isolation while keeping the proximal and distal interphalangeal joints extended. This tests the patient’s control of the intrinsic muscles. Test abduction of the fingers (a further test of small muscles in the hand).

Passive, stability and resisted

Test the power of the extensors, individually pushing down on each finger.

Superficialis tendon test. Flexor digitorum profundus usually has only one muscle belly supplying the tendons to all of the fingers. Profundus can therefore be immobilised by holding all the fingers bar the one being tested in full extension, grasping them in your hand. If the test finger is still able to flex, then superficialis to that finger is active (Fig. 20.40).

Profundus test. Flexor digitorum profundus is the only tendon that inserts in the distal phalanx. If the finger is held by the middle phalanx, the power of the profundus tendon can be tested (Fig. 20.41).

Intrinsics. The power of the intrinsic muscles of the hand is tested by asking the patient to abduct the fingers against resistance, and feeling for contraction in the first dorsal interosseous muscle on the index finger side of the web space (Fig. 20.42).

Froment’s test. The patient is asked to grip a sheet of paper between the index finger and thumb of both hands. If the intrinsic muscles of the hand are normal the patient can grip firmly with the thumb in extension. However, if there is weakness, particularly of the adductor pollicis, the thumb cannot remain straight while flexor hallucis longus contracts hard, so the thumb flexes (Fig. 20.43).

Abductors of thumb. The abductors of the thumb are supplied by the median nerve. Power is tested by asking the patient to raise the thumb from the palm against resistance (Fig. 20.44).
Summary

The examination of the musculoskeletal system follows a standard pattern whichever part of the body is being examined. The system is quick and simple, and ensures that no critical physical signs are missed.
Learning objectives
• To know how to investigate a patient who may have a fracture or dislocation.
• To be able to describe a fracture or dislocation concisely and correctly.
• To understand the principles of reduction and holding a fracture or dislocation.
• To know the common complications of fractures and dislocations, and how to check for them.
• To understand the basic pathophysiology of fracture healing.
Significance of fractures and dislocations

Fractures (breaks) and dislocations are failures of the skeleton to cope with the loads put upon it. When they do occur there are other structures which can also fail which may not be so obvious but which may have much more serious consequences. After the initial trauma, tissues tend to spring back into place. Nerves and blood vessels may also have been stretched far beyond their physiological limit at the time of trauma. If the nerve has been disrupted and the ends have separated, surgery may improve the prognosis dramatically. If the blood supply to that limb has been disrupted, then it is a surgical emergency to restore that circulation (Fig. 21.1).

The check for neurovascular damage in a traumatised limb is, if anything, more important than the diagnosis of the fracture or dislocation.
Importance of the history

The history gives important clues to the type of trauma likely. The energy of trauma is related to the mass and the square of the velocity. The direction of the trauma will also affect the injury that you should be seeking. The important thing to remember is that if the trauma was severe enough to fracture or dislocate the skeleton, then it is highly likely that there was enough energy to cause a second or even a third dislocation or a fracture.

Do not relax once you have found the fracture or dislocation — start looking for more.
Patterns of injury

The history of the injury will give a clue to the pattern of the injury. A fall from a height with the casualty landing on their feet will produce a characteristic pattern of injury. This might include bilateral fractures of the calcaneum, pilon fractures of the ankle (the talus is driven up into the lower tibia), depressed fractures of the tibial plateau, central dislocation of the acetabulum and crush fractures of the vertebrae (Fig. 21.2).
Examination

The musculoskeletal examination is described in Chapter 20. The key features are to make sure that the patient’s overall condition is stable by checking their airway, breathing and circulation before concentrating on the musculoskeletal injuries. The examination should then be systematic from top to bottom of the body, with complete exposure and care taken to check the patient’s back as well as their front. For each limb, be sure to check the distal circulation and neurogy. Finally, it is important to record these findings.
Describing a dislocation or fracture
Dislocations and subluxations
A dislocation is a complete disruption of a joint. The articular surfaces are no longer in contact. A subluxation is a partial dislocation. Some of the articular surface is in contact, but the congruence of the two joints has been lost. For either a dislocation or subluxation the joint needs to be named, and the direction of the disruption should be described (e.g. an inferior glenohumeral dislocation).

Fractures
Classification by quality of bone in relation to load
Fractures occur when the load to which they are subjected exceeds their intrinsic strength. A simple traumatic fracture occurs when an excessive load is applied to normal bone. A pathological fracture is produced when the strength of the bone is reduced by disease. In this case a force which is within normal limits leads to a fracture. The disease could be generalised osteoporosis, or a localised lytic lesion from a metastasis (Table 21.1).

If bones are subjected to a very large number of loads, none of which alone would be enough to break the bone, then the mechanical structure of the bone can gradually fatigue and the bone will then break. This is particularly a problem for people playing high-level sport and produces a stress fracture.

Partial or greenstick fracture. Bones in young people are very flexible. They bend and then may buckle or partially break, instead of breaking cleanly when overloaded (as bones in adults do). One characteristic of a greenstick fracture is that there may be a discontinuity in one cortex of the bone, but not in the other (Fig. 21.3).

Classification by direction of force
Compression fractures. If the load applied along the length of a bone exceeds that of its strength then it may collapse into itself. This is especially common in the elderly if the bones are osteoporotic, and so are less able to resist a heavy load. The fracture may be difficult to see. There may only be a small overlap of the cortical margins of the fracture, while the medulla may look diffusely radio-opaque (white) because the trabeculae have collapsed into each other. Overall, the bone will be shortened and may also be angulated.

Avulsion or distraction fracture. Here the two fragments of bone are pulled apart. In young patients a lipament or tendon may be stronger in tension than the bone into which it inserts. If the load is excessive the bone tears apart. These fractures are particularly common where strong muscles insert into small bones. Examples are the patella (the quadriceps muscle), the olecranon (triceps) and the fifth metatarsal head (peroneus tertius).

Spiral fractures. If a long bone is twisted along its axis a spiral fracture may result. The length of the spiral is easy to underestimate. It is especially important to see whether there is any extension into the articular surface of the bone. The tibia is particularly susceptible to spiral fractures when the foot is firmly fixed to the ground (by studs or another player’s foot) and the player’s body continues to twist.

Transverse fractures. If a long bone is bent along its long axis then a transverse fracture may result.

Butterfly fractures. If a bone is struck a direct blow, it is common for a more complex fracture to result where two break lines spread out obliquely from the point of contact of the blow, producing a free-floating ‘butterfly’ fragment between the two fractures.

Comminuted fractures. Comminuted fractures occur when a large amount of energy is dissipated into a bone. The bone breaks into fragments which may impact onto each other or separate and become displaced (Fig. 21.4).

Classification by anatomical site
A long bone is divided into three main zones. The diaphysis is the narrow part of the main shaft. It usually has a thick cortex and a medulla filled with trabecular bone. The metaphysis is the flare at each end between the diaphysis and the epiphysis (growth) plate. It has thinner cortical bone and its medulla is, again, filled with trabecular bone. The ends of a long bone beyond the epiphyseal plate are called the epiphyses.

Grade 1. In this case there is a small crack along the metaphyseal side of the epiphyseal plate. This side is made up of dying chondrocytes and ossifying cartilage. The fracture does not affect the blood supply to the epiphyseal plate nor does it affect the anatomy of the germinal layer. It therefore heals quickly and without long-term problems, like children’s bone elsewhere.

Grade 2. Here the fracture line again travels along the metaphyseal side of the plate but, before reaching the far cortex, it breaks out and tracks down into the metaphysis. This is by far the most common epiphyseal fracture, and for the same reason as given above has a good prognosis. Even if the fracture is markedly displaced the prognosis remains good. In children the bone will remodel and grow straight over the next year, especially if no rotatory abnormality is involved. In fact, one of the greatest risks in a grade 2 fracture is causing growth arrest by damaging the growth plate while reducing the fracture, especially if this is attempted after a few days when the fracture may already be united.

Grade 3. In this case the fracture line does not run along the epiphyseal plate at all. It crosses from the metaphysis to the epiphysis. If it is displaced then it may heal with a step in the epiphyseal plate. Bony union may occur across the epiphyseal plate and block further growth, causing a most disfiguring progressive deformity of the affected bone.

Grade 4. Here the fracture line travels along the distal (epiphyseal) side of the growth plate affecting both the blood supply and the anatomical integrity of the germinal cells. The fracture line does not travel the whole length of the epiphyseal plate but deviates off into the epiphyseal itself and out on the articular surface. This is a second reason why this fracture has a poor prognosis. Not only is the growth plate likely to be damaged, but the articular surface may be incongruent. This predisposes the joint to early arthritis. The key to successful management of this type of fracture is anatomical reduction. This will be best performed by open surgery. Once again, this type of fracture is rare.

Grade 5. This is a rare and difficult fracture to diagnose. The injury is a severe crush of the epiphyseal plate. The X-ray may only look abnormal in retrospect, and this is indeed how this type of fracture is usually diagnosed. The consequence of complete disruption of the growth plate is complete growth arrest. There is little that can be done to prevent this, or indeed deal with it, once it has occurred

Open fractures.
At the time of a fracture the soft tissues over the bone will also be damaged. If the skin is broken there is a high probability that at some time during the accident the fracturing bone came into contact with the outside world, and so could be contaminated with bacteria. If there is no broken skin anywhere near a fracture, the fracture can be assumed to be closed and will initially be free of infection. If, however, there is any break in the skin anywhere near the fracture it is important that the fracture is classified as open and treated as such. The bone will need exposing and a careful search made to allow all dead or contaminated tissue to be removed. The wound will also need washing out and should be left open. It is always best to err on the safe side, and if there is any doubt whatsoever to treat the fracture as ‘open’.

Classification by position
Bones have a very strong covering (the periosteum) which is invisible on X-ray. When a bone breaks the periosteum is torn, but it is unusual for the periosteum to be completely disrupted. This is very important for orthopaedic surgeons because the periosteum can be used to obtain a good position when reducing a fracture. It can even act before that. Its elasticity may serve to reduce the fracture after the trauma. If a fracture is seen to be undisplaced on X-ray, that does not mean that it was never displaced. It just means that much of the periosteum is intact. Even displaced fractures usually have at least part of the sleeve of periosteum intact (on the side of concave curvature), but once again the displacement at the time of trauma was always greater than that seen afterwards. This is why apparently innocuous looking minimally displaced fractures with a small puncture wound over them should be assumed to be open.

Deciding whether a fracture is stable or unstable is yet another type of classification, ‘classification by management’.
Classification by management

*Stable fractures* are those which are unlikely to move further. *Unstable fractures* are those which will continue to displace if action is not taken to hold the fracture secure. There is a gradation of stability which depends on the following factors.

- **Site.** Fractures in weight-bearing bones are more likely to be displaced by ‘normal’ loads than those in bones which can easily be protected from load, such as the long bones of the arm.
- **Shape.** Spiral fractures tend to be unstable, while impacted fractures tend to be very stable. The more displaced the fracture, the more unstable it is likely to be.
- **Displacement.** Undisplaced fractures may have the periosteum intact and are therefore stable. The more displaced the fracture, the more unstable it is likely to be.
- **Behaviour of the patient.** Patients who are prepared to be careful can maintain the position of a fracture which would become displaced in a young hard-drinking male, who is not prepared to take any advice.

**International classifications**

The AO classification is an internationally agreed classification of fractures using a simple alphanumeric code. The first number relates to the bone (humerus is 1, radius and ulna are 2, etc.). The second number relates to the position of the fracture on the bone (1 is proximal, 2 diaphyseal and 3 is distal). The position number is followed by a letter which defines the severity of the fracture. For proximal and distal fractures (types 1 and 3) ‘A’ is extra-articular, ‘B’ is partial articular and ‘C’ is intra-articular. For diaphyseal fractures (type 2) ‘A’ is a simple fracture, ‘B’ is a wedge or butterfly type and ‘C’ is comminuted or complex. This letter is followed by a further number which classifies the fracture still further.

Charts are available to help you to decide the exact classification of each fracture (see Fig. 21.8).

The advantage of this classification is that it is international and has been carefully validated to make sure that, as far as possible, everyone looking at the same fracture would classify it in the same way. The disadvantage is that a string of numbers is not very memorable. If you say to most trauma surgeons that a fracture is a 32B3.2, it is unlikely that they would immediately know that you were talking about a distal third comminuted fracture of the femur.

A second problem is that for a classification to be useful it should point to both treatment and prognosis. One of the key features which determines treatment and indeed prognosis in a fracture is soft-tissue damage (especially whether the fracture is open or not). A second major feature is whether a fracture is displaced or not, as this may make a big difference to any decision on management. Neither of these two important prognosticators is covered in the AO classification.
Principles of management

Early treatment (neurovascular problems)

The principle of management of fractures is to deal with life-and-limb-saving problems first. This means paying attention to ABC (airway, breathing and circulation) and to the neurovascular status of the limb before dealing with the fracture itself. If there is vascular compromise and the limb is distorted, it is always worth straightening the limb as far as possible in case it is simply the pressure of the displaced bone which is causing the problem.

Reduction of fractures and dislocations

Some fractures may not need reduction, especially if the minimal malunion which results will cause no cosmetic or functional problem. An impacted stable fracture, which is only slightly displaced, may actually be made worse by reduction. The position may be improved but the fracture will become unstable. This may make future management much more difficult.

Holding a fracture

Once a fracture has been reduced it needs to be held until it has united (the bone ends have joined together).

Rehabilitation

Once the fracture is stabilised, the patient may need help with rehabilitation so that they can return to as full and as independent a life as possible (Table 21.3).
Indications for reduction
If a fracture is allowed to heal in a displaced position the fracture will unite, but it may go on to malunion. This may be unacceptable either because it is ugly (deformity) or because it interferes with the function of the limb. Malunion is not usually painful.

Remodelling in children
Fractures in children remodel as the skeleton grows. Some deformity can therefore be accepted because this will correct itself over the following months. Grade 2 epiphyseal fractures in children are easy to reduce but may then slip back out of a satisfactory position. Re-reduction carries a risk of causing growth plate damage (especially if it is performed more than 2 or 3 days after the fracture). Under these circumstances it may be better to accept the malunion resulting from a slip rather than risk an epiphyseal arrest while trying to produce a perfect reduction.

Stable impacted fractures
If the fracture is stable and impacted then it will heal quickly with a minimum need for protection. Disimpaction (separation of the fragments) and reduction will automatically make the fracture unstable. The fracture will then need more sophisticated methods for holding it. In the elderly, a rapid return to independent existence may be more important than cosmesis. A stable distal radius (Colles) fracture in an elderly patient who is only just managing to cope with independent existence may be best left unreduced and managed in a removable splint for comfort. Within 2 weeks it will be almost painless and can be used for everyday activities. Reduction would require a plaster for at least 4 weeks, during which time bathing and cooking might prove impossible.
Reduction

Reducing a fracture involves trying to return the bones to as near to their original position as possible (Fig. 21.9). Reduction can be performed open, in which case the fracture is exposed surgically so that the fragments can be reduced under direct vision. If a fracture is reduced closed, then the accuracy of the reduction can only be checked on an X-ray. An advantage of closed reduction is that the soft tissues and blood supply should not be disrupted any further than occurred at the time of the trauma.

If a fracture is closed and can be reduced closed it should be. If it is already open, then the opportunity should be used when cleaning the wound to make sure that reduction is anatomical by performing an open reduction.

Emergency reduction

Emergency reduction should be undertaken immediately and without analgesia if the circulation or the skin of a limb is compromised (Fig. 21.10).
Principles of closed reduction

Closed reduction is always preferable to open reduction provided that a comparable reduction can be obtained and held. Closed reduction relies on the attachments of the bone to soft tissues (periosteum and/or ligaments) to obtain and to hold reduction. Intra-articular fractures, where fragments may not have any soft-tissue attachments, cannot usually be reduced closed. These fractures also need accurate reduction if traumatic secondary arthritis is to be avoided and so are best performed open to make sure that reduction is anatomical. In children the bones may not be clearly visible on X-ray because they have not yet fully ossified, especially around the elbow. Open reduction may be needed to be certain that reduction has been achieved (Table 21.4).

Pain relief

Patients need to be free of pain when reducing fractures, so a general anaesthetic will be required if a regional block is not possible. If there is no neurovascular compromise this is not an urgent operation, so time should be allowed for the patient’s stomach to empty before a general anaesthetic is administered. It may be best to send the patient home with a splint and analgesia so that the procedure can be performed as a semi-planned procedure on a fully staffed list the following morning. If there is any chance that the reduction will not be successful, and that the fracture will need to be opened, then this should be planned in advance (another good reason to leave the case over until the following morning). You will also need to plan how you are going to check that the fracture has indeed reduced satisfactorily, so you will need to book either an image intensifier or plain X-rays, and the patient will need to be positioned so that imaging in two planes is possible. You will also need to plan how to hold the fracture and what facilities (such as plaster or traction pins and frames) you will need.

Value of the periosteum

When a bone fractures the periosteum remains largely intact, especially on the concave side of the fracture. This strong membrane is not visible on the X-ray and so its value in guiding the fracture to a stable reduction may not always be fully appreciated. Impacted fractures which are also partially displaced will need disimpacting before the displacement can be corrected. Disimpaction is carried out by applying steady distraction to the fracture until you feel the bone ends separate. The force applied should be no more than 4 or 5 kg as otherwise there is a danger (especially in the elderly) of degloving the limb (pulling off the skin and soft tissues). If the fracture does not initially disimpact, then the fracture should be bent further than it is already angulated, ‘exaggerating the deformity’. This manoeuvre should disengage the jammed ends. The limb will lengthen slightly, and the fracture will become floppy. Traction should be continued for another couple of minutes to drive oedema out of the tissues around the fracture. This will allow the soft tissues to extend to their normal length and make the reduction easier.

Engaging the bone ends

The intact periosteum on the concave side of the fracture can now block reduction unless the tension is taken off it. This is done by angulating the fracture even further than before, and sliding the fractured end of the distal fragment up the cortex of the proximal fragment until it slips over the broken edge of the proximal fragment. As soon as this occurs the fracture can be rolled into place with the jagged ends of the fracture interdigitating like gear wheels. When the fracture comes to anatomical alignment, the intact periosteum on what was the concave side will become tight and prevent overcorrection of the fracture. Providing that any lateral pressure exerted on the fracture is in the direction of overcorrection the fracture will remain stable, splinted by the periosteum.

Open reduction of fractures

Exposure of a fracture should allow adequate access to see as much of the fracture as necessary while minimising damage to soft tissues. It should also minimise damage to the periosteum, which will be providing the bulk of the blood supply to the broken bone fragments. If that blood supply is lost then the fracture cannot unite. The incision will have to take into account any wounds already present and should be extensile (able to be extended if necessary). If a plate is to be put on the bone the incision should be planned to enable the plate to be put on the side of the bone which will be in tension. If there is skin and soft-tissue loss then incisions should be planned with a plastic surgeon to ensure that skin and soft-tissue cover of the bone and fixation can be obtained at the end of the operation. Fractures which are contaminated and those which are open (which must be treated as contaminated) are an emergency, but not a life-threatening one. Every hour that goes by increases the risk of the fracture becoming infected, so surgery needs to be performed as soon as the anaesthetist feels that it is safe.
Principles of holding fracture

There are two main ways in which a fracture can be held which make a profound difference to the way in which the fracture heals. Rigid fixation blocks the normal callus formation of bone healing. The bone appears to be unaware that there is a fracture if there is no movement at the fracture site. As the bone undergoes normal physiological remodelling, the fracture cleft is gradually obliterated by new bone. This takes about a year. During that time the fixation must share the loads normally taken by the bone. Most implants fatigue under the repetitive load imposed by the human body, and will soon fail if the bone does not heal and take over its original function. Fracture healing is therefore a race against time: the bone must unite before the implant fails or the construct will collapse. Nonrigid fixation (such as plaster of Paris) allows limited movement and loading of the fracture site. The aim is to allow movement and load to stimulate callus formation without allowing the fracture to re-displace. This delicate balancing act depends on the quality of the fixation, the type of fracture and the compliance of the patient (Fig. 21.11)

Pathophysiology of fracture healing

When a bone breaks there is disruption of periosteum, cortical bone, trabecular bone and the blood vessels which run in the periosteum and the medulla. There is haemorrhage and immediate release of cytokines. This signals to cells locally that damage has occurred. These cytokines attract macrophages which start the cleaning-up process. They also attract undifferentiated stem cells which migrate in and start differentiating into fibroblasts and bone-producing cells. These stem cells probably come from the periosteum and the endosteum, and normally lie latent.

The haematoma around the fracture is invaded with small capillaries while the macrophages remove the haematoma itself. At the same time connective tissue is laid down. The connective tissue slowly organises.

This pattern of layers of organised tissue appears first as a collar arising from the periosteum close to the end of each broken bone. The collars appear to grow towards the collar on the other bone. Eventually, the spurs of callus meet and bridge the fracture site. They become increa-singly thick and strong and fibrocartilage stabilises the fracture. This period, which in the adult occurs over the first few weeks after the fracture, is described as the fracture becoming stickly. It may still be possible to angulate the fracture but it is no longer possible to translate the fracture (move it from side to side). Meanwhile, in the fracture cleft itself, osteoclasts continue to resorb haematoma and other dead tissue and to eat away the broken bone ends. This can result in the fracture becoming more obvious on X-ray over the first few weeks and can be mistaken for a fracture which were initially invisible (e.g. the scaphoid). The callus of fibrous cartilage around the fracture cleft becomes calcified and then ossified (so that it is visible on X-ray). Ossification starts at the bone ends but in the centre of the fracture cleft, where oxygen levels may be very low, cartilage may be laid down initially rather than bone. This cartilage is then replaced by bone (endochondral ossification). It is not clear whether the callus is derived from the haematoma or from the periosteum, but it is clear that movement stimulates the production of a callus.

While the fracture can no longer be angulated with normal loads, and its not painful to try, the fracture is said to be clinically united. On X-ray, when the strands of callus can be seen to be stretching continuously from one bone end to another, the fracture is said to be radiologically united. In either case is the fracture at full strength yet, but at this stage limited activity can be undertaken safely. Finally, the callus forms a fat cuff of woven bone from one bone end to the other. This callus is at least as strong as the bone around it because biomechanically it has widened the diameter of the tube and this confers extra strength. This stage is called consolidation.

Over the next months the woven bone is replaced by Haversian cortical bone which remodels over the following years.

Rigid immobilisation. If the fracture is rigidly immobilised with a plate there is no stimulus for callus formation. Macrophages remove the haematoma and the dead bone ends. The normal process of remodelling produced by osteoclasts tunnelling through the bone and osteoblasts laying down new bone in their wake gradually obliterate the fracture cleft and reconstitutes normal bone. This process is slow and even in a young patient may take up to a year. If the fixation of the fracture is not completely rigid then some callus will form rapidly, but the patient may be able to resume near-normal function because the fracture is held stable if not immobile by the fixation. This partial rigidity therefore offers the best of both worlds, with rapid biological healing combined with the benefits of early mobilisation of the patient.

Types of fixation

Fixation can be divided into external and internal. Implants which are fitted directly on to or put down the inside of the bone and are then covered with soft tissues and skin are classified as internal fixation. Those where the mechanical strength of the construct is outside the skin are defined as external fixation.

Types of internal fixation

Screws can be used to hold plates on to bone or can be used in their own right to hold bone fragments together. In orthopaedics, screws have been standardised to an agreed set of size and length. They are designed to fit in bone in a standardised fashion, and for cortical and the other for cancellous bone. The size of these threads and their pitch (the distance between each thread) is specifically designed to give the best possible grip in healthy human bone. The drills, which create the holes for these screws, are also standardised to allow as snug a fit of the screws as possible without putting undue load on the bone. ‘Taps’ are also supplied which cut the grooves in the bone to take the threads of the screws. Tables are available in every orthopaedic theatre to show which drill should be used for which screw.

Lagging

If a screw is to be used to compress two bone fragments together it is important that the thread of the screw should only grip the distal fragment in which the tip of the screw is embedded. As the screw is tightened the shoulder of the screw (the part that tapers in the under the head) presses down on the proximal fragment and compresses the two fragments together. If the thread of the screw engages with the proximal fragment the screw can actually hold the fragments apart. There are techniques used to ensure that the fragments are drawn together as the screw is tightened. First, a screw can be used which has no proximal thread, just a smooth shaft. This is known as a ‘lag’ screw. An alternative strategy is to use a fully threaded screw, but to drill the hole in the proximal fragment to a slightly larger size so that the screw threads cannot engage with the wall of the hole. This is called lagging the drill hole and serves the same purpose as using a lag screw (Fig. 21.12)

Plates

The plates come in several sizes, each designed to be used with a standard set of screws. They are designed to fit on to the curved surface of bone and to be held there by screws. The plates can be used for several purposes and there are specific plates designed for each function (Fig. 21.14)

Buttress plates. Buttress plates prevent one fragment of bone slipping on another. They are especially useful in oblique fractures in load-bearing bones where they will stabilise what is a very unstable fracture configuration.

Dynamic compression plates (DCP). Dynamic compression plates have oval screw holes in them with tapered walls. If the screw holes are drilled into the bone at one end of these holes (there are drill guides to assist in doing this) then the plate slides along the bone as the screw is tightened home. If the plate has already been firmly fixed to the other fragment then the slip can be used to compress the fragments of bone tightly together. This has the benefit of stabilising the construct by increasing the area of contact. It also appears to stimulate healing by loading the bone edges in close apposition.

Neutralisation plates. Neutralisation plates are used to prevent bone ends from being distracted. They can therefore be used to resist angular forces by being placed on the side of a bone which goes into tension when load is applied (the side that opens when the fracture bends). Plates with screws are excellent at resisting tension and this is how they are used in neutralisation. Plates have very little resistance to bending and should never be put on the side of the bone which is in compression and which will go into concave angulation when load is applied.

Wires

Wires are much less traumatic than plates and screws. They can be used temporarily to hold fragments reduced while plates and screws are applied. They can also be used to resist shear where loads are not great. They are especially useful in children’s fractures where plates and screws could damage the epiphyseal plate (Fig. 21.13). Wires can cross the growth plate without causing long-term effects, and if left protruding from the skin can be removed when the fracture is secure without the need for a further anesthetic.

Kapandji wires are a technique which can be used in frac-tures where impaction may have left a defect which leaves the fracture unstable when reduced. After the fracture has been disimpacted and reduced, wires are introduced into the fracture cleft on the side of the defect. As soon as the tip of the wire is in the medulla the wire...
is tilted so that its tip travels proximally and embeds on the inside of the far cortex. One or more wires placed in this way substitute for the missing cortex and work with the intact periosteum on the other side to create a stable reduction.

**Figure of eight wiring** allows a strong wire suture to be woven over the cortex of bone which is in tension. The con-struct is not prominent and so fits well subcutaneously and is commonly used on the olecranon and on the patella (Fig 21.14).

**Nails**

Intramedullary nails. Implants driven down the medulla of a long bone suffer from a significant mechanical disadvantage because they must be narrower than the bone into which they are introduced. Nevertheless, the medulla can provide a natural guide for the implant and introducing the nail into one end of the bone (under image intensifier control) minimises the risk of infection from opening the fracture, and preserves the periosteal blood supply. In recent years the scope of intramedullary nails has been increased enormously by the introduction of the locking nail. This system has holes through the nail in the intercalated region. Using jigs or an image intensifier, screws can be passed through the bone, the hole in the nail and out through the opposite cortex of the bone. This produces a construct which holds the bone rigidly and is especially resistant to twisting. It allows an intramedullary nail to be used for a far greater range of long-bone fractures. Some of the newer nails can now be passed down the medulla without requiring any reaming in advance, the unreamed nails. This makes the operation quicker and reduces the trauma to the patient.

In summary, internal fixation can allow very accurate reduction of fractures under direct vision, and allows strong and stable fixation so that the patient can rapidly return to everyday activities with the minimum of inconvenience. The disadvantage is that the patient requires carefully planned and complex surgery which carries a risk of infection if sterile technique is not strictly adhered to.

**Disadvantages and complications of internal fixation**

The disadvantages of internal fixation are those of damage to soft tissues, especially blood supply. The rigidity of fixation slows the natural healing process, even though it allows earlier mobilisation of the patient. Internal fixation is technically demanding, requires a large range of implants and instruments, and is best performed in ultraclean theatres as infection is a disaster. Internal fixation requires careful pre-planning and the best surgery is performed if the fractures are drawn out on stencils first, and the problems of reduction and obtaining mechanical stability planned in advance. This includes size and type of plates, and position of screws. Only in this way can the operation be performed quickly and cleanly (minimising the risk of tissue damage and infection) so that the strongest fixation is obtained.

Internal fixation is best performed under a tourniquet, if possible, in order to obtain a blood-free view. There are complications inherent in using a tourniquet such as cuff damage to nerves as a result of inflow to an excessive pressure, and problems of reperfusion injury if the cuff is left up too long.

Exposure of the fracture may damage the soft-tissue attachments to the bone and produce avascular fragments, which will delay or even prevent fracture union.

Soft-tissue dissection should therefore be kept to a minimum, but must be adequate to obtain a clear view and access. All incisions should be designed so that they can be extended safely if necessary — *extensive exposure*.

The risk of infection can be minimised by cleaning out open fractures and leaving them open, with the fractures stabilised until it is certain that all dead and contaminated tissue has been removed. Only when they are clean should they be closed (delayed closure). When internal fixation is used infection is minimised by performing quick, tidy and well-planned surgery, and by adhering to strict theatre discipline on theatre sterility. Surgery should be covered by three doses of a broad-spectrum antibiotic which has good activity against *Staphylococcus* (the commonest infective organism) and *Streptococcus* (the second most common).

Internal fixation can also leave unsightly scars, and these should be planned to minimise cosmetic deformity without compromising access.

Drills and screws can damage nerves and vessels. Drill guards should always be used to prevent soft tissues being inadvertently dragged into a spinning drill. When the drill is cutting into the far cortex the hand that the surgeon is using to hold the drill should have a straight finger resting on the limb through which the drill is passing, and only light pressure should be applied to the drill so that when the drill then comes out through the far cortex it will not suddenly pene-trate deep into the soft tissues on the far side of the bone, where it might perforate a nerve or vessel.

**Removal of internal fixation**

Implants for internal fixation are made of surgical-grade stainless steel and should not corrode. Nevertheless, the alloys contain transitional metals such as chromium and vanadium whose salts are allergic, toxic and may even be carcinogenic. Despite this, there is little evidence that metal-ware left in patients for long periods causes any chemical or even allergic problems. Children should have metalware removed if it is likely to compromise growth. It should be removed as early as possible because peristeal bone grows rapidly over the plates and makes their removal difficult. Internal fixation also shields the bone around it from load, and so may cause local osteoporosis. The load passing down the bone may then peak at the end of a plate (a stress raiser) and cause a fracture. Internal fixation of a fracture next to an old plate already embedded in the bone is very difficult to manage. Despite this, it is now normal practice to leave plates and even intramedullary nails in the patient unless there is a specific reason why they should be given another anaesthetic and he subjected to a further operation to remove them.

**External fixators**

An alternative way to holding a fracture is to insert pins and wires into the bone on each side of the fracture, and to attach these to an external frame which provides the structural integrity. Fixators can be as simple as a set of pins incorporated into a plaster through single- and double-bar fixators, to ring fixators holding the bone subcutaneously and is commonly used on the olecranon and on the patella (Fig 21.14). There is a trade-off between cost, ease of fitting, adjustability, rigidity and convenience to the patient (Table 21.9) The choice of fixator will depend on what is available and the use to which it is to be put.

**Uses of an external fixator**

**Emergency use of the external fixator**

Fixators are used for two main reasons in an emergency.

Pelvis. They can be used to stabilise an unstable pelvic fracture to try to reduce life-threatening haemorrhage from the pelvic veins. Closing and stabilising an open pelvis fracture may reduce bleeding by reducing movement of the pelvic veins. This may stabilise clots and reduce haemorrhage. Closing the pelvis may increase the intrapelvic pressure and tamponade the veins to reduce bleeding. A bar fixator attached to pins inserted into the pelvic wings will need to be used. The bar should be set as low as possible to give enough room over the abdomen should a laparotomy be needed.

Neurovascular compromise. If a limb has an unstable fracture and has lost its blood supply the skeleton needs to be stabilised before the vascular repair can be performed. One option is to insert a stent and provide a temporary blood supply to the limb while a definitive orthopedic fixation is performed. An alternative is to use an external fixator which can be applied quickly to stabilise the fracture so that the vascular surgeon can start work with the minimum of delay. The disadvantage of this approach is that an external fixator may not be the optimal way of stabilising that particular fracture, but once it has been applied the risk of infection from the pin tracks makes a conversion to a plate or an intramedullary nail potentially risky.

**Nonemergency use of the external fixator**

Soft tissue damage. If there is extensive damage to the soft tissues then it may not be possible to achieve good cover of the bone. If bone is contaminated and/or exposed internal fixation may not be advisable. Under these circumstances an external fixator may offer the best option. The position of the pins can be planned with the plastic surgeons to enable them to rotate flaps without the fixator or the pins getting in the way.

Leg shortening and correction of deformity. Over the last decade one of the great advances in orthopaedics has been the discovery that bones can be lengthened gradually — *callus-stasis*. Segments of bone can be moved across defects and, if the periosteum is left as intact as possible, new bone will be laid down in the defect —
In order for the pins of the fixator to be able to move through the soft tissues as the bones move they need to be very thin, and it is now routine to use wires which gain their rigidity by being tensioned on a ring (the Ilizarov technique). The key to the technique is to move the bone so slowly that new bone can be laid down in its track, but not so slowly that the bone unites and prevents any further distraction. The fixation pins must be positioned to avoid damaging vital structures as they carve through the soft tissues. Care must also be taken to avoid overstrectching nerves and vessels, and to avoid contractures caused by ligaments, tendons and muscles failing to extend in concert with the bone.

Determining union

Clinical union

A bone is clinically united when putting load on the fracture produces no detectable movement and no pain. The fracture site will not yet be as strong as the bone around it, but it is united.

Radiological union

This is not the same as clinical union. It occurs when the callus around the fracture can be seen to pass from one broken bone end to the other without a gap between. The fracture across the medulla of the bone may still be visible, but the callus around the bone is continuous. The bone should now be able to cope with normal loads, but will not be as strong as the bone around it. From a management point of view, it is the time when movement and loading of the limb should be increased to build up muscle power, mobility and proprioception. If the patient plays sport or works in a job involving heavy labour they should not return to this unless the bone is protected, or until the fracture has consolidated (Fig. 21.16).

Consolidation

Consolidation takes much longer than union, and is defined as the time when the process of fracture healing is complete and the strength of the bone has risen to normal levels or even beyond. The formation of callus around a fracture creates a strong cuff. The diameter of this cuff is greater than the diameter of the bone itself, and so a consolidated fracture can be stronger than the original bone (Fig. 21.17).

Restoring function

When a fracture occurs, there will be damage to soft tissues. Muscles may be bruised or torn. Ligaments may be ruptured, joints filled with blood, and nerves and blood vessels damaged. The original philosophy in orthopaedics was that the key to management of fractures was immobilisation, and of injury was rest. This has now all changed. Fractures are stabilised to allow mobilisation of the limb and the patient. Rigid fixation of the fractures actually inhibits callus formation and slows healing. However, stabilisation of the fractures allows the patient to start moving the soft tissues to promote healing and reduce stiffness. It also allows the patient to return to a normal independent life sooner. Physiotherapy is a key element in the rehabilitation of trauma cases. It:

- allows early mobilisation of the limb while ensuring that loads are not so excessive that the fixation will fail;
- provides instruction and advice to the patient on their own rehabilitation;
- builds the patient’s confidence;
- re-trains proprioception so that the feedback loops between sensors of joint position and tendon load start to co-ordinate with motor nerves serving the muscles.
Complications of limb injury

The complications of injuries can be divided into early and late, local and systemic, and those specific to certain methods of fixation (Table 21.6).

Early local

The key complication is the loss of circulation distal to the injury. A second commonly missed problem is degloving of the skin and subcutaneous fat, which lose their blood supply as they are torn from the deeper tissues. This injury is easy to miss, but if a careful check is made for loss of sensation and capillary filling, and there is a high coefficient of suspicion from the history, then appropriate action can be taken as soon as all of the dead tissue needs to be removed and skin cover is urgently needed. Compartment syndrome is a condition which develops if an injured muscle swells inside a compartment bounded by an inelastic fascia. The most common sites for this problem are the forearm and the muscle compartments surrounding the tibia and fibula. As the muscle swells the pressure within the compartment rises until it becomes so high that it actually cuts off the blood supply to the limb. If urgent action is not taken the muscle dies and scars up, producing Volkmann’s contracture ([Fig. 21.18]). An identical situation can be created if a dressing is put on too tight or if a complete plaster is applied to a limb without adequate padding, and before the limb has finished swelling. For the first few hours after trauma it is wise to put on only well-padded back-slab plasters and only complete them on the following day. If the fracture cannot be held without a close-fitting plaster it may be better to wait before carrying out the definitive reduction as the patient needs to be admitted to hospital and to be put under very close observation. The simplest test for developing compartment syndrome is severe pain on extending the digits distal to the injury. Loss of pulses and/or loss of sensation can be late and unreliable signs which should not be relied on. Measuring intracompartmental pressures with a wick catheter is also unreliable and should only be relied on if the patient is unconscious and no other technique is possible. If there is any suspicion that a compartment syndrome might be developing then all dressings should be removed, even if this means losing the fracture position. If this does not lead to an immediate improvement then the patient should be taken to theatre and a fasciotomy performed. The compartment should be opened from end to end and left open until the swelling has settled.

Fracture blisters

These are a side effect of the soft tissue trauma ([Fig. 21.19]). They are fragile and quickly burst, creating an open wound which is contaminated. They are a contraindication to internal fixation because of the risk of infection.

Swelling

Soft-tissue swelling is commonly associated with fractures. If it is severe it is a hindrance to open reduction and internal fixation (ORIF) because the swelling may make it impossible to close the wound at the end of operation. If severe swelling is expected (it is very common with ankle fractures) there is a short window within hours of the accident when surgery may be feasible, after that there may be a period of several days when surgery is impossible. During that time every effort should be made to reduce the swelling as quickly as possible. The techniques for reducing swelling are given by the acronym RICE: Rest, Ice, Compression and Elevation. Pneumatic stockings can pump away the swelling by intermittent compression. Elevation should be used with care if the circulation to the limb is already compromised.

Early systemic

The main complications arise secondary to hypovolaemic shock. The second problem is that injuries come in clusters, and so a careful search must be made for other injuries to the patient, including those to soft tissues and vital organs, such as the lungs.

Late local

Limbs that are injured tend not to be moved. In limbs that are not moved the joints become stiff, the muscles waste and the circulation deteriorates, so that the healing of the limb may be compromised.

Osteomyelitis

If wounds were not cleaned properly or surgery became contaminated the fracture may become infected. Once infection is established it can be very difficult to eradicate, in fact some would say that chronic osteomyelitis is never cured as it can break out again at any time.

The principles of management are to remove all dead and infected bone, then to try to achieve union with strong bone and adequate soft-tissue cover. The amount of bone that needs to be removed is always difficult to estimate and more than you had originally hoped.

Nonunion

Fractured bones which have lost their blood supply, either because of the energy involved at the time of injury or because of the handling of soft tissues at the time of surgery, may go on to atrophic nonunion. The bone ends become thin and point, and there is no sign of any attempt at union.

If the fracture moves too much then a hypertrophic nonunion may result (overabundant callus), but with a persisting fracture cleft held open by excessive movement at the fracture site. If the fracture unites in a bad position (malunion) the limb may look very ugly, but may also not work properly. If the radius and ulna unite in a poor position the forearm will lose all ability to pronate and supinate ([Fig. 21.20]). A common cause for malunion is a failure to supervise the healing of a fracture adequately. If protection is removed too soon, or the patient is not seen often enough, then the fracture may slip and then unite in a poor position. Avoid calling a patient back as an outpatient more than absolutely necessary, but while the fracture is still ununiting be sure that the next appointment occurs before union has occurred, so that if there is a slip there is time for a correction of reduction and to secure fixation. Intra-articular fractures which are not anatomically reduced will lead to rapid onset of osteoarthrosis. Accurate reduction can be difficult to obtain, especially if there is bone loss, and can be even more difficult to maintain until union has occurred if early movement of the limb is also a priority.

Late systemic

The late systemic complications can be divided into organic and psychiatric. The initial period of hypovolaemia, and even hypoxia, in polytrauma can lead to irreversible damage locally and systemically. The key to the management of these conditions is prevention. Early aggressive management of the trauma with oxygen and fluids should minimise the time and severity of the insult. If there has been a significant injury then there is a high risk of multorgan failure which is best managed on an intensive care unit. If there is an open wound with muscle necrosis and this dead tissue is not excised, there is a risk of infection including gas gangrene. Even if the dead tissue does not become infected, there will be a release of muscle degradation products into the bloodstream as the tissue revascularises. These products include myoglobin, which darkens the urine to a dark-brown colour, but also clogs the glomeruli, causing renal failure. The treatment once again is prevention. First, where possible, tissues should not be allow-ed to become ischaemic. Trapped limbs should be released as quickly as possible, and patients should be kept well oxygenated and well perfused. Dead muscle should be excised and wounds left open for further inspection and excision until cleared of all dead and contaminated tissues. The patient should be given plenty of fluids to maintain diuresis. It is thought that rapid flow of fluids through the kidneys may reduce the build-up of myoglobin and reduce the risk of renal failure.

Shocked lung

This condition develops in patients who have been involved in major trauma. Over the days after the trauma the patient’s oxygenation deteriorates despite adequate ventilation and perfusion. The lungs become stiffer and more difficult to ventilate, and chest X-ray shows diffuse clouding. The condition appears to be more likely to occur if the patient is severely hypovolaemic for long periods. This is yet another reason to aim for early aggressive rehydration.

Psychiatric disorders

Patients who survive a suicide attempt may remain deeply psychiatrically disturbed. As soon as they are conscious a psychiatric opinion needs to be sought. If when they start to be mobile they continue to want to take their lives special measures may need to be taken, especially if the orthopaedic wards are not on the ground floor. Patients who were not psychiatrically disturbed at the time of the accident may become depressed afterwards. This is especially true if the patient lost a close relative or friend in the accident, or if there are awkward questions over who was to blame. It can also occur if treatment takes some time, or the patient is severely scarred, requires an amputation or is left in continuous pain. The modern limb reconstruction techniques, involving multiple plastic and orthopaedic operations which are so-time-consuming and technically demanding, can leave a patient physically capable but a mental invalid. You should give careful consideration to the possibility that early amputation with rapid return to normal life in a well-fitting prosthesis could give a better result for a patient with a mangled limb than many months spent reconstructing a limb which could end up useless, painful and ugly.

Congenital abnormalities

Sprengel’s deformity

This is the most common congenital abnormality around the shoulder, and results from a failure of normal descent of the scapula. In the embryo, the scapula forms in the midcervical region, and then descends to its midthoracic position. With the Sprengel deformity, the scapula is high, small and rotated, and in approximately 50 per cent of cases the scapula is connected to the cervical spine by the omovertebral body, a fibrous or bony bar. In addition there may be other congenital deformities, which include rib abnormalities, scoliosis of the thoracic spine, or cervical spine abnormalities including the Klippel—Feil syndrome (congenital fusion of the cervical vertebrae) (Fig. 22.1).

Treatment

The major problem is usually cosmetic rather than functional, and this is particularly true for unilateral deformities. In these cases excision of the omovertebral body or superior angle is performed. Surgery is occasionally required to improve function, and in these circumstances more complex reconstructive procedures are carried out.
Acquired conditions

The painful shoulder

After back pain, shoulder pain is the second most common musculoskeletal problem seen by primary care physicians. The commonest causes of the painful shoulder in adults are disorders of the rotator cuff, particularly the supraspinatus tendon. Although conditions such as the painful arc syndrome, impingement, rotator cuff tears and cuff tear arthritis are often considered as separate conditions, in reality they are part of a spectrum of disorders of the supraspinatus tendon. Other causes of shoulder pain include calcific tendonitis, frozen shoulder and degenerative disease.

Disorders of the rotator cuff

In common with some other tendons of the body, the supraspinatus tendon has a relatively poor blood supply, and this can predispose to both degenerative changes and tearing of the tendon. The anterolateral portion of the tendon is initially affected and swelling of this portion may lead to impingement between the greater tuberosity of the humerus and the anterior acromion with its attached coraco-acromial (CA) ligament. This leads to pain, particularly on active abduction or flexion, and initially leads to a painful arc between 60-120degree.

Abnormalities of the bone occur, with hooking of the anterior acromion. These are probably secondary changes, rather than the primary cause of the pain, but surgical treatment is often directed against the acromion and the CA ligament.

History and examination

The patient is usually middle aged, and the initial symptoms may be due to a specific traumatic incident or a period of overuse of the arm, or there may be no precipitating events. The pain is activity related, particularly on overhead activities, such as reaching up to shelves or hair washing. Gardening and household activities often produce symptoms. Some patients complain of significant weakness, and this may indicate the presence of a rotator cuff tear.

On examination, there is often no local tenderness. Active movements may be limited, and usually reproduce the symptoms, which occur between 60-120degree of abduction and flexion (Fig. 22.2). There is usually much less pain on passive movements, and this confirms the mechanical nature of the pain. Weakness of both supraspinatus and infraspinatus may be demonstrated, and suggest the possibility of a tear in the cuff. Specific impingement tests have been described and help to confirm the diagnosis (Figs 22.3 and 22.4). Radiographs may be normal, but usually there are signs of subacromial sclerosis.

Subacromial injection of local anaesthetic and cortisone often leads to improvements in the symptoms and they are used for both diagnostic and therapeutic purposes. If the diagnosis is correct, the symptoms are usually improved. The benefit may only be short lived, but this is a valuable diagnostic aid. Improvement in symptoms occurs for a few weeks after the injection, but subsequent relapse commonly occurs.

Further investigations

A subacromial injection is the most useful diagnostic test, and this is easily performed in the out-patient clinic. Further investigations such as ultrasound and magnetic resonance imaging (MRI) are used to determine the presence of a tear of the rotator cuff if surgery is contemplated; they have little place in the diagnosis of impingement (Fig. 22.5).

Treatment

It is likely that most patients will settle with conservative treatment. The initial treatment is by cortisone injection, and this is repeated up to three times if there is prolonged relief of symptoms. Specific physiotherapy has a role, particularly in the early stages, but most patients who present to specialist clinics will only have a limited response. Surgery is eventually required in 50 per cent of these patients, and is indicated when symptoms, sufficient to limit activities, have been present for over a year. Decompression of the rotator cuff is carried out, either arthroscopically, or by an open procedure, with removal of the anterior overhang and division of the CA ligament. In addition, repair of a rotator cuff tear may be required. In the absence of a rotator cuff tear, the prognosis is good.

Rotator cuff tears

Patients with rotator cuff tears are usually slightly older than patients with impingement. Tearing of the supraspinatus muscles also starts at the front lateral edge of the tendon, and can progress posteriorly along the tendon, detaching it from the greater tuberosity. The tendon retracts medially leading to a U-shaped tear. The patient is usually unaware of the rotator cuff tearing, and large tears of several years’ duration may be present before the patient seeks medical attention (Fig. 22.6).

Small tears of the supraspinatus

These are very common and may be found in up to 20 per cent of the normal population, in the absence of any specific shoulder symptoms. The tear is usually less than 1 cm in length and, in the absence of significant pain, is not of a sufficient size to cause weakness of the shoulder.

Treatment of small tears. Treatment is dependent on the presence and severity of impingement symptoms. In the absence of symptoms, the tear can be left unrepaird, and the patient kept under review. Progression of the tear is an indication for repair. If impingement is a significant problem, decompression is carried out, and the tear can be repaired if appropriate.

Intermediate tears

Tears of 2—3 cm (as measured on ultrasound) are usually associated with symptoms of impingement or weakness of the shoulder, and these will often require decompression and repair of the supraspinatus. This can be carried out through a lateral Sabre-type incision. The tendon is mobilised, and then sutured into a bony trough created on the edge of the greater tuberosity, using osseous sutures. Results of repair are good for intermediate tears, but full recovery will take several months.

Large tears of the supraspinatus

These are often 5 cm or greater, and may extend into infraspinatus. They are usually associated with weakness of the shoulder, and abduction may be limited to 600, often with a characteristic bunching of the shoulder (Fig. 22.7). With massive tears of the rotator cuff, superior migration of the humeral head can occur, and this further impairs function. In addition, secondary osteoarthritis of the glenohumeral head may occur due to the resulting incongruity of the joint.

Treatment of large tears. If symptoms of impingement or weakness are sufficient, decompression and repair should be considered.
Unfortunately repair is not always possible as the medial edge of the tendon retracts, and it may be impossible to mobilise this to close the defect. Tendon grafts and synthetic meshes have been used to close this defect but the results are less than satisfactory. This is due to degeneration and disuse atrophy of the supraspinatus associated with a chronic tear, and although the gap may have been closed there is poor function from the repaired tissue.

In many patients with large tears, the predominant symptom is still pain rather than weakness and in these patients if the tear is irreparable by direct suture, simple decompression is carried out. Up to 80 per cent of these patients will have good relief of symptoms and improved function, despite the unrepaired rotator cuff tear.

**Acute tears of the rotator cuff**

Most tears of the supraspinatus are due to degeneration and, as discussed above, will be associated with impingement symptoms. Occasionally a large tear of the rotator cuff can result from trauma, in the absence of any previous shoulder symptoms. These patients present soon after the event with profound weakness and loss of function but minimal pain. On examination, there is marked restriction of abduction, usually to less than 90°, with a characteristic hunching of the shoulder. This is due to elevation and rotation of the scapula to attempt to aid abduction. Diagnosis is confirmed by ultrasound or MRI, and early exploration and repair is indicated. Unlike the large degenerate cuff tears the acute tear is usually repairable if surgery is carried out early. Often no decompression is necessary, as the front edge of the acromion is normal with no evidence of overhang. In middle-aged and elderly patients an acute cuff tear can occur after shoulder dislocation.

**Frozen shoulder**

This is a painful shoulder condition of unknown aetiology that affects the capsule of the shoulder. The rotator interval between supraspinatus and subscapularis is affected predominately. The disease most commonly affects females in their 50s, and is more common in diabetics and patients with heart or thyroid disease.

**History and examination**

The pain is often of sudden onset and may follow minor trauma. It is severe and often disturbs sleep, and fractures or joint infection may be considered in the differential diagnosis. In the early stages, the shoulder is difficult to examine owing to the pain, but as the disease progresses the range of motion is reduced, both actively and passively. Local tenderness is often felt anteriorly over the rotator interval. The pathognomonic sign of frozen shoulder is loss of external rotation and this differentiates it from rotator cuff disease. Plain X-rays exclude other intra-articular pathology.

**Clinical course**

The clinical course of frozen shoulder can be divided into three stages as follows.

- **Stage 1** — a *painful phase* — can last for 2—9 months. The shoulder becomes increasingly painful, especially at night, and the patient uses the arm less and less. The pain is often very severe, and may be unrelieved by simple analgesics.

- **Stage 2** — a *stiffening phase* — can last for 4—12 months and is associated with a gradual reduction in the range of movement of the shoulder. The pain usually resolves during this period, although there is commonly still an ache, especially at the extremes of the reduced range of movement.

- **Stage 3** — the *thawing phase* — lasts for a further 4—12 months and is associated with a gradual improvement in the range of motion.

The clinical course runs over a period of 1—3 years and usually resolves without any long-term sequelae.

**Treatment**

Often no treatment is required and the condition will usually resolve as described above. The range of motion may be slightly reduced compared with the unaffected side, but the vast majority of patients has no functional problems.

Treatment in the acute stage is pain relief. Corticosteroids may be tried but have variable effects. Active and passive mobilisation can be carried out if comfort allows but aggressive physiotherapy should be discouraged.

Surgery is usually reserved for prolonged stiffness affecting function but can also produce good pain relief in the acute stage. Surgical treatment has a limited place in management. Manipulation under anaesthetic may produce an increased range of motion. Arthroscopic distension of the joint with saline allows inspection of the shoulder before treatment. If these measures fail to produce any benefit, open release of the rotator interval can be carried out through an anterior approach.

**Calcific tendonitis**

This is a common disorder of unknown aetiology which results in an acutely painful shoulder. Calcium is deposited within the supraspinatus, and it is thought that this may be part of a degenerative process. The differential diagnosis includes frozen shoulder, with both conditions occurring most commonly in middle-aged women.

**History and examination**

This pain is usually of rapid onset, often with no precipitating cause. In common with impingement, the pain is felt on the anterolateral aspect of the shoulder and is worse with activities, particularly overhead activities. The pain can be very severe and usually disturbs sleep. On examination, the shoulder is tender anterolaterally, and there is often some restriction of active and commonly passive motion. External rotation will be possible and this differentiates the condition from frozen shoulder.

The calcific deposits can be seen on plain radiographs, lying within the supraspinatus tendon, inferior to the acromion and just medial to the tuberosity of the humerus. They can also be seen on ultrasound (Fig. 22.8).

**Treatment**

Simple analgesia should be tried together with physiotherapy, although specialist referral is commonly indicated. Calcific tendonitis usually
Rupture of the distal insertion of biceps is an uncommon condition that usually occurs in younger patients, particularly after a sporting injury. This condition is treated conservatively, and the patient can be reassured that the pain will ease and the power return, although this may take several months.

### Treatment

The patient usually complains of something giving, often when they are lifting. The arm is often bruised and when the patient flexes the elbow a lump is evident in the middle of the biceps. The lump is initially tender and power is diminished.

### History and examination

The pain is activity related and, unlike most causes of shoulder pain, it is well localised, with the patient pointing to the AC joint as the source of the pain. On examination, there is usually a bony abnormality, with prominence of the distal end of the clavicle. This may be tender and movement of the joint by depressing the clavicle whilst pushing up the humerus will reproduce the pain. Flexing and adducting the arm to place the hand behind the opposite shoulder will also produce pain. An intra-articular injection of local anaesthetic will confirm the joint as the site of the pain. If the symptoms are related to the inferior osteophytes, the pain is less well localised, and impingement signs and symptoms are present.

### Treatment

Intra-articular injection of corticosteroids will usually produce some benefit and a course of three injections may be tried. If medical management fails, then surgery may be appropriate. The distal 1/2 to 1 cm of the clavicle is excised by a direct approach, with good relief of the pain. If the symptoms are related to the inferior osteophytes, the pain is less well localised, and impingement signs and symptoms are present.

### Rupture of the biceps tendon

Rupture of the long head of biceps is a relatively common condition, occurring in middle age and in the elderly. The condition is closely related to rotator cuff disease and the tendon usually ruptures owing to chronic attrition. Although many patients present acutely, an asymptomatic biceps rupture is a relatively common finding during arthroscopy for rotator cuff surgery.

### History and examination

The patient usually complains of something giving, often when they are lifting. The arm is often bruised and when the patient flexes the elbow a lump is evident in the middle of the biceps. The lump is initially tender and power is diminished.

### Treatment

This condition is treated conservatively, and the patient can be reassured that the pain will ease and the power return, although this may take several months.

Rupture of the distal insertion of biceps is an uncommon condition that usually occurs in younger patients, particularly after a sporting injury.
Again pain and weakness are present but, unlike rupture of the long head, the weakness will not improve. Surgical repair is indicated.

**Instability of the glenohumeral joint**

Traumatic dislocation of the shoulder will be considered in the next section but recurrent instability is a common sequel of dislocation. Recurrent traumatic instability is age related, with over half of shoulder dislocations becoming recurrent in the under 25 year olds. In some patients, the shoulder may dislocate after relatively little force, and a further group of patients with shoulder instability may be able to dislocate the shoulder at will. The diagnosis is based on an accurate history and further investigations, other than plain radiographs, are not usually required.

**Classification**

There are many ways of classifying shoulder instability, based on direction, the degree of violence required as well as considering subluxations and true dislocations. There is a spectrum of instability but, in general, three groups of patients can be considered as follows (Fig. 22.12).

Recurrent traumatic instability. This is predominately in one direction, most commonly anteroinferiorly. There is a definite traumatic event initially, although less violence is required subsequently. The patient is aware of apprehension on certain activities and sport may be made difficult. The shoulder may sublux or dislocate and often the dislocation has to be reduced in a medical facility. On examination, there is a full painless range of motion but apprehension on forced abduction and external rotation (Fig. 22.13). Other joints are usually normal. As discussed in the section on trauma, there is usually a Bankart defect with detachment of the anteroinferior glenoid labrum and damage to the humeral head (Fig. 22.14).

**Treatment.** Conservative treatment has little place and, if the instability causes functional difficulties, surgery is indicated. For anterior instability, repair of the Bankart defect, in addition to some tightening of the capsule, will produce good results in 90–95 per cent of patients. This is carried out through an anterior deltopectoral approach (Fig 22.15). For recurrent posterior instability (uncommon) tightening of the posterior capsule through a posterior approach is carried out.

Atraumatic instability. Although there may be an initiating event, this is often less traumatic, for example a fall climbing stairs rather than a sporting injury. In many cases there is no initial injury and the instability may occur in more than one direction. The shoulder usually subluxes rather than dislocates and the patient can often reduce the shoulder themselves. The subluxation is painful and the patient will not dislocate the shoulder at will. On examination, generalised ligament laxity is commonly present and the shoulder can often be subluxed inferiorly to produce a sulcus sign, with a lateral sulcus appearing beneath the acromion as the arm is pulled down. Apprehension tests are again positive but often in more than one direction.

**Treatment.** Physiotherapy, by an experienced therapist, should be tried first in these patients. As well as muscle strengthening re-education of the patient and shoulder is necessary, and specific muscle groups may need to be targeted.

Approximately half of the patients will require surgery and a capsular tightening procedure is carried out through an anterior approach. This is a successful procedure but there is a higher failure rate than with patients found to have a Bankart defect. Arthroscopic shrinkage of the capsule may have a place in these patients, and this is currently being evaluated.

**Habitual dislocation.**

This is a much smaller group of patients, but one which does not respond well to surgical treatment. The patient is able to sublux the shoulder at will and this is usually not painful (Fig. 22.15). There is underlying joint laxity, which is usually generalised, and there is rarely a significant traumatic event. The patient may sublux the shoulder as a ‘party trick’, or for emotional or psychological reasons.

**Treatment.**

It is vital that these patients are assessed and managed by an experienced therapist. The patient must be educated to avoid subluxing the shoulder and shown exercises as appropriate. Surgery is associated with a high failure rate and should be avoided.
Disorders of the elbow

Tennis elbow

Excluding traumatic conditions, this is the most common cause of pain around the elbow, and usually occurs in patients in their 30s—50s. The exact cause is unknown but the condition commonly follows a period of overactivity, particularly an unaccustomed activity that involves active extension and supination of the wrist. The tendon of extensor carpi radialis brevis is most commonly involved and, at exploration, a partial tear and chronic inflammatory tissue have been described.

History and examination

The patient complains of pain around the lateral epicondyle and in the back of the forearm. This is activity related and often a particular activity is implicated. There is not usually a history of trauma, but the patient may relate the onset to a period of unusual activity. On examination, the patient is locally tender, which is commonly just distal and anterior to the lateral epicondyle rather than the epicondyle itself. Forced palmar flexion and pronation against resistance reproduces the pain. The diagnosis is essentially a clinical one, although ultrasound and MRI may be indicated if there is any doubt.

Treatment

The prognosis is generally good. Many cases probably resolve without the need for any medical input, particularly if the precipitating activity can be avoided. Simple analgesia may be sufficient, but often a local injection of hydrocortisone is required. This can be repeated if there is some response, but repeated injections should be avoided. Physio-therapy, particularly local measures including ultrasound, can help, as can a tennis elbow splint, which is designed to alter the pull of the muscle. Surgery may be occasionally indicated and local excision of the abnormal tissue will produce good results in 70—80 per cent of patients.

Golfer’s elbow

This is less common and involves the flexor origin around the medial epicondyle. Ulnar nerve entrapment should be considered in the differential diagnosis and treatment is on similar lines. If medical treatment fails and surgery is being considered, further imaging such as ultrasound or MRI is appropriate to localise any abnormal tissue.

Arthritis of the elbow

Rheumatoid arthritis

The elbow is commonly involved in rheumatoid arthritis and can be a source of considerable discomfort and functional limitation. Medical management is initially tried but surgery is commonly required. If the elbow has good preservation of joint surfaces, then chemical synovectomy may be indicated, but again this is not commonly carried out in RA. If there is considerable pain and restriction of pronation and supination, rather than flexion and extension, radial head excision and synovectomy is appropriate. This produces good short-term improvement but there is a high relapse rate.

With end-stage disease, particularly with gross joint destruction, elbow arthroplasty is indicated. This is becoming more commonly performed and good results with 80—90 per cent of patients problem-free at 10 years (Fig. 22.16).

Osteoarthritis

Primary osteoarthritis of the elbow is rare and most cases of degenerative disease are due to previous trauma, osteochondritis dissecans or congenital problems such as epiphyseal dysplasia or radial head abnormalities. The patient is usually male, in their 40—60s and often works in a profession that requires heavy use of the upper limb. Pain is the chief complaint, although on examination there will usually be a 20-30 degrees fixed flexion deformity and limited supination. The history and examination should concentrate on differentiating the pain of a degenerate joint, which is activity related and predictable, from that of sudden unexpected pain and locking, which suggests loose bodies within the elbow (see below). In addition, ulnar nerve symptoms are more common in the arthritic elbow.

Treatment. Often no treatment is required other than reassurance about the nature of the condition. Osteoarthritic elbows seldom deteriorate rapidly and often the symptoms will improve after retirement. For the patient who is unable to carry out his normal activity, early retirement or a change of work is the best solution, as there is no satisfactory surgical procedure that will guarantee a return to a heavy manual job. Débridement is practised in the USA and will increase the range of motion; however, lack of movement is seldom a major complaint by the patient. Resurfacing arthroplasty using tendon or fascia has been tried but, in general, gives a less than satisfactory outcome. Joint replacement should not be carried out in a patient who wishes to return to heavy work but is indicated for severe pain and functional problems in a more sedentary patient. Arthrodesis of the elbow is rarely carried out.

In general, the results of elbow replacement for osteoarthritis are not as good as for RA. This may be related to the different lifestyles of the patients.

Loose bodies

After the knee, the elbow is the second most common site of symptomatic loose bodies. The most common cause is osteo-arthritis but in the younger patient osteochondritis dissecans is the usual cause. Most patients complain of sudden un-expected pain and locking of the elbow, and often they have to shake or manipulate the elbow to relieve it. Plain radiographs will confirm the diagnosis in 90 per cent of cases and further investigation is not necessary. Arthroscopic removal is indicated and, in the presence of mechanical symptoms, good results can be expected in most patients. In the absence of an appropriate history simple removal of loose bodies from a degenerate elbow will not result in any lasting benefit.

Osteochondritis dissecans

Osteochondritis dissecans is much less common in the elbow than the knee, and usually affects the capitellum. Teenage boys are usually affected and the condition is often related to sporting activities. The main symptoms are pain and swelling, and on examination there is a loss of full extension. Treatment is normally conservative with a rest from sport, but arthroscopy may be required if the fragment detaches and the patient develops mechanical symptoms suggestive of a loose body.

Olecranon bursitis
Inflammation of the olecranon bursa is relatively common. The elbow is often very red, warm, swollen and painful, and a septic arthritis may initially be suspected. The signs and symptoms are, however, confined to the back of the elbow (Fig. 22.17) and movement within an arc of 30°-130° is usually possible. The bursitis is usually chemical rather than infective, and management consists of rest, ice, anti-inflammatories and a compression dressing. If there is any suspicion of a penetrating wound, antibiotics should be administered but formal drainage of the bursa should be avoided, unless purulent material is present.

Chronic bursitis can occur and may be associated with small calcific nodules. In general these should not be removed and surgical excision of the bursa should be avoided if possible.

Ulnar nerve compression

This is the second commonest nerve entrapment after carpal tunnel syndrome. The most common sites of compression are around the elbow and there is a number of possible sites:

• the arcade of Struthers and the medial intermuscular septum — as the nerve passes into the posterior compartment of the distal humerus;
• medial epicondyle — particularly if osteophytes are present;
• cubital tunnel — as the nerve passes between the two heads of flexor carpi ulnaris (Fig. 22.18).

A nerve palsy may also be due to a flexion or a valgus deformity of the elbow.

History and examination

Unlike carpal tunnel syndrome, compression of the ulnar nerve may not be painful and the patient may present with weakness of the hand in association with paraesthesia. On examination a positive Tinel’s sign is usually present, particularly at the site of compression, and wasting and weakness of the intrinsic muscles of the hand are evident. Nerve conduction studies are usually carried out, unless the site of compression is obvious. In addition, plain radiographs of the elbow should be obtained, particularly if any deformity is present.

Treatment

Despite the absence of pain, decompression of the nerve should be carried out. The nerve can be explored through a medial or posterior approach. Opinion is divided on whether simple decompression is sufficient or whether there is a need for formal anterior transposition of the nerve. Transposition is usually necessary in cases of deformity, or if the nerve is unstable after decompression. For most other situations decompression without transposition is sufficient, provided all sites of possible compression have been explored.

Any paraesthesia should resolve but the prognosis for the return of hand power should be guarded as the recovery is unpredictable.

Compression of both the radial and median nerves at the elbow occurs but this is much less common than ulnar nerve compression (Fig. 22.19).
Infections of the upper limb

Osteomyelitis

Osteomyelitis of the upper limb is very uncommon in adults, unless there are specific predisposing factors such as penetrating wounds. As with other sites, staphylococci and streptococci are commonly implicated, although in the immunocompromised patient other organisms may be encountered. The treatment of osteomyelitis of the upper limb does not differ from other sites.

In children, osteomyelitis of the proximal humeral metaphysis can occur but this is much less common than osteomyelitis of the proximal femur or around the knee.

Septic arthritis

In both adults and children, septic arthritis of the shoulder or elbow is uncommon. Arthroscopy is preferred to formal arthrotomy for washing out the shoulder. The elbow may be washed out arthroscopically or via a lateral Kocher-type approach.

Tuberculosis

The shoulder and elbow are relatively uncommon sites for tuberculosis (TB) and treatment is along conventional lines. Secondary degeneration can occur and may be difficult to manage. A previously infected joint is one of the few indications for shoulder arthrodesis but the elbow presents a dilemma. Arthrodesis of the elbow is not a good procedure and there is little information on the outcome of other methods of treatment after previous TB.
Tumours of the upper limb

Tumours are unusual around the elbow but the proximal humerus is a relatively common site. It is the third most common site for both osteosarcomas and fibrosarcomas, after the distal femur and proximal tibia. Treatment is on conventional lines. The shoulder is the second most common peripheral site after the proximal femur for chondrosarcomas, and the scapula body is also a common site. The principal method of treatment for chondrosarcomas is surgical excision and this may be technically difficult around the shoulder. Subtotal excision of the scapula can be carried out with good preservation of function if the glenoid can be left. The humerus is also a relatively common site for lymphomas and Ewing’s tumour. Treatment is, again, along conventional lines.

Benign and intermediate tumours such as osteochondromas, giant cell tumours and aneurysmal bone cysts are also relatively common. The proximal humerus is the most common site for unicameral bone cysts, which are thought to represent an abnormality of cells of the growth plate. They commonly present as pathological fractures in children around the age of 10 and affect boys more commonly than girls. The lesion may resolve after fracturing but local medical treatment is often required (Fig. 22.20).

The humeral shaft is a common site for secondary deposits and intramedullary nailing may be required for pathological fracture or impending fracture. The majority of primary tumours is found in the breast or prostate, but secondary spread from the thyroid, lung, kidney and bowel can also occur.
Fractures of the upper limb in adults Introduction

Fractures of the upper limb are very common injuries in all age groups. In adults, between the ages of 15—49, these injuries are more common in males and are usually due to high-energy mechanisms such as road traffic accidents. Between the ages of 65 and 89 there is a considerable increase in the incidence of fractures, particularly in females. These are associated with osteoporosis and may follow minor trauma such as a fall from a standing height. Many of these injuries are relatively minor, for example clavicle fractures, which usually require no more than symptomatic treatment. Some injuries, such as displaced forearm fractures, require internal fixation but the final result is usually good. Some of the injuries, however, particularly complex fractures of the proximal humerus, often result in poor results despite aggressive management including primary joint replacement.

Specific injuries

Fractures of the clavicle

Fractures of the clavicle are very common, accounting for 5—10 per cent of all fractures. Males are more commonly affected than females (2.5:1) and, in males, the most common age group is the under 20s. The fracture is usually due to sporting injuries or road traffic accidents. In females the elderly are commonly affected, often following a simple fall. The fracture may be caused by direct trauma or indirectly such as a fall on the outstretched hand. The majority of fractures is closed injuries.

Most fractures occur in the midshaft of the bone and are often associated with overlap of the fragments. Fractures of the lateral end of the clavicle may result in superior displacement of bone if the coracoclavicular ligaments are involved. Fractures of the medial end of the clavicle are uncommon.

Treatment. The vast majority of clavicle fractures is treated conservatively with the limb rested in a broad arm sling. Mobilisation can be commenced as comfort allows, with a return to full activities within 3—6 weeks. Attempts at reduction, including bracing back the shoulders with a figure-of-eight bandage, are rarely necessary. Malunion is common but is not usually a functional problem. Nonunion may occur in up to 5 per cent of fractures and is more common after high-energy mechanisms such as road traffic accidents (Fig. 22.21).

Surgery. Open reduction and plate fixation are occasionally required and may be indicated for open fractures associated neurovascular injuries or fractures of the lateral end of the clavicle with significant displacement of the fragments. Internal fixation and bone grafting are indicated for symptomatic nonunions.

Acromioclavicular joint injuries

Disruption of the AC joint is a relatively common injury and is typically seen in young males. It is usually caused by trauma, commonly sporting injuries, and is associated with superior subluxation or dislocation of the lateral end of the clavicle (Fig. 22.22).

Classification.

• Type 1 — the capsule and coracoclavicular ligaments are damaged but not ruptured, and no subluxation of the joints occurs.
• Type 2 — the joint is subluxed, with some superior displacement of the clavicle; this is associated with increased damage to, but not rupture of, the ligaments.
• Type 3 — the ligaments are ruptured and the clavicle dislocates superiorly.
• Type 4 — the lateral end of the clavicle dislocates and lies subcutaneously due to severe soft tissue injury.
• Type 5 — the clavicle dislocates and lies posterior to the acromion (rare).
• Type 6 — the clavicle dislocates and lies inferior to the acromion (rare).

Treatment. Most injuries can be treated conservatively, with good results expected. A broad arm sling can be used, with mobilisation as comfort allows. In certain circumstances, early surgery may be indicated, especially for the less common type 4—6 injuries. Late reconstruction of the AC joint is occasionally required for persistent displacement of the clavicle associated with pain and functional impairment.

Scapular fractures

These are uncommon injuries and are usually caused by direct trauma, often due to road traffic accidents. Most can be treated conservatively. Internal fixation is indicated for some articular fractures of the glenoid.

A glenoid fracture usually represents a fracture dislocation of the shoulder. The size and displacement of the fragment must be assessed and this can be done by computerised tomography. Conservative treatment with immobilisation will be required for minimally displaced fractures, although rarely for more than 3 weeks. Indications for internal fixation, usually by a lag screw technique, include large displaced fragments and an unstable shoulder. Operative approach, method of fixation and postoperative mobilisation will be determined by the fracture pattern and fixation achieved at surgery.

Dislocation of the glenohumeral joint

Approximately 45 per cent of all joint dislocations in adults occur at the glenohumeral joint. Most dislocations occur anteriorly and result from a forced abduction/external rotation mechanism, often due to sporting injuries. The injury is therefore more common in males in the age group 21—30, although glenohumeral dislocation does occur in elderly females. In this age group rotator cuff damage may occur in association with the dislocation.

Dislocation is frequently associated with damage to the glenoid labrum and detachment of the anteroinferior segment, the Bankart lesion. In addition, damage to the back of the humeral head can occur as a Hill—Sachs lesion (Fig. 22.14). Both of these abnormalities predispose to recurrent dislocation. Less than 5 per cent of primary dislocations are posterior.

Treatment. The dislocation should be reduced as early as possible and this can usually be accomplished under sedation. There are three common methods of reduction dislocations. Following reduction, the arm is rested in a sling for approximately 1 week and mobilisation
commenced. Prolonged immobilisation, as previously recommended, does not seem to influence the recurrent dislocation rate.

Hippocratic method. The patient lies supine on a bed, although classically the patient lies on the ground. Traction is applied to the arm with the elbow extended and the arm is flexed and abducted at the shoulder. As traction is continuously applied, the humeral head is eased back into the joint by the surgeon’s stockinged foot.

Kocher’s method. Traction is applied to the arm, with the elbow flexed to 90°. The arm is slowly externally rotated, and then internally rotated and flexed across the body to reduce the shoulder. This may be modified by abducting as well as externally rotating the arm, and a collar and cuff bandage can be used to provide counter-traction over the humeral head. All these manoeuvres should be carried out gradually as spiral fractures of the humerus and brachial plexus injuries have been reported.

Hanging-arm method. This method may be tried without sedation. The patient is placed face down on a bed or bent over a chair. The arm is allowed to hang free, with the elbow extended; an intravenous fluid bag can be tied to the arm to provide traction.

Complications. Nerve palsy. Neurological dysfunction is common after shoulder dislocation and electrophysiological tests have revealed abnormalities in over half of the patients. Significant problems occur in approximately 5 per cent of patients, with the axillary nerve, or occasionally the supra-scapular nerve, involved. The majority of palsies recovers with conservative treatment.

Recurrent dislocation. This is age related and is usually due to the presence of a Bankart lesion. In the under 25s approximately 60 per cent will have further instability and approximately half of these will require surgery. Only 25 per cent of the over 34 age group will have further problems. Instability of the glenohumeral joint is considered in more detail in the previous section.

Posterior dislocation of the glenohumeral joint is much less common and has been associated with epilepsy and electrocution. The humeral head appears light-bulb shaped on anteroposterior radiographs, an appearance that is normally seen on a lateral or an axillary view. Reduction is achieved by applying traction to the abducted arm and then gently externally rotating the arm.

Proximal humeral fractures

Fractures of the proximal metaphysis of the humerus are one of the most common fractures in the elderly with a dramatic increase in incidence after the age of 60. They account for approximately 5—7 per cent of adult fractures and are most common in elderly females.

Classification of fractures. Proximal humeral fractures were classified by Neer in 1970 and this is still an accepted classification. Minimally displaced fractures are ignored, and the fractures are classified by anatomical location and the number of main fragments. The more severe injuries consist of four main parts: the shaft, the articular surface, together with separate, displaced greater and lesser tuberosities (Fig. 22.23).

Treatment. Treatment of these injuries is dependent on the severity and displacement of the fractures. The majority of fractures is minimally displaced and treated conservatively with good results expected. Two to three weeks of immobilisation in a sling is recommended. Displaced fractures, particularly in the younger patient, are treated by internal fixation with a plate and screws, multiple pins or an intra-medullary device; again good results can be anticipated.

The treatment of four-part fractures in the elderly osteoporotic patient is still unresolved owing to the unsatisfactory results with all methods of treatment. Conservative treatment can result in a stiff painful shoulder but operative treatment often results in the same outcome. A number of methods of fixation have been described including plates and screws, multiple wires, tension band wiring and intramedullary devices. Insecure fixation in the osteoporotic bone, together with difficulties in reattaching the tuberosities and sub-sequent rotator cuff problems, will produce poor results. Primary replacement of the humeral head, with a metal prosthesis, is frequently performed and was originally recommended by Neer for severe injuries. Unfortunately hemiarthroplasty is also frequently complicated by stiffness or rotator cuff problems.

Avulsion of the greater tuberosity

This fracture is included in the classification described by Neer but should also be considered separately. The injury is often associated with dislocation of the glenohumeral joint and represents a rotator cuff injury. The fracture may appear to be minimally displaced after reduction of the dislocation.

Treatment. Displaced fractures should be anatomically fixed with screws through a lateral approach. Undisplaced fractures may be treated conservatively but regular review, initially with weekly radiographs, is required. Malunited fractures will lead to impingement symptoms which do not respond as well to later decompression.

Humeral shaft fractures

These injuries account for approximately 3 per cent of adult fractures and are most common in patients in their 70s, usually as a result of a simple fall; approximately 80 per cent of the patients are female. A second, slightly smaller peak in incidence occurs in patients in their 20s. In this group 80 per cent of the patients are male and the injury is due to a road traffic accident or sport. The majority of humeral shaft fractures is closed injuries, with open fractures and associated injuries being more common in the younger age group (Fig. 22.24).

Treatment. The majority of humeral shaft fractures can be treated conservatively, particularly in the elderly, with good return of function anticipated. A sling or splintage is employed for 2—3 weeks, at which time mobilisation can be commenced. Hanging casts have been recommended, but can result in distraction of the fracture site and increased risk of nonunion.

Surgery. Operative treatment is indicated in patients with open fractures, associated vascular injuries and particularly in patients with multiple injuries. Open reduction and plate fixation is the most common method of stabilisation, although intramedullary nailing from either a proximal or distal entry point is commonly used. External fixation is occasionally indicated for associated severe soft tissue problems.

Complications. Nonunion. Up to 10 per cent of humeral fractures will be complicated by nonunion, particularly transverse fractures of the midshaft of the bone. Treatment is usually internal fixation and bone grafting of the nonunion site with subsequent healing in most cases.

Nerve palsy. Radial nerve palsy can also occur in up to 10 per cent of patients, with a wrist drop and loss of extension of the fingers. The majority will recover and therefore the injury is treated conservatively, with the patient managed with physiotherapy and a radial nerve splint. Up to 10 per cent of these patients will have no recovery of function and may require exploration of the nerve at about 3 months after the injury. Early exploration is indicated if the nerve is initially intact but dysfunction occurs after closed or open management.
**Distal humeral fractures**

These are the least common of the metaphyseal fractures of the upper limb, and commonly require internal fixation and early mobilisation to produce good results. As with clavicle fractures, the injury is more common in young males and is usually due to moderate to severe trauma. In the elderly distal humeral fractures are more common in females and again are usually due to mild or moderate trauma.

Anatomy and classification of fractures. The elbow consists of a medial and lateral column, with an articular surface at the distal end. The trochlea at the end of the medial column articulates with the ulna and contributes to flexion and extension at the elbow. The capitellum, the articular surface of the lateral column, articulates with the radial head and contributes to pronation and supination at the elbow.

Anatomically the fractures may involve the medial or the lateral column in isolation, with separation of the condyle from the rest of the humerus. These are relatively uncommon, accounting for only 5 per cent of elbow fractures in adults. The more complex injuries involve both columns, with complete separation of the articular surface from the diaphysis, together with a fracture through the articular surface. It is these T- or Y-shaped fractures that can be particularly difficult to treat.

**Treatment.** Minimally displaced fractures can be treated conservatively with splintage followed by gentle mobilisation as comfort allows. In adults immobilisation of the elbow for longer than 2—3 weeks should be avoided as stiffness and functional restriction can occur. This is particularly true for complex injuries, or following operative management of the fractures.

For displaced fractures internal fixation is recommended for all age groups; stable fixation with plates and/or screws should be used to allow early mobilisation. Single column fractures can usually be stabilised through a limited approach but the complex T- or Y-fractures require a wide exposure of the joint to ensure accurate reduction, and usually two plates are necessary for stable fixation to the humeral shaft. In order to gain the necessary access, osteotomy of the ulna is usually required and these injuries require surgical skill and experience to achieve good results.

In the elderly osteoporotic patient, especially with very distal fractures, stable internal fixation is not possible. In these patients primary elbow replacement has been carried out with good results. This avoids the need for an osteotomy, with its risk of nonunion and implant problems, and allows immediate mobilisation of the elbow.

**Radial head fractures**

These are relatively common fractures; the majority occurs in females, in the age group 20—50, after a fall on the outstretched hand.

Approximately 40 per cent of fractures are undisplaced, involving only part of the articular surface. In a further 40 per cent a fragment of the radial head is displaced, with depression of the articular surface. The remainder of the fractures involves all of the articular surface, either as a single fragment with a fracture of the radial neck or as a comminuted fracture of the radial head.

Some fractures are not visible on plain radiographs, although evidence of an effusion can often be seen. This injury should be suspected in patients with a typical history, pain over the radial head and restricted movement of the elbow.

**Classification.** A number of classifications has been described but one of the most commonly used is that described by Mason (Fig. 22.25):

- **type 1** — undisplaced partial articular (marginal) fractures;
- **type 2** — displaced marginal fractures;
- **type 3** — comminuted fractures of the radial head.

**Treatment.** Undisplaced fractures are treated by a temporary collar and cuff support, followed by early mobilisation. If the elbow is particularly painful, aspiration of the haemarthrosis can be carried out followed by intra-articular injection of local anaesthetic. Aspiration can be safely carried out through the centre of the triangle formed by the lateral epicondyle, radial head and the olecranon.

The treatment of displaced, partial articular fractures is dependent on the size and displacement of the fragment. Small fragments (<25 per cent of the articular surface) are treated conservatively, unless the range of motion is significantly restricted. In these circumstances aspiration of the joint and injection of local anaesthetic is carried out. If there is still a block to extension, and particularly full supination, exploration of the elbow via a lateral incision is indicated. Large fragments are treated by open reduction and internal fixation with small screws if possible; smaller fragments can be excised.

More complex injuries are treated by internal fixation, although this may not be possible if significant comminution is present. In these circumstances excision of the radial head can be carried out. If, however, there is any damage to the collateral ligaments of the elbow or the intraosseous membrane of the forearm, prosthetic replacement may be indicated. This is seen in patients sustaining high-energy injuries, such as road traffic accidents or falls from a height. In these patients radiographs of the entire forearm including wrist should be obtained, and the distal examined carefully, both clinically and radiologically.

**Olecranon fractures**

These are common injuries and are usually due to indirect trauma such as a fall on the outstretched hand. The injury is

(c) A grossly displaced fracture of the radial head and neck.

essentially an avulsion fracture due to the pull of the triceps muscle. Most fractures are intra-articular, although extra-articular fractures do occur with a small bony fragment avulsed (Fig. 22.26).

**Classification.** A number of classifications has been described but the main factors that determine the treatment are the location and displacement of the fracture, and the number of fragments.

**Treatment.** Undisplaced fractures can be treated conservatively, but late displacement can occur and regular review is necessary. Most fractures are displaced and internal fixation is indicated. Extra-articular and two-part intra-articular fractures can be treated with a tension band wiring system, using a figure-of-eight wire and intramedullary wires or screws. Stable internal fixation should be achieved to allow early
mobilisation of the elbow. A tension band wire is not suitable for comminuted articular fractures or more distal fractures, and plate fixation is recommended.

The prognosis for this injury is good, with a full functional recovery expected. The metal is often prominent and can be troublesome. It can be removed, if necessary, after the fracture has healed.

Elbow dislocation

Approximately 20 per cent of all dislocations occur at the elbow and most occur in children and young adults. The elbow usually dislocates posteriorly and is due to axial loading on a slightly flexed elbow. Fractures of the distal humerus, radial head and coronoid may be associated with the injury (Fig. 22.27).

Treatment. The elbow should be reduced as soon as possible and this is usually accomplished by closed means. Traction is applied with the arm slightly flexed and the olecranon can usually be pushed over the distal humerus, reducing with a definite clunk. Postoperatively the arm is immobilised in a collar and cuff, and mobilisation commenced after 1 week. Prolonged immobilisation should be avoided as the elbow often becomes stiff.

Complications.

Instability. In most cases the elbow is stable after reduction but occasionally there is a tendency for the elbow to redislocate in extension. In these circumstances, after reduction, the elbow is managed in a cast brace preventing full extension initially. The extension block can be gradually reduced over 2—3 weeks. Late instability is rarely a problem after simple dislocation and is more usually associated with complex fracture dislocations.

Stiffness. Some loss of extension is not uncommon after elbow dislocation but is rarely a functional problem unless the arm has been immobilised for long periods.

Forearm fractures

These account for approximately 5 per cent of adult fractures and the majority occur in young adults as a result of moderate to severe trauma. In contrast to many other fractures, these are unusual in the more elderly osteoporotic patient.

Most of these fractures involve both bones and result from indirect trauma. Single bone injuries can occur and are usually caused by direct violence, such as a blow with a stick. Single bone fractures can also occur in association with a joint injury of the other forearm bone, and this injury must be considered. Radiographs of the elbow and wrist joints should be obtained in all forearm fractures.

Treatment. The vast majority of these fractures is displaced, and open reduction and internal fixation with plates is indicated. Both bones are usually plated, through separate incisions, with early postoperative mobilisation. Conservative treatment is not usually recommended as rotation at the fracture site is difficult to correct or control in plaster. Full functional recovery can be expected in these patients. The forearm plates, particularly the radial, should not be removed unless there are specific indications, as a high complication rate has been reported.

Specific injuries. Montalgia fractures. Proximal ulna fractures may be associated with dislocation of the radial head but these account for only 1 per cent of forearm fractures. If the ulna fracture is reduced accurately, the radial head usually reduces and no specific treatment is necessary (Fig. 22.28).

Galeazzi fractures. Again these are relatively uncommon and consist of a distal radial fracture with disruption of the distal radio-ulnar joint.

Open reduction of the distal radius is carried out and the reduction of the distal ulna confirmed. If this is unstable, immobilisation in supination or even cross pinning to the radius is carried out.
Fractures and dislocations of the upper limb in children

Introduction

It must be realised that children are not merely small adults, and this is particularly true with fractures and dislocation of the upper limb. Although superficially the injuries may appear to be the same, the pattern and prognosis of the injuries are often very different. Fractures of the proximal humerus in adults are a major problem; they are often complicated by nonunion, avascular necrosis and a poor functional outcome, and the patient may require joint replacement. In children the fracture usually represents an epiphyseal injury and the prognosis is very good, often without treatment, despite significant angulation at the fracture site. Shoulder dislocation, a common adult condition, is very uncommon in children. Apparent dislocations in children are often due to epiphyseal fractures and again may not require treatment. It is therefore necessary to be aware of the ossification centres of the upper limb when dealing with these injuries.

Ossification

A large part of the body of the scapula is ossified at birth. A secondary ossification centre appears in the coracoid during the first year and fuses by about the 15th year. The acromion usually develops two ossification centres, with all ossification centres fused by about the age of 20. These may be confused with fractures on radiographs or predispose to epiphyseal separation. Failure of fusion of the acromion resulting in an os acromiale occurs in about 5 per cent of the population, although there is a number of different reports of the incidence in the literature.

The clavicle develops two ossification centres around the fifth to sixth week of foetal life. These fuse within a few weeks of their appearance; failure of this may produce a congenital pseudoarthrosis of the clavicle. A secondary ossification centre appears in the medial end of the clavicle in the late teens. An epiphyseal injury may occur before the appearance of this ossification centre giving the appearance of a sternoclavicular dislocation. This epiphysis fuses by about the age of 25. The lateral end occasionally develops a secondary ossification centre at the age of 18—20. This is usually small and rapidly fuses to the shaft.

The shaft of the humerus is evident at birth, with the head appearing by about 6 months. The greater and lesser tuberosities appear around the age of 2 and 5 years, and fuse by the age of about 6 to produce a conical growth plate. In children under the age of 6 fracture through this growth plate is usually a Salter and Harris type I injury, as before the tuberosities fuse the growth plate is more transverse. In the older child a Salter and Harris type II fracture occurs through the conical growth plate. The proximal growth plate accounts for 80 per cent of the humeral growth.

There are six ossification centres around the elbow and the usual order of appearance is shown below in Table 22.1, together with the approximate time of appearance. In general ossification centres appear earlier in females than males.

The shafts of both the radius and ulna are evident at birth.

General principles

With any childhood injury the possibility of child abuse must always be considered. In general this does not apply to injuries around the shoulder, as most of these injuries occur in those over 5 years old, an age at which child abuse resulting in fractures is uncommon. In the under 5 year old a proximal humerus fracture is rarely due to child abuse, although clavicle fractures especially in those under 18 months should be viewed with suspicion. Spiral fractures of the humerus in young children should also be considered as nonaccidental injuries, although distal humeral fractures and elbow fractures in general are usually not due to child abuse. If, however, the mechanism of injury does not fit the history given or there was a significant delay in presentation, then nonaccidental injury should be considered.

In a child of any age, an open fracture must be treated by operative debridement and stabilisation of the fracture site. In children, as in adults, polytrauma is a relative indication for surgical treatment.

Epidemiology

The risk of at least one fracture up to the age of 16 in a boy has been reported to be 42 per cent. In girls the quoted figure is 27 per cent. Of these, fractures of the distal forearm are the most common, accounting for about 20 per cent of the total. Fractures of the clavicle accounted for 8 per cent, the fourth most common site of fracture in children, with the midshaft of the forearm and the supracondylar region of the humerus both causing about 3 per cent of the fractures. The proximal humerus accounted for 2 per cent, and other fractures around the shoulder accounted for less than 1 per cent of all childhood fractures.
Specific injuries

Sternoclavicular joint
Dislocations of this joint are rare in children and most apparent dislocations, even in adults up to the age of about 25, represent epiphyseal separations. True dislocations and epiphyseal injuries can be manipulated and are often stable, even if unstable fixation of these injuries should be avoided. Internal fixation may damage nearby structures with disastrous results, and wires should be avoided as migration into the chest has been reported. Rapid healing and remodelling will occur. Posterior displacement may be a surgical emergency if vital structures are compromised.

Fractures of the clavicle
Fractures of the medial end of the clavicle are considered above.

Fractures of the shaft of the clavicle account for the majority of clavicle fractures. Many are caused by a fall on the outstretched hand; a bicycle, climbing frame, or bunk bed is commonly involved. Green-stick fractures commonly occur and may be missed on initial radiographs. Temporary rest in a sling for a short period is all that is required for most of these fractures. Displaced fractures of the clavicle are very common but rarely require reduction. In many countries, including many American centres, attempts are made to reduce the displacement with a figure-of-eight bandage to retract the scapula. To be effective this has to be tight, often uncomfortably tight, and needs constant adjustment. A broad arm sling for 2—3 weeks until comfortable is all that is required. Malunion is very common but rarely a functional problem; nonunion is very uncommon in children. Relatives can be reassured that the prominent callus will usually resolve over the subsequent months.

Open reduction and fixation with wires or a plate may be occasionally required. The indications are similar to those in the adult; open fracture, skin compromise, vascular injury, etc.

Fractures of the lateral end of the clavicle may also be confused with joint dislocations, as discussed below.

Acromioclavicular joint
True dislocations of this joint are unusual in children, especially in the younger child. The ligaments around the joint are very strong and often the lateral end of the clavicle will fracture, although this may not be apparent on radiographs if ossified. Even with true dislocations the inferior periosteum may be left behind with the conoid and trapezoid ligaments intact. These will heal and remodel with conservative treatment, with a sling for comfort followed by early mobilisation.

Scapular fractures
In children as in adults fractures of the body of the scapula are uncommon injuries and usually represent direct violence. The significance of this injury is the likely injury to the chest wall and possible pulmonary contusion rather than the scapula fracture itself. These injuries will almost always be treated conservatively with analgesia and a sling for comfort. The arm should be mobilised as comfort allows.

Fractures of the lateral end of the scapula are also very uncommon injuries in children.

Dislocation of the glenohumeral joint
Shoulder dislocation in children is unusual except in the adolescent as the ligaments are stronger than the epiphysis; usually a Salter and Harris fracture of the proximal humerus will occur. In adolescents as in adults, glenohumeral dislocation is commonly due to a sporting injury and is nearly always an anterior dislocation. Treatment is along adult lines with early closed reduction using standard techniques. The redislocation rate is age related and is higher in the child or adolescent, with a recurrent dislocation rate of 70—80 per cent reported in the age group 12—16. Approximately 50 per cent of these patients require a stabilisation procedure. Atraumatic dislocations can occur in children with joint laxity or connective tissue disorders.

Proximal humerus
Fractures of the proximal humerus usually occur in the older child or adolescent. Not only are accidents more common at this age but the perichondral ring may be weaker just before skeletal maturity. The majority of injuries occurs through the growth plate; Salter and Harris type II in the older child and type I in the younger child. In the younger child, child abuse should be considered, although humeral shaft fractures are more common in child abuse. Salter and Harris type III and IV are very uncommon injuries of the proximal humerus.

Fracture displacement is common and is due to the pull of the pectoralis major attaching to the distal fragment which tends to pull it anteriorly and medially. Although residual shortening is common, the majority of patients will have satisfactory functional results. It has also been reported that manipulation of a displaced fresh fracture did not improve the final outcome when humeral growth or function was assessed.

Treatment. Treatment therefore is generally conservative; not only because of the remodelling potential but also because of the malalignment that can be accepted around the shoulder generally. Forty-five degrees of angulation and 50 per cent of displacement can be accepted. In the younger child 70 per cent angulation and any bony contact should heal with good functional results. The fracture is usually treated in a collar and cuff sling, although rarely a hanging cast may be used in the older child with significant shortening or angulation.

If the position is unacceptable closed reduction is attempted and the fracture held with two or three wires. These wires can be removed after 3 weeks.

Open reduction may occasionally be required for soft tissue interposition often the biceps tendon and this can be achieved through a standard deltopectoral approach. Fracture stabilisation is carried out as described as above.

Metaphyseal fractures
This may occur with direct trauma or may occur as a pathological fracture, classically through a unicameral bone cyst. Displacement is not usually significant; angulation may occur but rarely produces a functional problem. The fractures usually heal rapidly with conservative treatment in a sling. The proximal humerus is the only common site for pathological fractures around the shoulder.

Humeral shaft fractures
These injuries are less common in children than in adults. The fracture is usually transverse or short oblique in pattern, and is due to direct
violence; an appropriate history should be available. Nonaccidental injury should always be considered with this injury, particularly in the younger child or with spiral fractures which are due to a twisting force.

**Treatment.** The vast majority of fracture can be treated conservatively with either a simple collar and cuff or a plaster U-slab. Union is usually rapid, particularly in the younger child, considerable remodelling can occur and so malunion rarely results in a functional problem. Nonunion is uncommon in children.

Internal fixation is occasionally required for open fractures, associated vascular injuries and the polytrauma patient.

**Supracondylar fractures of the humerus**

This is the most common fracture around the elbow in children and usually occurs in children under the age of 10. The injury is usually due to a fall on the outstretched hand with an extended elbow and this results in a hyperextension injury with posterior angulation, with or without posterior displacement of the distal fracture. Between 1 and 5 per cent of supracondylar fractures are caused by a flexion injury and associated with an anterior deformity.

**Radiological diagnosis.** Displaced fractures are readily diagnosed by plain radiographs but angulated fractures may be difficult to assess. Comparison views of the other elbow can be taken but a number of radiographic lines can be assessed on the injured elbow, as follows.

- *Capitellum angle.* The capitellum is normally angulated and displaced anteriorly to the humeral shaft. In the normal elbow, a line drawn through the centre of the capitellum joins a line drawn down the humeral shaft at an angle of 300.
  - **•** Anterior humeral line. A line drawn along the anterior cortex should pass through the central portion of the capitellum.
  - **•** Anterior coronoid line. A line drawn along the coronoid process of the ulna should just pass through the anterior portion of the capitellum.

All of the above lines are drawn on true lateral radiographs. In addition, on a true anteroposterior view, Bauman’s angle can be assessed. This is the angle formed between the growth plate of the capitellum and a line perpendicular to the humeral shaft. The normal angle is approximately 300 and can be used to assess the adequacy of reduction of a fracture (Fig 22.29).

**Classification.** As noted above supracondylar fractures can be divided into extension types and the much less common flexion types. Extension types are further subdivided into three types dependent on the angulation and displacement (Fig. 22.30).

- **Type 1.** The fractures are undisplaced but the radiographic lines should be carefully assessed to confirm this.
- **Type 2.** The fractures are angulated posteriorly, but the posterior periosteum remains intact, and prevent displacement and overlap of the fracture fragments.
- **Type 3.** The fractures are completely displaced with shortening and overlap of the fragments.

**Treatment.** Type 1 fractures can be treated conservatively in a collar and cuff, with 900 of flexion at the elbow. This is maintained for 2—3 weeks, with a check radiograph taken after 1 week. As with the initial film, the undisplaced nature of the fracture should be confirmed by plotting the appropriate lines.

- **Type 2** fractures should be treated by closed reduction if the position is unacceptable. Thirty degrees of extension can be accepted due to the remodelling that will occur in the younger child. Bauman’s angle should be corrected if there is any varus or valgus deformity as this will not remodel. Significant rotational deformity is uncommon with this type of fracture. Reduction is usually straightforward and the position can be maintained at the elbow at 900. Rarely wires may be required to hold an unstable reduction (Fig. 22.31).

- **Type 3 fractures** usually require reduction but this is often difficult and the fracture site is commonly unstable after reduction, with a significant rotational element. Under genera) anaesthetic traction is applied to the supinated forearm. The mediolateral displacement of the distal fragment is reduced by direct finger pressure and the carrying angle restored by comparison with the uninjured side. The extension element of the fracture is the last thing to be corrected by flexing the elbow maximally while applying posterior pressure to the distal fragment. The reduction should be confirmed radio-graphically, however the X-ray source rather than the arm should be moved to obtain the views. This avoids the risk of fracture displacement if the arm is rotated.

If the reduction is satisfactory, the position can be maintained by maximum flexion but this may cause vascular compromise, and loss of reduction may occur if the elbow extends. It has been recommended by a number of authors that the reduction should be held by two wires. Cross wires through both condyles may be used but care must be taken to avoid an ulnar nerve palsy, as the nerve may be difficult to locate in the swollen elbow. An open technique may be used on the medial side, or the wire may be inserted through an anterior starting point. Alternatively, two wires may be inserted from the lateral side but biomechanically this is not as strong a fixation.

Failure to obtain a reduction is an indication for open reduction but in the very swollen elbow, traction is a better option. This may be temporary, until the swelling reduces, but can be used as a definitive method of treatment. Traction may be applied using a bone crew inserted into the ulna, or by longitudinal skin traction. Surprisingly, the patient becomes relatively pain free very quickly (Fig. 22.32).

**Complications. Vascular injury.** Occlusion of the brachial artery is an uncommon but serious complication. Despite the absence of a radial pulse, the arm has a good collateral supply and will not necessarily become ischaemic. Both skin temperature and colour should be assessed, together with Doppler investigation of the pulse.

The treatment of vascular compromise is early reduction of the fracture under general anaesthetic. If the pulse returns the arm should be monitored carefully. Failure of circulatory return is an indication for exploration of the artery and fracture site, with open reduction and internal fixation with wires. An arteriogram may be obtained but should not be allowed to delay exploration.

**Neurological injury.** Transient neurological problems are relatively common after supracondylar fractures. The radial nerve is reported to be the most commonly affected, followed by the median nerve. Treatment is conservative for 3 months initially with good recovery expected.

**Volkman’s Ischaemic contracture.** Flexion contractures of the fingers and wrist are caused by fibrosis of the anterior compartment of the forearm due to a missed compartment syndrome. It can usually be prevented by avoiding immobility in excessive flexion of the elbow. If
greater than 900 of flexion is required to maintain a reduction, the reduction should be held by wires and the elbow extended.

Disproportionate pain in the forearm, particularly on passive extension of the fingers, should be treated by immediate release of all dressings, even if this compromises the reduction. If pain persists fasciotomy is indicated.

**Malunion.** Some degree of malunion is relatively common after supracondylar fracture. A flexion or extension deformity will remodel and observation is indicated. Varus malunion, with a gunstock deformity, is unsightly but is usually not a functional problem. Corrective osteotomies, if necessary, should probably be delayed until skeletal maturity. Valgus deformity may be associated with a tardy ulnar nerve palsy and may require treatment.

**Condylar and epicondylar fractures**

Lateral condyle. This is a relatively common injury and, after supracondylar fractures, is the second most common elbow fracture in children. It is usually due to a fall on the outstretched hand. Although this injury can occur in younger children the diagnosis is usually apparent on plain radiographs due to the early appearance of the ossification centre of the capitellum (see above) (Fig. 22.33).

**Classification.** Milch has classified this injury based on the location of the articular fracture. A type I fracture either passes through the ossification centre of the capitellum or just passes through the aspect of the trochlea. In either case the majority of the trochlea is intact and the elbow does not dislocate. In type II fractures the fracture line passes at or medial to the trochlear groove and the elbow joint may dislocate if the fracture displaces.

**Treatment.** Undisplaced fractures can be treated by immobilisation for approximately 3 weeks, but check radiographs are required. Most fractures are, however, displaced, and open reduction and internal fixation is required as closed reduction is seldom possible. Anatomical reduction is required and wires or screws can be used.

**Complications.** Nonunion occasionally occurs, often as a result of missed fractures or inadequate fixation. This may lead to a valgus deformity and tardy ulnar nerve palsy. Internal fixation and bone grafting can be utilised, either at presentation or at skeletal maturity.

Medial epicondyle. This is the third most common fracture around the elbow and is usually seen in older children. It is due to an avulsion injury and, despite the proximity of the ulnar nerve, it is rarely affected. Diagnosis can usually be made on plain radiographs, although, as with all children’s fractures, comparison views of the other side can be taken if there is any doubt (Fig. 22.34).

**Treatment.** Undisplaced fractures can be treated conservatively, with early mobilisation as comfort allows. Displaced fractures are usually internally fixed, especially if instability of the elbow is present.

**Other elbow fractures**

Fractures of the medial condyle, lateral epicondyle and intercondylar fractures are rare in children; treatment depends on displacement.

**Elbow dislocation**

This is an uncommon injury in children. As with adults the elbow usually dislocates posteriorly and radiographs should be studied carefully for associated fractures. Treatment is early reduction; instability is rarely a subsequent problem.

**Proximal radius fractures**

These are the fourth most common of the fractures around the elbow in children. They differ from the intra-articular radial head fractures seen in adults as, with children, the injury usually occurs through the epiphysis of the radial neck, and the articular surface displaces as a single piece. The injury usually results from a fall on the outstretched hand, although it can occur in association with a posterior dislocation of the elbow. This fracture usually occurs after the ossification centre of the proximal radius appears and so the diagnosis is readily made on plain radiographs.

**Treatment.** In common with many children’s fractures there is considerable potential for remodelling. Up to 300 of angulation can be accepted, provided there is growth remaining. These injuries can be treated with a simple sling followed by early mobilisation.

If angulation exceeds 300, manipulation under anaesthetic is carried out, which can be aided by the use of a percutaneous lever to push the radial head. For irreducible or completely displaced fractures (commonly seen after elbow dislocation) open reduction is carried out. This is usually supplemented by wire fixation, but wires should not be placed across the radiocapitate joint. These are removed after 2—3 weeks followed by mobilisation.

**Olcleanon fractures**

These are uncommon injuries and are often minimally displaced. For the occasional injury with significant displacement, open reaction and tension band wiring along adult lines is recommended.

**Fractures of the forearm bones**

Fractures of the radius and ulna are the most common fractures in children. The distal third of the bones is most commonly involved and the injury can occur in all age groups after the age of walking. Many injuries are green-stick fractures, often with angulation at the fracture site. Completely displaced fractures do occur and can be difficult to manage by closed means. The combination of a completely displaced distal radius fractures with a green-stick fracture of the distal ulna is also common and can be difficult to control in plaster.

**Aetiology.** In common with many injuries of the upper limb, forearm fractures are usually due to a fall on the outstretched hand. It is believed there is also a rotational element with forced supination. Diagnosis is readily made on plain radiographs, although a fracture line may not always be evident; in this situation the cortical bulge of the torus or buckle fracture can be seen.

**Treatment.** Many of these fractures are minimally displaced and can be treated conservatively with 2—4 weeks in plaster, depending on the age of the child. Fractures of the distal sixth of the forearm can be managed in a below-elbow plaster; more proximal fractures require the elbow to be immobilised.

Manipulation under anaesthetic should be considered if angulation of the fracture site exceeds 200. The age of the child and the potential for remodelling should be considered, as correction of up to 100 per year is possible. Although remodelling of an angulation of 30—40 degree is
possible in the younger child, parental pressure to correct the obvious deformity may be an indication for manipulation.

Displaced fractures can also be managed by manipulation, as a periosteal hinge often remains intact and can be used to hold the reduction. Failure to reduce the fracture is an indication for open reduction and internal fixation, usually with a plate; small two- to four-hole plates can be used in younger children. Instability of the fracture site after a satisfactory reduction, either at the original operation or at subsequent out-patient review, is an indication of a temporary thin wire to maintain reduction. Thin wires can be safely passed across the distal radial epiphysis, provided care is taken and repeated attempts are avoided. The wire is removed after 2—4 weeks.

One fracture pattern which is notorious for loss of reduction is a completely displaced fracture of the distal radius with an intact or green-stick fracture of the ulna; wiring of the radius at the initial operation should be considered.

**Complications. Malunion.** This is relatively common after closed reduction of a displaced fracture. Often, by the time the malreduction is diagnosed, the fracture is too sticky to allow remanipulation and the position has to be accepted. For fractures of the distal forearm with volar or dorsal angulation, considerable remodelling, as described above, can occur and the patient can be reassured. For malunions involving a rotation element, particularly with shortening of one bone, take down of the fracture site or osteotomy has to be considered.

**Refracture.** This is not an uncommon complication and usually occurs in the first few weeks after the plaster is removed. Although it may be due to inadequate immobilisation, the usual cause is a return to the original cause of the injury. Although a pathological process should considered it is not usually present and treatment should follow similar lines to a first-time injury.

**Compartment syndrome.** This is uncommon after a simple forearm fracture and severe pain is usually due to a tight dressing. All patients requiring a general anaesthetic for manipulation should be admitted overnight and the limb elevated. Severe pain should be treated by immediate splitting of the plaster and all dressings down to the skin. In the vast majority of cases this will provide immediate relief but a compartment syndrome should be considered if pain persists, particularly in patients with complicated injuries. Compartment syndrome is treated by fasciotomy, irrespective of the age of the child.

**Monteggia fracture**

This injury, characterised by a dislocation of the radial head at the elbow together with a (usually proximal) ulna fracture, is uncommon in children, accounting for less than 1 per cent of all forearm fractures. As in adults it is imperative that the joint above and the joint below a fracture should be visualised radiographically. With the forearm, if a fracture of only one bone is evident, the wrist and elbow joints must be examined and radiographs obtained.

In children this injury can often be managed by manipulation and immobilisation in an above-elbow plaster. Follow-up radiographs must be obtained as redisplacement can occur. If a reduction cannot be achieved open reduction and internal fixation is indicated.

**Galeazzi fracture**

In children this injury is also uncommon and often consists of a distal radius fracture with separation of the distal ulna epiphysis, rather than a true joint disruption. It often occurs in the older child and, as with proximal humeral fractures, may be due to a weakness of the perichondral ring. Closed reduction is usually possible with this injury.

Fractures of the pelvis

Fractures of the pelvis are relatively common in osteoporotic elderly patients. In this age group they are low-energy injuries and may, in fact, be pathological fractures. A careful check should be made for abnormalities which might suggest a benign lytic lesion or a metastatic tumour. In young patients, a pelvic fracture is associated with very high-energy accidents and carry a mortality of up to 20 per cent. This is because of the associated injuries. The pelvis is a stable ring, made up of bones and ligaments. If there is a displaced fracture of the pelvis then it must be broken in at least two places, and the ring is likely to be unstable. Unstable pelvic fractures carry a very poor prognosis because they are associated with torrential retroperitoneal bleeding from the pelvic veins. Immediate temporary stabilisation of the pelvic ring may be life-saving by helping the pelvic veins to clot off through tamponade, and by reducing the chance of movement displacing the clot. Pelvic fractures are also associated with damage to the rectum, the vagina and the urethra (especially in the male). A careful examination of all these structures should be performed in any patient with a significant pelvic fracture.

Classification of pelvic fractures

Fractures outside the ring

These fractures do not disrupt the structure of the ring and occur either following a direct blow or as a traction injury of an epiphysis. In fractures of the sacrum a careful check should be made for nerve damage as the sacral nerves are likely to be involved.

Fractures of the coccyx can occur when the patient falls on to their backside. The fracture is very painful but usually settles after a few weeks. If it does not, then treatment is very difficult as coccydynia (pain in the coccyx) seems to be associated with a neurotic personality. Neither injection of the fracture site with local anaesthetic and steroids nor excision of the coccyx reliably relieves the pain.

Traction injuries

The origin of rectus femoris can be avulsed when, for example, a patient kicks a heavy wet football. Similarly, in Fig. 23.1 the adductor tubercle can be avulsed if the leg is forcibly abducted. Both of these fractures settle with rest.

Fracture of the iliac wing

The iliac wing can be broken following direct trauma, or indeed when harvesting bone graft (Fig. 23.1). No active treatment is necessary.

Single fractures of the ring

These fractures are by definition undisplaced and commonly occur either through the pubic or ischial ramus (Fig. 23.2). They are common in the elderly following a fall and may be pathological, through a metastasis or even a lytic lesion created by hyperparathyroidism (Brown tumour).

Fractures in or around the acetabulum

A fall from a great height on to the feet or a direct blow to the greater trochanter can fracture the pelvis around the acetabulum. The femoral head can be driven centrally through the floor of the acetabulum into the pelvis (the central acetabular fracture) (Fig. 23.3). Alternatively, either the front wall (the anterior pillar) or the back wall (the posterior pillar) of the acetabulum can be fractured. In extreme cases a combination of these injuries occurs. A simple anteroposterior (AP) and lateral view of the pelvis does not reveal the true nature of the injury, and it is usual to take oblique X-rays which show more clearly the extent of the injury to the anterior and posterior pillar. Computerised tomography (CT) scans with three-dimensional reconstruction can give even further information about the nature and extent of the fracture, and the number and extent of displacement of the fragments. This information is important for planning the treatment. If there is damage to the posterior pillar of the acetabulum then a careful check must be made for damage to the sciatic nerve which runs close to the posterior pillar (Fig. 23.4).

Treatment. Fractures around the acetabulum can be treated nonoperatively with skeletal traction for 6—8 weeks. Although this method of treatment is uncomplicated and safe, the results are poor if there is a displaced intra-articular fracture.

Traumatic osteoarthritis of the hip is inevitable, and subsequent treatment with an arthrodesis or even a joint replacement will be required within a few years. This may, however, be the only option if the patient’s overall condition is so poor that major surgery is dangerous, or if the relevant surgical expertise is not available. The alternative is surgical reconstruction of the pelvis using plates bent to the contour of the surface of the pelvis and screws to stabilise fractures. This type of surgery is both difficult and complex, and carries a significant morbidity and mortality to the patient through blood loss and damage to the nerves around the pelvis. If, however, a stable congruent surface to the acetabulum can be recreated the prognosis to the patient is very good indeed.

Double fractures of the ring

Displaced fractures of the pelvis must by definition involve a fracture through two parts of the pelvic ring. It is not always possible to see the second fracture line as it may pass through the sacral iliac joint. These fractures are very high energy and are intrinsically unstable (Fig. 23.5). They are associated with a high mortality because of associated injuries and the massive retroperitoneal haemorrhage involved. Therefore for the reasons described above, they may need stabilising immediately with an external fixator to reduce haemorrhage when the patient is turned (Fig. 23.6).

They are also associated with damage to the nerves of the sacral plexus as well as injuries to the pelvic organs, particularly the male urethra.

Treatment. Initially these patients may be too sick to embark on a formal reduction and stabilisation of the pelvic ring (Fig. 23.7). The operation therefore may have to be delayed for up to 10 days. Beyond that the operation becomes difficult because callous formation prevents fracture reduction.
The hip

The hip is one of the 'bread-and-butter' joints in orthopedics, and provides a very substantial proportion of the total workload of an orthopaedic surgeon. In infants the problem of congenital dislocation of the hip is important because it is treatable if diagnosed early. The hip is also susceptible to septic arthritis, especially in the newborn (Table 23.1). In children, Perthes' disease, an avascular necrosis of the hip, poses a major therapeutic challenge. In the young adolescent slipped upper femoral epiphysis needs early diagnosis if problems are to be avoided for the rest of the child's life. In the young adult hip dysplasia may start to cause problems which will eventually go on to arthritis of the hip and which will pose severe problems for future hip replacement. In the elderly primary osteoarthritides of the hip is so common that, in Britain alone, over 50 000 total hip replacements are performed each year. Osteoporosis and problems of balance in the elderly also brings about a rapid rise in the incidence of fractured neck of femur. This, too, requires surgical treatment, providing the majority of major operations needed in trauma services.

Principles of history and examination of the hip

**Pain — localisation and radiation**

Patients find pain originating from the hip very difficult to localise. Children presenting at the clinic with a limp, a painful knee and a normal knee X-ray (King's triad) will usually be found to have a problem in the hip not the knee. Similar problems occur in the elderly, who may complain of pain down the front of the thigh and into the knee, when the diagnosis is osteoarthritis of the hip. However, pain originating from the back can radiate down into the buttocks into the greater trochanter. Examination of a patient complaining of pain in the hip needs to concentrate on determining whether this pain is arising from the spine, the knee or the hip itself.

**Disability — activities of daily living**

Patients with a stiff hip complain primarily of difficulty getting in and out of the bath and low chairs, as well as problems with getting socks and shoes on. The combination of pain and stiffness from osteoarthritis may also limit their walking distance.

**Deformity**

Problems in the hip lead to flexion and adduction of the joint. This leads to a tilt of the pelvis and a leg which appears to be shortened. The patient will therefore stoop and limp because of pain, weakness and deformity.

**Osteoarthritis**

Most osteoarthritis is called primary because there is no known preceding cause. There is a genetic effect, but the reason why some joints apparently last the lifetime of a patient while others disintegrate is not well understood. Secondary arthritis can occur following congenital subluxation of the hip, Perthes' disease secondary to trauma or an inflammatory arthritis such as rheumatoid (see Table 23.2).

**Prevention**

There is some evidence that young people involved in high-intensity sport and/or heavy-duty work are more susceptible to osteoarthritis later in life, but the affect is surprisingly small. Secondary osteoarthritis may be prevented by mini-missing the damage to the joints caused by the primary disease. In trauma articular fractures should be anatomically reduced. In inflammatory joint disease every effort should be made to reduce the level of inflammation.

**Treatment**

In the early stages osteoarthritis affects the patient in all three main areas of orthopaedic endeavour. It causes pain, disability and some deformity. It may also cause high levels of anxiety in the patient who may be worried that the condition is going to rapidly deteriorate and spread to other joints, destroying their quality of life. Many patients are resistant to taking tablets of any sort. There is no evidence that painkillers or anti-inflammatory drugs do anything but relieve the symptoms, and they may even accelerate the pathological changes. The key issue at this early stage for the quality of life of the patient is to maintain mobility and to avoid deformity. Physiotherapy should be used to show the patient how to keep joints mobile and muscles in good condition. The psychological benefit of this is also almost certainly important.

More severe osteoarthritis

As the condition becomes more severe regular analgesia may be needed. The use of centrally acting pain killers, such as paracetamol, combined with nonsteroidal anti-inflammatory drugs appears to provide a synergistic effect in terms of pain relief, but care must be taken to avoid gastric irritation and ulceration.

**Indications for joint replacement**

Indications for joint replacement are:

- pain;
- stiffness;
- loss of independence.

In the elderly, loss of independence through disability is a crucial issue. A painful stiff and deformed hip may prevent a person from sleeping, from doing up their shoes, from going out to do their shopping and even from using a car or a bus. This combined with chronic pain may convert a cheerful outgoing involved member of society into a depressed and isolated individual reliant on others for their needs. The cost to the individual and to society is out of all proportion to the pathological effect of the disease itself. A total hip replacement reverses this cycle. Combined with the judicious use of physiotherapy and occupational therapy, this gives the patient the confidence to return to an active independent life. In the patient over 65 years with a life expectancy of around 20 years, total hip replacement is the treatment of choice for osteoarthritis. In the younger patient the likelihood is that the joint replacement will not last the lifetime of the patient. They can be replaced (a revision operation) but this is technically difficult and the next operation does not last as long as the first. In younger patients secondary osteoarthritis is more common than primary and in these patients fitting the hip replacement securely in the abnormal anatomy may be much more difficult than in a simple elderly patient. The patient may also put greater loads on the hip. If a patient has a normal life expectancy, the younger the patient the more carefully alternatives to total hip replacement must be considered.
Rheumatoid arthritis

Total hip replacement in patients with rheumatoid arthritis is a successful operation. Perhaps this is because the patient has put very little load on the hip, but the relief of pain and the increase in mobility can have a dramatic effect on the quality of life of the patient.
Alternatives to total hip replacement

Juvenile chronic arthritis

In these patients the disability in other joints and the lack of demand that they make on the hip replacement makes it the treatment of choice despite their young age. Nevertheless, there are considerable technical difficulties; these patients have all the complications of long-term steroid therapy and the hip joint may be too small for normal implants because it was damaged with arthritis before it had fully developed.

Hip dysplasia

Patients with hip dysplasia may start to develop arthritis in their teens or early 20s. X-rays will show subluxation of the hip joint which rides up the deficient acetabular wall and there may already be signs of point loading on the edge of the acetabulum with osteoarthritis starting to form. The treatment of this condition is contentious but most surgeons would recommend some form of osteotomy to try to obtain better cover for the femoral head. The purpose is to spread the load of the hip joint over a larger articular surface, and so an osteotomy on the acetabular side is the preferred technique. The whole acetabulum can be detached from the rest of the pelvic ring and rotated so that an adequate roof is produced. The operation is technically very difficult to perform and there is a risk of causing complete avascular necrosis and chondrolysis of the acetabular cartilage.

An alternative is to cut through the ilium immediately above the acetabulum and to displace the acetabular inwards under this shelf, so creating a new roof for the acetabular. This operation too is difficult to perform and, given the rarity of the cases and the problems of finding matched controls, there is no evidence that this operation or any other for that matter makes any difference to the outcome of the hip. A third operation is to lift a wedge of bone on a proximally based cortical pedicle and create a roof by packing bone graft inside the wedge. This is the simplest of the operations but the least attractive from a biomechanical point of view. If these operations are successful and a new roof is created for the acetabulum in one way or another the secondary advantage of this type of surgery is that it makes total hip replacement in the future much easier. Otherwise there are great difficulties in setting the cup in the pelvis because there is no bony roof to provide support for it.

Hip dysplasia

Pelvic osteotomy

Pelvic osteotomy spreads the load and may make total hip replacement easier

Osteoarthrosis secondary to trauma in the young adult

Young, fit adults put a great load on the total hip replacement and will also have a life expectancy in excess of 30—40 years. They may be in severe pain and will push hard for a total hip replacement having heard of the marvelous results which can be obtained in the elderly. It is important to explain to them that the lifetime of the hip may be as little as 5 years in a young patient and that subsequent revisions are likely to have an even shorter life. The better option in the young fit patient is a hip arthrodesis. The operation, if successfully performed, will completely remove pain and produce a strong, stable hip. This should last their lifetime without further problems. It is even possible to unpick an arthrodesis and replace it with a total hip replacement if problems start in the other hip or in the knee below the arthrodesis. The disability of a successful hip arthrodesis is slight. The patient can walk and run, but can usually only climb ladders one step at a time. The stiff hip does not apparently interfere with the ability to have sexual intercourse or to have children, and the only time when it is particularly a problem is when sitting in a chair. Because the hip is only fused in slight flexion the patient may have to slump in a chair with the leg sticking out in front. This posture can appear very intimidating to fellow passengers in a bus if they are not aware of the reason for it. Technically, the arthrodesis can be difficult to perform, but with the advent of modern techniques (using cobra plates) and bone graft a secure arthrodesis should be obtainable. It is important to make sure that the hip is arthrodesed in a good position. The ideal is neutral or slight abduction with some 20-30 degree of flexion. It is all too easy to let the hip slip into adduction when there will be unnecessary relative shortening. If the hip is fixed in too much abduction then the leg is too long and it may be difficult to obtain adequate swing through. However, there will be some shortening from fixing the hip in a little flexion (to allow sitting) so a little abduction may compensate for that.

Hip arthrodesis

• Produces a painless hip
• Does not wear out
• Can be replaced with a total hip replacement later
• Ideal for a young active patient

Secondary osteoarthrosis in the older patient or in a patient who has a disease in other joints

Arthrodesis should not be considered in patients who already have back problems or who have arthritis in other joints. In these cases it increases the patient’s disability and may exacerbate the pain from osteoarthrosis in the other joints. An alternative in the older patient who is still too young for a total hip replacement is the femoral osteotomy.

The femur is divided in the intertrochanteric region and then fixed securely using a dynamic hip screw or a plate. It has been suggested that the cause of the deep pain in osteoarthrosis is venous hypertension, and that the osteotomy relieves this hypertension. This cannot be the only explanation as, radiologically, there may be a dramatic improvement in the joint surface with apparent regrowth of articular cartilage. One element of the osteotomy is to change the angle of the femoral head so that a new area of little worn articular cartilage can be brought to bear on the acetabulum.

If the osteotomy also shortens the femur slightly then the pelvis will dip down in compensation and in effect the acetabulum will give more cover to the femoral head and it too will bring a new area of articular cartilage into the load-bearing zone. Femoral osteotomy gives a variable relief of pain from osteoarthrosis, but it is reasonable to offer the patient up to 5 years of pain relief, and it may be much longer. There is nothing to stop a total hip replacement being performed after an osteotomy, so the advantage of using an osteotomy to buy time in a patient who is a little too young for a total hip replacement makes this a very attractive option. The operation needs to be planned carefully in advance with tracings made from the X-rays to decide exactly what type of wedge, if any, is to be taken out of the femur. If the femur is to be rotated as well then it is advisable to put pins into the femur either side of the osteotomy so that the angle of rotation can be carefully measured. The osteotomy is fixed with either a blade plate or with a dynamic hip screw. If the fixation is secure then the patient should be able to weight-bear partially using crutches immediately after surgery and can start full weight-bearing at 3 months.
Indications for osteotomy in hip arthritis

- Young patients not suitable for total hip replacement
- Problems in more than one joint not suitable for arthrodesis

Total hip replacement

Total hip replacement is the mainstay of treatment for osteoarthritis and rheumatoid arthritis of the hip, and for patients over the age of 65 years is the operation of first choice. In patients between the age of 55 and 65 years the pros and cons should be weighed up carefully against osteotomy. Below the age of 55 years total hip replacement should only be undertaken in exceptional circumstances and arthrodesis should be the treatment of choice.

Management of hip arthritis

- > 65 years — total hip replacement
- 55—65 years — osteotomy
- < 55 years — arthrodesis

Indications for surgery

The indications for an operation are primarily pain when it can no longer be controlled by using pain killers. A secondary indication is interference with mobility and quality of life.

Types of total hip replacement

There are nearly 100 different designs of total hip replacements currently on the market and in almost none of them is there an adequate long-term follow-up which a surgeon could use to decide which design to use (Fig. 23.8). Designs can be classified into some simple categories which are given in Table 23.3 (see also Fig. 23.9).

Methods of fixation

Traditionally, hip replacements were fixed into a bed of polymethyl methacrylate (PMMA) cement. The cement is a gushing agent, in other words it acts as a spacer between the implant and the irregularly shaped cavity into which it is being put. A powder of PMMA cement is mixed with the monomer which is itself quite toxic to both patient and staff. The two are mixed together until an exothermic reaction starts and the cement begins to set. This takes 5—7 minutes. The cement is then put into the cavity and the implant pushed in on top of the cement until it is properly bedded in. Over the next 10 minutes the cement sets, becoming quite hot as it does so. The cup is cemented into place first. The process is then repeated with the femoral component. As the cement sets, some of the methyl methacrylate polymer is released into the patients blood stream and can cause a drop in the patient’s blood pressure. The heat produced by the cement setting may cause a layer of bone necrosis around the cement and it has been suggested that this may lead to early loosening. If fragments of the cement break away and get into the joint they will act as an abrasive and cause third-body wear. This destroys the artificial joint surface and releases a large amount of debris, which then sets up an inflammatory reaction. If the cement around the implant breaks or becomes loose it too will release particles which stimulate an inflammatory response. This too can lead to resorption of bone around the implant. This is called aseptic loosening as there is no evidence that infection has any role in this type of loosening. In response to these findings surgeons have attempted to design implants which can be fixed into the bone without the use of PMMA cement. In dentistry there has been considerable success with bone bonding to implants made of titanium for osseous integration and those which are coated in a layer of hydroxyapatite ceramic. Unfortunately, in joint replacement surgery this success has not been reproduced. Implants designed for cementless implantation are much more expensive to manufacture and need to be fitted much more carefully is there is to be any chance of good binding between the bone and the implant. Once they have been implanted the load on the interface should be kept to a minimum until osseous integration has had a chance to take place. Unfortunately, if this ever occurs it is likely to take many months, and even if a patient does not weight-bear during that time the micromovement between implant and bone may prevent osseous integration. This is because the hip joint is a fulcrum to powerful muscles around the hip. Even lifting the leg up off the bed may produce loads through the hip joint of three or four times body weight. One further practical advantage of cementless joint replacement is that when these implants do come loose, they should be easier to change as there is no need to remove all the cement from inside the femoral canal. Unfortunately, this too is only a theoretical advantage. Cementless hip replacements which start loosening and become painful may, nevertheless, have small areas where osseous integration has occurred. This can make them quite as difficult to remove as a cemented implant. There is currently no evidence whatsoever to support the use of the more expensive and difficult to implant cementless implants, although hydroxyapatite coating looks promising.

Joint surfaces

The original total hip replacements designed by Charnley eventually used a joint surface of metal on high-density polyethylene. The coefficient friction between these two surfaces is far higher than articular cartilage, but because a small head size was used the actual force on the implants remained low. High-density polyethylene has good shock-absorbing properties but does wear slowly over the years producing small particles which can stimulate an inflammatory response in the joint. It is felt that this inflammatory response can, once again, be responsible for aseptic loosening. The macrophages actually start to resorb bone and may stimulate osteoclasts to do the same. There has therefore been a move towards using joints which do not produce wear particles. Ceramic femoral heads bearing on polythene cups have far lower friction, but ceramic femoral heads on ceramic acetabular cups have the lowest friction of all. They are, however, very difficult and very expensive to manufacture. Metal-on-metal implants should also have a low coefficient of friction and produce very few wear particles. These implants were frequently used in the early days of joint replacement but had a bad reputation for loosening. It is currently claimed that this was because they were not manufactured to a high enough tolerance, and that the surfaces were binding together, loosening the implant. There is as yet, however, no evidence that the newer metal-on-metal implants offer anything but theoretical advantages.

Head size

The original implants used a small head size of 22 mm to reduce friction (Fig. 23.10). This has the added advantage of allowing plenty of room inside the acetabulum for a thick polythene cup which has plenty of room for wear and which should have good shock-absorbing capabilities. The small head, however, does carry a theoretical higher risk of dislocation, because the diameter of the head is so small that a relatively small
displacement of the hip out of the socket allows it to dislocate. Biomechanical calculations show that the load on the polythene cup produced by a small head is close to the limits which can be tolerated by the polythene, and therefore recently manufacturers have been moving towards a larger size of femoral head. The disadvantage of this increased head size is that the friction increases and so the force on the interface between the acetabular cup and the bone will be increased. Theoretically, this will increase the chance of loosening.

Choice of implant

Currently, the best long-term results have been obtained with some of the older and cheaper cemented implants. In good hands these implants should give over 50 per cent of the patients a trouble-free joint for over 10 years. In younger patients the figures are not so good, and once a joint has been revised the lifetime of the second implant appears to be shorter. New designs (Fig. 23.11) should not be introduced on to the market without proper trials being performed. Surgeons should be able to explain to their patients who will be performing the operation, the published results of the design that they are using and the ongoing results of the design in their own hands.

Surgical technique

There are three commonly used approaches to total hip replacement. The fact that there are three suggests that there are advantages and disadvantages to each.

The anterolateral approach

The anterolateral approach has been popularised by many surgeons, particularly Hardinge. The patient can be positioned on the table either in the lateral position or supine with a sandbag under the buttock to raise it clear from the table. If the supine position is used then the patient needs to be placed as close to the edge of the table as possible as otherwise access is restricted. A 15-cm incision is centred over the greater trochanter curving 45° backwards above the greater trochanter and running straight down the line of the femur below the greater trochanter. Tensor fascia lata is divided over the greater trochanter and held apart with a self-retaining retractor. Gluteus medius is divided off the front of the greater trochanter, until the capsule is exposed. The fibres of gluteus medius are gently divided above the greater trochanter for a few centimetres (no further or the neurovascular bundle may be damaged). A sharp retractor can now be introduced over the capsule and the front of the femoral head into the anterior wall of the acetabulum, taking care not to damage the femoral nerve. The anterior capsule is divided removing as large an ellipse as possible but taking care, particularly inferiorly, not to cut blind into veins running in the soft tissue just outside the hip joint. The assistant now takes the patient’s leg, bending the knee at right angles, and dislocates the hip by external rotation. Great care should be taken not to use too much force during this manoeuvre as otherwise the femur will be fractured. If the hip cannot be dislocated safely then the femoral neck should be cut and then the femoral head removed using a bone screw in the same way as the femoral head is removed during surgery for a subcapital fractured neck of femur.

The trochanteric approach

This is an important approach because it gives excellent access to the hip, and is also a very useful approach for reconstruction of the pelvis after pelvic fracture. However, in all but expert hands realignment of the greater trochanter after surgery has given significant complications. Nonunion of the greater trochanter can be painful and weakens the hip considerably. The approach should only be used after careful training.

The patient can be placed supine on the table and a straight or curved incision made centred over the greater trochanter. Tensor fascia lata is divided along the lines of its fibres and the soft tissue cleaned off the lateral side of the femur and the greater trochanter. A Gigli saw is passed over the top of the femoral neck beneath the insertion of the abductors and the greater trochanter taken off with an oblique osteotomy continuing the line of the femoral neck across the femur. Some people insert a Steinmann pin into the lateral cortex of the femur to tent the Gigli saw so an oblique chevron-type osteotomy is performed. The hip can now be dislocated anteriorly. Before the femoral component is cemented into place wires are laid in place ready for reattachment of the greater trochanter.

The posterior approach to the hip

This approach is quick and easy. Access is good but there is an increased risk of posterior dislocation after surgery.

The patient is placed in the full lateral position and an incision is made centred over the greater trochanter with the upper arm curving backwards at 45° and the lower arm passing straight down the femur. Tensor fascia lata is divided along the line of its fibres and retracted. The hip is internally rotated by the assistant holding the lower leg. This exposes the short external rotators of the hip. The sciatic nerve runs over these muscles and should be identified and carefully retracted. The short external rotators are then divided on stay sutures and are folded back over the sciatic nerve to protect it. The capsule is now divided; a wide ellipse may be needed to be taken before the hip can be dislocated. Alternatively, an H-shaped incision can be made so that the capsule can be repaired once the hip replacement has been performed.

Performing the total hip replacement

The knee should be bent to 90° and a strawberry reamer pushed in along the line that the acetabular cup will occupy when it is placed in the acetabulum. Reaming should continue until the osteophytes around the central fovea have been removed. The size of the strawberry reamer should be increased until it is just gripping the edges of the old acetabulum. Reaming should be continued until all the articular cartilage has been removed and subchondral bone is exposed. Keyholes need to be drilled in the subchondral bone to provide extra support for the cement, avoiding the weight-bearing superolateral area. The keyholes do not need to be more than a couple of millimetres deep and should not broach the medial wall. They are therefore best placed into the anterior and posterior pillars. Choose the correct size of acetabular cup for the reamer that has been used so that a thin mantle of cement will lie all the way around the implant. Check that the acetabular cup when inserted will lie comfortably just inside the acetabulum and that its superolateral margin is bearing on the superolateral margin of the acetabulum when it is placed with 30-45° of cover and 10-20° of anteversion. The acetabulum should then be packed with a dry swab and the retractors removed.

The femur should now be rotated to expose the cancellous bone in the femoral neck and to deliver the femur up and out of the wound so that rasps can be inserted without touching the gluteal muscles or the skin. A sharp lever may need to be inserted under the greater trochanter to help this. Spoon out the medullary contents of the femur keeping the convex side of the spoon always facing the dorsum of the femur. This will prevent the spoon inadvertently being driven out through the lateral cortex of the femur. Clear out the cancellous bone, particularly in the
greater trochanter, until the spoon can be inserted straight down the femoral canal. Insert rasps into the femoral canal, always applying pressure so that the shoulder of the rasp is pressing back against the greater trochanter and the tip is pressing towards the medial cortex of the femur. Once again, this will avoid the all too common complication of the rasp penetrating the lateral cortex of the femur. Continue rasping until a trial prosthesis can be inserted into the femur and lies comfortably with the tip resting against the medial cortex of the femur. Wrap a swab around the neck of the trial component and carry out a trial reduction with a trial acetabulum in place.

The purpose of the trial reduction is to check the orientation of the femur and the acetabulum, and to check that tension in the soft tissues is adequate to stabilise the components but not so great that this reduction will prove impossible once cementing has been performed. If the reduction is satisfactory mix the first batch of cement and, when it is no longer sticky but wrinkles when compressed, change gloves and insert the cement into a clean, dry acetabulum. Insert the chosen cup, apply pressure directly up the line of the cup allowing for adequate cover and anteversion. Remove excess cement from around the cup, particularly posteriorly. When the cement has set, check that all extraneous cement has been removed and cover the acetabular component with a swab. Insert a cement restricter into the femoral canal. Wash out the femoral canal with copious volumes of saline and then pack the canal with dry swabs and start mixing the cement for the femoral canal using a cement gun. When the cement is ready, remove the swabs and inject the cement into the femoral canal from the bottom up. Insert the femoral component, ensuring that the rotation does not change as the implant is inserted and that the tip of the femoral component runs down the centre of the canal, or even slightly medially. Continue to apply pressure to the femoral component once it has bedded down, and remove all extra cement.

When the cement has set check that all extra cement has been removed and that there are no fragments lying loose in the wound. Reduce the implant and test stability in full internal and external rotation in both full extension and full flexion. Make a note if stability is compromised in any way so that postoperative care can make allowance for this. Wash out the wound with copious volumes of saline. If the sciatic nerve was visualised, check once again that it is intact and undamaged. Close the muscles in layers over two drains, one deep and one superficial.

Postoperatively, the patient should be managed in troughs or with an abduction pillow to keep the legs slightly abducted. If there is gross instability then a plaster spica may need to be applied, including the feet if rotation needs to be controlled. After an uneventful total hip replacement the patient can be mobilised as soon as resources are available. If the patient has already been taught how to use crutches before surgery then mobilisation will be much easier. The patient should avoid sitting on a low seat or on a lavatory seat which has not been raised for at least 6 weeks after surgery as this position invites dislocation. If social circumstances are satisfactory the patient can be discharged home between day 7 and day 10. An annual review should be performed for the rest of the life of the patient in order to gain information about the natural history of total hip replacement and to identify aseptic loosening early before there is too much damage to the bone. The results of this annual review should be used to build up a bank of information on a unit’s success with joint replacement. It should also be made available to any national register so that long-term results on large numbers can be used to see how the successful joint replacement process may be improved.

Prophylactic antibiotics

There is good evidence that at least three doses of a broad-spectrum antibiotic should be used to cover total hip replacement. If this is combined with the use of laminar flow operating theatres, the chance of a total hip replacement becoming infected should be less than 2 per cent. One dose of the antibiotics should be given at induction and the other two doses to cover the next 24 hours. There is no evidence that giving antibiotics for any longer than this confers any added benefit.

Thromboprophylaxis

The total death rate after total hip replacement is around nine deaths per 1000 patients in the first 90 days. Three of those deaths would have occurred in the normal population even if they had not had a total hip replacement. Therefore the excess number of deaths is six people per 1000, i.e. less than 1 per cent. Only a small proportion of those deaths is caused by pulmonary embolus, the major cause of death being myocardial infarct and stroke. There is no evidence that thromboprophylaxis affects the overall death rate or, more particularly, the very low death rate for pulmonary embolus. There is clear evidence that thromboprophylaxis reduces the rate of deep vein thrombosis, but it is not clear whether this translates into a reduction in pulmonary embolus or even postphlebitic limb. There has been little research into the complications of thromboprophylaxis. Haematoma formation is associated with an increased rate of infection but no studies have been performed to determine whether thromboprophylaxis affects the infection rate or, indeed, loosening of total hip replacements. There is also no evidence that mechanical methods such as stockings or even foot pumps affect the death rate after total hip replacement. There is some evidence that compression stockings can, in fact, increase the instance of deep vein thrombosis. Despite the prodigious efforts by the pharmaceutical industry to prove the efficacy of thromboprophylaxis, there is as yet no evidence to support its use or, indeed, to show that it does more harm than good. Therefore, under the present circumstances there is no merit in using any form of thromboprophylaxis.

Consent for total hip replacement

Consent for total hip replacement should involve, like any other consent, checking what the patient knows about the operation after introductions have been made. You should then explain to the patient exactly what the operation involves. It is very helpful here to have a model of a hip replacement for the patient to look at and to feel. Patients also like to be told where they will be when they wake up, when they can first have visitors and when they are likely to go home. You should then deal with the outcome of the operation in terms of pain relief and mobility. The patient also needs a clear explanation of the alternatives to the operation. In other words, what is the likely natural history of their disease if they do not have surgery, as it is only if they have the knowledge of the choices available to them that they can make an informed decision. There are unlikely to be any variations to the operation under anaesthetic and therefore these do not have to be described as they do in some other operations, but the patient does need to have described to them the common complications and the serious ones (Table 33.4). In British law it is usually accepted that any complica-tion more common than 1 per cent needs to be described to the patient. In the case of total hip replacement the risks are:

- dislocation (2—5 per cent), damage to the sciatic or femoral nerve (1—2 per cent), infection (1—2 per cent), fracture or penetration of the femur (1—2 per cent), death from any causes (< 1 per cent). The patient also needs to be warned that they may have an inequality of leg length after surgery.

The patient needs to be warned that they are likely to receive a blood transfusion during the operation.

Postoperative care

Most patients, especially males, are prone to urinary retention. If they are not catheterised at surgery then they should be carefully observed postoperatively. Nerve damage is one of the commoner complications. As soon as the patient awakes a check should be made that there is no damage to the nerves around the hip, especially the sciatic nerve. A simple test is to ask the patient to dorsiflex the foot. The patient should be carefully nursed to avoid flexion or adduction of the hip joint.
Revision of total hip replacement

A significant number of total hip replacements now coming to operation is revisions of primary total hip replacements which are loose. There are two main causes for loosening. The first is sepsis and the second is aseptic loosening (Fig. 23.12), possibly due to an inflammatory response secondary to particle wear. A hip replacement, which is becoming loose develops increasing pain. Septic loosening usually starts within months of the operation and the history may give a clue to the problem. The patient may have had a persistent discharge after surgery and pain relief may not have been complete. The organism involved is usually a low-grade pathogen such as *Staphylococcus epididymis*. The infection cannot be eradicated using antibiotics, but the symptoms may improve if adequate doses of the correct antibiotics are used. A needle aspiration of the synovial fluid may give a positive culture, but normally it is only at the time of surgery that the diagnosis can be made. It is now normal to send tissue for frozen section histology at the time of surgery. If signs of infection are seen in the histology then the implant is assumed to be loose because of infection.

Revision of the infected total hip replacement

If it has been decided from preoperative aspiration or from frozen section at surgery that the hip replacement is infected then further specimens of the membrane surrounding the hip need to be sent for formal culture. Then, and only then, should the patient be given the first dose of antibiotics. The infective organism is likely to be a *Staphylococcus* and so it is normal to give an antibiotic with good cover for this organism. Both femoral and acetabular components are removed with all the cement. The acetabulum and femoral canal are irrigated with saline and a further check is made that all foreign material and fibrous membrane have been removed. A decision must be made as to whether to insert gentamycin-impregnated beads and to leave the patient on traction for 6 weeks without a hip joint to allow any infection to settle before inserting a new implant (a so-called ‘two-stage revision’). The alternative is to replace the joint at the same operation (a ‘one-stage revision’). Either way there is good evidence that the new implant should be put in using antibiotic-impregnated cement as this reduces the likelihood of a recurrence of infection. A special revision implant may need to be used which may have a longer stem (Fig. 23.13).

Management of aseptic loosening

In this case a one-stage revision is performed. Some people would, nevertheless, use an antibiotic-impregnated cement in case an occult infection had been missed. It is wise to take multiple bacteriological swabs of the membrane around the hip before prophylactic antibiotics are given. Postoperatively, there is a much higher risk of dislocation and it is normal to keep the patient in bed for several days and then to mobilise with great care. Before embarking on this operation patients need to be consented for the possibility that they may wake up without a hip replacement (the Girdlestone operation).
Fracture. of the upper femur

Epidemiology

Fractures of the upper end of the femur are both common and serious. In children a slipped upper femoral epiphysis (a fracture of the epiphyseal plate) will lead to a lifetime of pain and disability. In adults a fracture of the upper end of the femur is a very high-velocity injury which is difficult to treat. In the elderly fractured neck of femur is the ‘bread-and-butter’ of orthopaedic trauma practice, with over 100 000 cases of fractured neck of femur each year in Britain alone.

Subcapital fractured neck of femur

This is a very common fracture in the elderly osteoporotic patient. The sclerosis produced by osteoarthritis tends to protect the patient from this fracture so the hip joint itself is usually healthy at the time of the accident. The problem with this fracture is that the majority of the blood supply to the femoral head travels up the femoral neck. A subcapital fractured neck of femur (Fig. 23.14) may destroy the blood supply to the femoral head. The older the patient, and the more displaced the fracture, the less likely the head is to recover its blood supply.

History

Some patients actually give a history of feeling the femur break and then falling as a result of this, while others appear to break the femur as a result of the fall. Either way, they complain of severe pain in the hip and are usually unable to walk.

Examination

The leg may appear shortened and externally rotated.

Investigation

On an AP X-ray the fracture may be difficult to see, but it will be shown more clearly on the lateral view as the head may displace posteriorly. On the AP X-ray the only clue to the presence of a fracture may be a discontinuity in the trabecular lines running up the femoral neck into the head.

Treatment

The Garden classification divides these fractures into four grades (see Fig. 23.15 and Table 23.5):

• grade 1 is an incomplete fracture of the neck;
• grade 2 is a complete fracture of the neck without displacement;
• grade 3 has moderate displacement of less than half the diameter of the femoral neck;
• grade 4 is a complete off-ended femoral head as seen in the AP or lateral X-ray.

If grade 1 or 2 fractures are left untreated they may rapidly displace and become grade 3 or 4.

In grade 1 fractures it is generally agreed, whatever the age group, that the treatment of choice is AO screws or other pins introduced up the femoral neck to hold the femoral head in position. In grade 4 fractures, whatever the age group, it is unlikely that the femoral head will survive. In patients under 50 years of age they should be taken to theatre as quickly as possible to reduce and pin the head as quickly as possible, and fix with screws (Fig. 23.16). The hope is that the femoral head will revascularise before it collapses. In patients older than this, the chance of survival of the femoral head is so low that it is best to replace it straight away. In young patients (under 65), a total hip replacement should be performed, but in older patients a hemiarthroplasty can be used. In the hemiarthroplasty the acetabulum with its normal articular cartilage is left alone but the patient’s femoral head is replaced by an implant whose head has the same diameter as the head being removed. This articulates with the patient’s normal acetabulum. The cemented variety of this implant is usually known as a ‘Thompson’ prosthesis; the uncemented variety is known as an Austin Moore’ (Fig. 23.17). There is good evidence that the cemented hemiarthroplasty does better than the uncemented in the long term. In the older patient (with a life expectancy of 5 years or less) it is normal to go ahead and perform a hemiarthroplasty on patients with a Garden 2, 3 or 4 fracture. The risk of avascular necrosis is so high and the destruction of quality of life when this occurs so great, that it is simpler to sort out the problem in one go. The chance of the hemiarthroplasty giving the patient good function to the end of their days is high and so this is the operation of choice.

Problems

If the femoral head is retained reduction can be difficult to achieve and if pins are used they may displace into the acetabulum. Avascular necrosis is then a risk depending on the age of the patient, the degree of displacement and the time to reduction. If the head is replaced then dislocation, bleeding and infection are early complications, as well as damage to the nerves around the hip when replacing the joint. Late complications are loosening of the replacement, and sometimes the acetabulum can be eroded away by the implant, creating a protrusio-type arthritis (Fig 23.18 and Fig 23.19).

Subcapital fractured neck of femur

• Common in osteoporosis
• Treatment depends on displacement and age
• Complication — avascular necrosis
Avascular necrosis of the hip

Epidemiology

Avascular necrosis is a rare but important problem in all age groups (Table 23.6). In the infant it may follow as a complication of septic arthritis, the pressure of the effusion denying the head of the femur its blood supply. In children, spontaneous avascular necrosis is called Perthes’ disease. In adults it may be caused by steroids or heavy alcohol intake, and can occur in people who work in an environment which is at high pressure (divers or people who work in tunnels). It is also found occurring spontaneously in patients with blood abnormalities such as sickle cell anaemia and thalassaemia. It is a very common problem in the elderly following a displaced subcapital fractured neck of femur. These are managed by replacing the dead femoral head with a hemiarthroplasty before the sequelae of avascular necrosis can develop.

Pathophysiology

The head of the femur is one of the areas of the body most susceptible to avascular necrosis. The underlying pathophysiology of the condition is not known but it is believed that the blood supply to the femoral head is lost either through thrombosis of the vessels entering the head or because of interosseous hypertension. The marrow of the femoral head becomes replaced with fat and the bone dies. Subsequently, there will be a zone of revascularisation which will be incomplete if the avascular area is large. Finally, there is a zone of reossification. During this period the joint is at risk of collapse. Once collapse has occurred full recovery is not possible and secondary arthritis sets in.

History

The patient may complain of sudden onset of pain in the hip or gradually increasing joint pain.

A careful family history will be needed to exclude sickle cell and thalassaemia. A social history should carefully cover alcohol intake, and a history of having worked underground or under water using high pressure. This exposure might have taken place some years before the onset of symptoms in the joint.

Medical history should specifically cover treatment with steroids.

Examination

On examination there may be nothing to find, except for a painful limitation of range of movement.

Investigation

Ultrasound may reveal a small effusion around the hip but X-rays are normal unless the avascular necrosis has been caused by a fracture. A radioisotope scan will show a dead area of the femoral head later surrounded by a hyperaemic area of revascularisation. Magnetic resonance imaging (MRI) may also show one or more avascular areas. If any of these areas are in the weight-bearing part of the femoral head then there is a risk that the femoral head will collapse before revascularisation occurs. If this does occur, secondary osteoarthritis of the hip starts and a total hip replacement may be needed. If the diagnosis can be made early before the femoral head has collapsed, there is a chance of protecting the femoral head until it revascularises. This may prevent collapse.

Treatment

If the femoral head has not collapsed a ‘forage’ operation (where a core of bone is removed from the femoral neck and femoral head through a window in the lateral femoral cortex) can be used to decompress the femoral head. There is no clear evidence that this operation makes any difference to the natural history of avascular necrosis. If the avascular area is in the main weight-bearing area of the femoral head a further option is to perform an osteotomy. The head is rotated to bring a healthier part of the head into the main weight-bearing area of the hip joint to prevent collapse.

Problems

Once the femoral head has collapsed osteoarthritis is inevitable, with pronounced shortening as the hip collapses followed by stiffness as the joint becomes incongruent and osteoarthritis sets in. The options then are an arthrodesis or a hip replacement. Osteotomy is unlikely to help at this stage.

Avascular necrosis

• Idiopathic in children = Perthes’ disease
• Complication of alcohol and steroids in adults
• Complication of sickle cell and thalassaemia in all ages
• Avoided by hemiarthroplasty following subcapital fracture in the elderly

Pertrochanteric fractured neck of femur

Epidemiology

Fractures through the trochanters of the femur are as common as subcapital fractured neck of femur. They can occur in patients with osteoarthritis of the hip and are caused by a trip or a fall on to the hip.

Pathophysiology

Unlike subcapital fractures these can occur in association with arthritis of the hip. In the younger adult they can occur with high-velocity trauma.

History

The patient complains of sudden severe onset of pain in the hip and is unable to weight-bear.
**Examination**

On examination the leg is often short and internally rotated.

**Treatment**

The fracture is highly unstable (Fig. 23.20) and the patient cannot mobilise until it has been stabilised. This fracture can be managed on traction but it is very difficult to reduce the fragments and the patient would need to in bed for a minimum of 12—18 weeks.

The patient is usually very elderly and this length of time in bed would destroy their sense of independence and put them at risk for developing hypostatic pneumonia, urinary tract infection and bed sores. The blood supply of the femoral head is not affected by this fracture and therefore avascular necrosis is not a problem. However, the fracture requires a very strong fixation because of the enormous forces which go through the hip. The dynamic hip screw (DHS) is made up of two parts which can slide in relation to each other but do not allow binding (Fig. 23.20). The first part is a heavy-duty plate which is fixed to the lateral cortex of the femur with cortical screws. The second part is a rod which passes up through a slot in the plate into the femoral neck. Its threaded end crosses the fracture line to engage and hold the femoral head. As the patient weight-bears on the healing fracture the broken ends of the bone collapse into each other and compress the fracture. The sliding-rod mechanism of the DHS allows this to happen without allowing the hip to fall into varus. This prevents the plate breaking at the fracture, or indeed the rod penetrating through into the femoral head and acetabulum.

**Problems**

Some fractures are difficult to reduce and can result in poor placement of the DHS. If this happens the fixation will fail, and the fracture collapses into a painful nonunion which is difficult to reconstruct.

Pertrochanteric fractured neck of femur

- Common in the elderly
- Does not cause avascular necrosis
- Nonoperative treatment is slow and difficult
Fractures of the shaft of the femur

Fractures of the shaft of the femur can occur in any age group. In young children the spiral fracture of the femur is one of the fractures which occurs commonly in nonaccidental injury but rarely at any other time. The force required to cause a spiral fracture of a child’s femur is so great that it is unlikely that the child can exert this force by falling. In the adult a shaft fracture of femur is usually associated with a high-energy injury such as a motorcycle crash. In the elderly this fracture is again associated with pathological fractures secondary to a lytic lesion. It is unusual for this fracture to be associated with neurovascular damage, but in a high-velocity accident in a young adult this must always be born in mind.

Causes of fractures of the shaft of the femur

- In children, may be nonaccidental injury
- In adolescents, usually high-velocity injury
- In the elderly, may be pathological

Treatment in children

This fracture heals very quickly in children and the fracture can be stabilised with nonoperative means (Fig. 23.24). In children under the age of 2 years, vertical skin traction can be used to hang the legs off the bed. Static traction can be used and the legs raised until the child’s bottom is floating just off the bed. Surprisingly, the children do not find this traction uncomfortable and nursing is easy. It is easy to tell when the fracture has united as the child starts spinning around and hanging off the bed by its legs. In the young child the femur is capable of considerable remodelling, so a perfect reduction is not necessary.

Treatment of fractured shaft of femur

- In infants — gallow traction
- In children and adolescents — balanced traction
- In adults and the elderly — locked nail

Treatment of the fractured shaft of femur in the child before epiphyseal closure

If there is still growth potential in the femur then internal fixation should be avoided as this may cause damage to the epiphyseal growth plate. The majority of growth in the femur occurs in the distal epiphysis, but nevertheless both should be protected if at all possible. A fractured femur in an adolescent can be managed on Hamilton Russell balanced traction or on static traction using a Thomas splint, but in this case it is wise to use a Fisk hinged knee piece to allow early mobilisation of the knee joint to prevent stiffness in the knee (Fig. 23.25). If traction is applied through a tibial pin, care must be taken not to apply the traction for too long as there is a risk of causing stretching of the ligaments around the knee. This produces a permanently lax and unstable knee (a frame knee). As soon as the fracture is sticky, there may be place for taking the child off traction and putting the leg into a cast brace with knee hinges so that they can start mobilising. Great care must be taken to watch that the femur does not fall into varus at this stage. Initially, weekly check X-rays will be needed.

Treatment of fractured femur in the adult

Traction for fractured mid-shaft femur can also be used in the adult but requires that the patient stay in bed for 12—16 weeks. Once the fracture has been settled into a satisfactory position there is no reason why the last weeks of this traction should not be carried on at home where the patient can be nursed by his or her family (Fig. 23.26). Traction may also offer some advantages when the fracture is open and the femur heavily contaminated. There will invariably be an increased risk of infection if plating or an intramedullary nail is used, and it may be advisable to leave the patient on traction at least for a few days until the wound has settled down. However, this is not an excuse for failing to be aggressive about removing all contaminated tissue from the wound at the time of the accident (débridement). The wound should be left open, and re-exploring and clearing away of dead or contaminated tissue should continue until the wound is clean. An external fixator can be applied to the lateral side of the femur to stabilise the fracture but the thick muscles overlying the bone can produce problems with pin tract infections. Internal fixation of the femur can be performed either with a plate or with an intramedullary nail.

If a plate is to be used then it should be very heavy duty and the exposure will need to be extensive, as there will need to be at least four holes for fixation of the plate above the fracture and four holes below the fracture. If the fracture is spiral then lag screws will need to be placed to draw the fragments together, either through or separate from the plate. If the medial cortex is deficient then this will need to be buttressed with bone graft and great care will need to be taken when mobilising the femur as the plate will be vulnerable to bending loads. The femoral shaft is ideally suited to an intramedullary nail which, if the equipment and expertise is available, can be introduced closed from the proximal end and then locked both proximally and distally. This will give adequate stability to both bending and rotation forces to allow the patient to weight-bear immediately (partial weight-bearing if it is an unreamed nail) and to leave hospital as soon as they have recovered from the surgery and are able to walk safely. The operation must be performed with great care as the complication rate even in the best hands is high. The common complications are listed in Table 23.7.

Alternatives to intramedullary nailing

A simpler alternative to intramedullary nailing is the use of rush pins introduced through the lateral and/or medial condyles of the femur. Rush pins are flexible rods which can be passed into the femur through a small skin incision at the knee and which are slightly curved so that by twisting them they can be used to cross the fracture site and pass up into the femoral neck. The femur can be stacked with rush nails until a relatively tight fixation is obtained. Four or five rush nails passed up the femur are not as strong as an intramedullary nail and are particularly poor at controlling rotation. They do, however, prevent translation at the fracture site but do not prevent impaction. Although they are relatively simple to insert they do tend to back out, and a patient should certainly not be encouraged to more than toe touch with the leg until the fracture has started to unite.

Metastases in the femur which have not yet fractured

Wherever possible, secondaries in the femur or any other long bone should be referred to an orthopaedic department before the pathological fracture occurs. They are much easier to man-age at this stage than they are after the fracture has occurred through the lytic lesion. It is said that the femur is at imminent risk of pathological fracture if a lytic lesion has eroded more than half the thickness of the cortex or there is erosion over more than 2 cm of the cortex. If either of these signs is present then immediate action needs to be taken to stabilise the femur before it breaks. Before embarking on surgery X-rays should be taken of the whole length of both femurs as there is likely to be more than one
metastatic lesion and this may affect the choice of surgery. The purpose of the surgery is to fix the bones so that they do not break, so that the last weeks or months of the patient’s life are not spent in pain and disabled. However, the patient must be warned of the risks of the surgery which are high (particularly death from pulmonary embolus). As soon as the bones are fixed the patient can be transferred back to medical care for radiotherapy or cytotoxic drugs, depending on the most appropriate management.

Indications for prophylactic fixing of lytic lesions in the femur

- 50 per cent of the cortex eroded
- > 2 cm invaded
- Check for other lesions

Supracondylar fractures of the femur

Supracondylar fractures occur in young adults involved in very high-energy accidents or in the elderly who fall awkwardly. There are many different patterns of fracture, but not uncommonly a fracture line enters the knee joint through the intercondylar notch creating an unstable Y-shaped fracture. The X-rays may be difficult to interpret because the fracture line down into the knee joint may be hidden behind the patella but a careful check must be made for this as it alters the surgery required. In the elderly neurovascular compromise is unusual, but in the young high-velocity accident the popliteal vessels and nerves lie close to the fracture and may easily be damaged.

The nonoperative management of the supracondylar fracture of the femur

This fracture is normally unstable. It is too close to the knee joint to manage in plaster and even in traction the distal fragment tends to flex. If it is not possible to move the knee early the gastrocnemius tends to become tethered down to the fracture site and permanent stiffness in the knee results. The nonoperative management of the supracondylar fracture therefore tends to end with a malunion and a stiff knee.

Operative management of supracondylar fractures

Special plates have been designed for the management of supracondylar fractures, and it is a fracture where preoperative planning, of drawing out of the fragments on tracing paper and then fitting templates to the reduced fragments allows a logical operation to be designed.

If there is an intercondylar fracture this may need to be fixed first with large lag screws and then a blade plate introduced to attach the distal fragment to the proximal. Bone grafting may be needed on the medial side if there is a defect. Internal fixation allows early mobilisation of the knee but weight-bearing may need to be protected with a cast brace until union has been achieved.

Supracondylar and intracondylar fractures of femur

- Check carefully for extra fracture lines
- Nonoperative treatments lead to malunion and stiffness
- Plan surgery with templates drawn on to tracings of X-rays
- Mobilise early
The knee

The knee does not feature prominently in children's orthopaedics, but commonly poses problems in adolescents with anterior knee pain otherwise known as chondromalacia patellae. Subluxation and dislocation of the patella may also start to cause problems at this age. In the young adult prob-lems with the knee are exceptionally important. All contact sports and high demand sports, such as skiing, produce a rich crop of sports injuries. Rheumatoid arthritis affects the knee in the later stages just as it affects the hip, and in the elderly osteoarthritis of the knee is as common as osteoarthritis of the hip, and within the next few years total knee replacement may become as common an operation as total hip replacement. Certainly, it is already quite as successful.

History of knee injury

The history of an accident can be divided into three types:

acute extrinsic, the patient was struck on the knee; acute intrinsic, something snapped or gave way in the knee; and chronic, where the onset was gradual and not related to any specific event. Each of these kinds of history is related to a completely different diagnosis (Table 23.8).

Investigation for torn meniscus

A torn meniscus only shows up on X-ray if dye is used (an arthrogram — see Fig. 23.27). It also shows up very well on MRI. The investigation of choice is therefore MRI. If, however, the history is absolutely clear of mechanical locking, then arthroscopy is the investigation of choice, as it is going to be necessary anyway and it allows treatment to be undertaken at the same time. If, however, the diagnosis is in doubt than a noninvasive investigation such as MRI is the first line of investigation, the only problem being that interpretation of the MRI can be difficult and there is an incidence of false positives.

Ruptured anterior cruciate ligament

This is an epidemic in modern sport. It occurs when a very high twisting force is applied to the bent knee. If contact sports did not allow the use of studs on boots the injury would probably almost disappear. It is only when the foot is fixed firmly to the ground and the body continues to twist fast on it that the injury is inevitable. The patient often hears a loud crack in the knee and collapses. They cannot play on both because the pain is severe and because the knee swells rapidly and is unstable. The other common cause for an acute haemarthrosis following an acute intrinsic injury to the knee is dislocation of the patella. A careful history and examination will distinguish the two conditions. In patella dislocation the patient may have noticed something out of place immediately after the accident or have had the problem before. Sometimes the patella remains dislocated.

Aspiration of the joint will produce a dramatic reduction of pain. If there are fat globules in the aspirate then a fracture must be suspected as marrow has escaped into the joint (Fig. 23.28).

Treatment of the ruptured anterior cruciate ligament

In the child the anterior cruciate avulses with a fragment of bone. It is relatively simple to fix this fragment back into the tibia either with a bone screw or with sutures passed through to the front of the tibia. In the adult the anterior cruciate tears its central part, where there is no capacity to heal. This does not necessarily mean that surgery to substitute the ligament is required. In a significant number of patients intense physiotherapy rebuilds the control of the knee to levels where the absence of an anterior cruciate does not hamper performance. In other patients whose performance is compromised by an anterior cruciate deficient knee it is a perfectly valid option for the patient decide to modify their lifestyle to cope with their disability. For example, they may decide that the time has come to give up contact sport. It is only after these first two options have been exhausted that the possibility of repairing surgery to substitute for the anterior cruciate ligament should even be considered. Even then the surgery is complex, the rehabilitation is difficult and there is no evidence in the long term that functionally the knee maintains any greater stability, or that reconstruction protects the knee from osteoarthritis. There is also now good evidence that some of the synthetic ligaments used are not strong enough for the loads exerted on them and break up in the knee. If they do so the debris may cause an inflammatory arthritis. Finally, it is very difficult to make sure that the substitute ligament has the right biomechanical properties and is correctly positioned to give a stable knee without causing stiffness. A substitute ligament cannot have a proprioceptive function in the knee, a role that some people feel is one important facet of the anterior cruciate ligament’s role.

As the ligament does not heal, the alternatives are either to realign the structures outside the knee to prevent the instability caused by anterior cruciate deficiency or a second possibility is to take a ligament from elsewhere in the patient and route it through the track of the anterior cruciate to re-create the function of the ligament. A third option is to put in a synthetic ligament. A ligamentous augmentation device (LAD) is a synthetic ligament which in itself is not strong or elastic enough to undertake the function of an anterior cruciate but combined with tendon material from the patient is supposed to perform this function.

Extra-articular repair

The Macintosh operation involves reefing the lateral dynamic structures of the knee. It pulls back on the lateral tibial plateau in flexion in an attempt to stop it sliding forward in an uncontrolled way (the pivot shift), which makes the knee so unstable in twisting and turning.

Intra-articular repair
Intra-articular repairs can be performed either through the arthroscope or open. The Jone's repair involves freeing the proximal end of the middle third of the patella tendon and rerouting this tendon through the knee along the line of the anterior cruciate. Semitendinosus tendon can be used in a similar way or a synthetic tendon can be inserted. The key issue surgically is to make sure that the origin and insertion of this new ligament are in the correct plane to allow free movement of the knee without undue laxity.

**Posterior cruciate**

A posterior cruciate tear is commonly associated with a hyperextension injury and disruption of the posterior structures of the knee (Fig. 23.29). Treatment of the knee in a plaster usually allows the posterior capsule to heal up. There is then little functional disability despite the fact that the posterior cruciate does not heal.

**Rupture of the medial collateral ligament**

Ruptures of the medial collateral ligament occur when the leg is forced into valgus usually by a blow on the outside of the leg. With moderate trauma there is usually only a tear of the short cruciate ligament. If the force is greater then the medial collateral ligament disrupts. The knee is grossly unstable when stressed into valgus. If on ray a flake of bone can be seen avulsed from the femur then reattachment using a screw is relatively straightforward. The medial collateral ligament inserts into the tibia well below the knee joint and avulsion in this area can also be repaired surgically by suturing the tendon back. Midsubstance tears at the level of a joint are more difficult to repair, and surgery is not necessary. A cast brace for 6 weeks allowing for flexion of the knee but protecting it from valgus forces will encourage good healing.

**Anterior knee pain — chondromalacia patellae**

This condition tends to start in the teens and is more common in girls than in boys. It may follow an injury to the knee, particularly a dislocation of the kneecap. The patient gives a history that they have pain on stairs, particularly going down stairs when the knee may actually feel unsafe. They also experience severe pain when sitting for any length of time. When they try to move after the knee has been still for a while the pain may be so severe that the knee feels locked. This is not true mechanical locking. It seems to be more to do with synovial inflammation. On examination, there may be some quadriceps wasting, there is not usually an effusion but there is tenderness if the synovium around the patella is pressed against the patella itself. This is sometimes confused with tenderness beneath the patella; it is the synovium caught between your finger and the patella that is causing the pain as there are no nerve fibres under the patella itself.

**Management**

There is no proven treatment for this condition, but because its severity fluctuates it is a diagnosis which has attracted all sorts of unusual therapies. There is little doubt that pain killers and nonsteroidal anti-inflammatory drugs make little or no difference to the pain. Strapping and tubigrip can actually make the pain worse, and there is no evidence that avoiding activities which make the pain worse makes any difference to the natural history of the condition. The use of crutches, plaster cylinders and even wheelchairs merely seems to confirm the child in the role of an invalid. There is always quadriceps inhibition and eventually wasting, so exer-cises to build up the quadriceps, particularly the vastus medialis, should be encouraged. Unfortunately, these exer-cises can be quite painful, but if the child is encouraged to contract the muscles isometrically (without moving the knee) the pain can be minimised. There are several surgical operations described for this condition but there is no evidence that any of them do any good and some of them certainly make the condition worse, so they should be avoided.

**Dislocating kneecap**

It is most common to see a patient who has had a previous dislocation. The kneecap normally relocates itself, but if it has not the patient can be given nitrous oxide. When the knee is straightened the patella will relocate. Immediately after a dislocation the patient will have a quadriceps lag and should therefore be protected with a back slab and crutches. Physiotherapy should be started at once. If there have been recurrent dislocations, then swelling may be minimal but quadriceps wasting may be marked. It is then even more important to arrange physiotherapy to build up the muscles around the knee if further dislocations are to be avoided.

Surgery for the dislocated patella (Fig. 23.30) should only be undertaken as a last resort. If the patient has built up the quadriceps well but the kneecap is still unstable then initially a soft-tissue realignment of the patella should be considered by performing a lateral release. This involves dividing the lateral retinaculum of the patella so that the pull on the patella is more medial.

**Dislocation of the knee**

In high-energy accidents the knee can be dislocated. The tibia is driven backwards and dislocates posteriorly. The key feature in this injury is that there is a high risk of neurovascular injury. The pulses to the foot must be intact before and after relocation, and even if they return great care must be taken that a compartment syndrome does not develop. The knee can then be treated in a plaster for 6 weeks with active quadriceps exercises.

**Fractured patella**

There are two types of fractured patella. The first is a direct blow to the patella, which tends to shatter the patella into many fragments which do not displace as the patella tendon and the fibres which run over the patella itself are usually intact. The second type of fracture is an avulsion fracture where the patella snaps in half under the load of the quadriceps muscle trying to prevent the knee from being forcibly flexed. In the latter case the fracture is usually transverse and displaced.

**Management of the comminuted undisplaced fracture**

There is often an open wound over the patella and this needs cleaning. If it is contaminated it should be left open for delayed primary closure. It is unlikely that the patella can be reconstructed when it is in a large number of fragments, and therefore the choice is either to treat the patella as a ‘bag of bones’ (simply mobilised without any attempt at reduction) or to excise it. The patella acts as a fulcrum for the quadriceps tendon and a stabiliser, so if it is excised the knee may subsequently be weaker and less stable. However, if it is mobilised early as a ‘bag of bones’ the articular surface may be smoothed but will never be truly congruent and early oesteoarthritis in the patellofemoral joint is inevitable.

**Management of the displaced transverse fracture of the patella (avulsion)**

The fracture can be managed in exactly the same way as an olecranon fracture with wires passed through the patella and a figure-of-eight tension band passed around the outside of the patella. The load of the quadriceps passing through the patella and down the patella tendon into...
the tibial tubercle serves to compress the fracture provided that the outer cortex is held together with a tension band (Fig. 23.31). The patient is mobilised with partial weight-bearing until the fracture is healed. The pins and wires are then removed as otherwise they cause skin irritation.

Tibial plateau fractures

Tibial plateau fractures occur in the elderly when the knee is forced into varus or valgus and the osteoporotic bone fails before the ligaments. Fracture can also occur in the young adult but are then associated with very high-energy injuries which may also have damaged the ligaments and caused fractures elsewhere. The pattern of fracture of the plateau depends on the direction of the force exerted. If the knee was forced into valgus then there tends to be a depressed fracture of the lateral plateau; if the knee is forced into varus then, similarly, the medial plateau will be fractured. If there is an axial force then both plateaux may be damaged. A check should always be made on the contralateral side of the fracture for ligamentous disruption as the compressed side will have acted as a fulcrum for the load to come on to the opposite ligament. There are two main types of tibial plateau fracture. The first is a vertical cleft fracture where a whole fragment is displaced downwards. The second is an egg-shell-type fracture where the plateau is buckled in by the femoral condyle. Most fractures are a mixture of these two types. The buckle ‘egg-shell’ fracture can be quite difficult to see on an X-ray, as it is often only part of the plateau (usually the posterior part) that is depressed. Unless a careful check is made the intact part of the plateau will give the appearance that the knee is normal in both the AP and the lateral directions. Fractures in which there is more than 2 mm displacement in the articular surface or in which the joint is unstable need open reduction and internal fixation in all but the most elderly and frail patient. The investigation of choice is therefore tomography or a CT with reconstruction of the tibial plateau in the vertical axis to show the size and depth of the depressed section. The final decision on whether knee needs reconstructing may have to be made under anaesthetic when the stability can be tested.

Management of vertical shear fractures

If the fracture is a pure vertical shear fracture with displacement of more than 2 mm then the fragment needs to be exposed, elevated, and fixed back with a buttress plate and lag screws across the knee. Early partial weight-bearing and mobilisation can then be started.

Management of depressed fractures

In these cases the joint may need to be opened so that the fragments can be elevated under direct vision. The incision should be extended down beside the tibia and a small window opened in the cortex into which a punch can be introduced. The fragments can then be elevated from inside the bone and the cavity packed with bone graft. If there is combined vertical shear fracture then this can be fixed with a buttress plate (Fig. 23.32). Most of the load to the knee goes through the medial side so a fracture of the lateral plateau may only need protecting with a cast brace to prevent the knee going into valgus, but a fracture of the medial plateau should be non-weight-bearing for some weeks.

Rheumatoid arthritis of the knee

Rheumatoid arthritis commonly affects the knee, but the diagnosis is simple as it is one of the later joints to be affected. In the first instance the problem is pain and swelling secondary to an aggressive synovitis. At this stage medical treatment, nonsteroidal anti-inflammatory drugs, painkillers, splints and physiotherapy are the best choice. Synovectomy can be performed chemically using short acting radioisotopes. Surgical synovectomy can also be performed through an arthroscopy. This is technically difficult because of the florid synovitis and should only be undertaken if there is still a good range of movement and the articular surfaces are well preserved. In the later stages of rheumatoid arthritis there is severe arthritis in the lateral compartment with a contracture of the lateral structures of the knee, producing external rota-tion of the tibia and a fixed flexion deformity. Total knee replacement is now the operation of choice but this may need to be combined with a careful soft-tissue release to obtain a stable straight knee.

Management of osteoarthritis of the knee

Osteoarthritis of the knee may be idiopathic or secondary to trauma. The disease may affect all three compartments of the knee: the patellofemoral joint as well as both the medial and lateral compartments of the knee, but its main effect appears to be on the medial compartment. Initially the patient may present with pain on walking. Weight-bearing X-rays may show slight narrowing of the medial joint space. If medical treatment and physiotherapy are no longer controlling the symptoms and there appears to be a major inflammatory element to the disease then an arthroscopic washout should be considered. It is not known how this operation works but it can give considerable relief of pain in the short term. A valgus osteotomy may help to transfer the weight-bearing away from the medial compartment and more equally into the medial lateral compartment. This is only suitable if the lateral compartment shows no sign of arthritis on X-ray, the knee is stable and there is a good range of movement (at least 90°).

Operative technique for high tibial osteotomy for osteoarthritis

The degree of yams (Fig. 23.33) should be measured carefully on long leg X-rays. The size of wedge which needs to be removed from the tibia should then be calculated with the aim of putting the knee in neutral or very slightly into valgus. At operation a laterally based wedge is removed from tibia just below the joint surface leaving the medial cortex intact to stabilise the osteotomy. An alternative procedure is the ‘dome osteoto-my’, where a series of drill holes in the shape of an arch is drilled through from the front of the tibia to the back and then joined using a sharp osteotome. The distal tibia can then be rotated in the dome to correct the alignment of the knee. As with the wedge osteotomy, the new position can then be held using a long leg plaster. Care must be taken in either operation to avoid damaging the vessels immediately behind the knee, which lie very close to the bone especially if the knee is extended. These procedures are therefore best all performed with the knee well flexed.

Knee replacement

Most knee replacements are total condylar knee replacements (Fig. 23.34). The femoral component replaces both femoral condyles and there is a tibial plateau component which covers the tibia. An optional extra is a resurfacing component for the back of the patella. Unicompartmental knee replacements are available, but unicompartmental arthritis is not that common, and technically these implants can be difficult to insert.

Operative technique for total condylar knee replacement

The patient is placed supine on the table. It is not necessary to use a tourniquet although many people do. The risk of causing vascular damage, especially in the elderly, outweighs any possible advantages in obtaining a blood-free field. A long midline anterior incision should be made from 10 cm above the patella to 3 cm below the tibial tubercle. This incision can be curved slightly medially. The incision is carried down to the patella and patella tendon without undercutting the edges. The medial margin of the patella tendon and of the patella is now exposed and the incision carried on through this tissue to the knee joint. Above the patella the incision is brought round to the midline of the patella and then extended vertically up the quadriceps muscle in the midline for 10 cm above the knee. The patella is turned upside down and dislocated laterally and the knee flexed up to 90 degree. Any bleeding in the wound edges should now stop so that a tourniquet would now serve no further useful function. The fat pad and menisci are excised and a jig is placed on the femur. The jig should be sized so that the femoral component...
will be the same size as the condyles it is replacing.

Having checked that rotation is correct the anterior and posterior cuts should then be made on the femur. Very little of the anterior condyles should be removed. Each fragment of the posterior condyle should be about the size of a thumb nail and no thicker than the thickness of the replacement metal component. The tibial jig should now be applied. Two types of jig are available. One is fitted on a rod passed down the medulla of the tibia and relies on the tibial shaft anatomy being normal and the entry hole being in the centre of the tibia. The second type of jig (extramedullary jigging) relies on the surgeon clipping the jig to the tibia and achieving the correct alignment by eye. This second system relies more on the surgeon’s skill and expertise, and tends to be used more by experienced knee surgeons who may wish to make allowances for abnormal anatomy. The cut on the tibia should only remove as much tibia as is needed to make room for the thickness of the thinnest of the tibial components. If there is a defect in either the medial or the lateral plateau no attempt should be made to remove the defect by cutting lower, as the defect can be filled with cement or, indeed, with special components that can be fitted to the implant. The gap between the cut top of the tibia and the posterior cut of the femur should be measured with the knee in 90° of flexion using the spacers provided on the instrument tray. This gap measured will include the thickness of the tibial component and of the femoral component.

With the knee now extended, and using the same spacer, a mark should be made on the femur so that the distal cut of the femur is made at a height that will keep the components in the same amount of tension through flexion and extension. If, however, it is found that it is difficult to get the distal tibia in the correct alignment to the femur in extension (70° of valgus) then a soft tissue release may need to be carried out on either the medial or lateral collateral ligaments. The lateral ligament is best released from the femur; the medial side can be released from both femur and tibia until the knee is in correct alignment in extension. A similar amount of bone should then be cut from the femoral condyles as the thickness of the metal of the components, allowing for any defects in the femur caused by osteoarthritis. The distal cut in the femur should now be carried out using a jig to ensure that it is at the correct angle to the anterior and posterior cuts. The corners are trimmed where necessary, and a trial femoral component can be fitted to test against a trial tibial component. It is now possible to see whether the cuts have been put in the right place and whether the tension of the knee in both flexion and extension is correct. On good designs the tension in flexion should be slightly less than in extension to allow rotation of the tibia on the femur in flexion. If the alignment and tension are good then the components can be cemented into place. There is no evidence that resurfacing the back of the patella makes any difference to the long term outcome, and the complications of this thin implant are well described. Nevertheless, the patellofemoral joint is clearly a potential source of pain and some surgeons argue that it should be replaced.

The patella is reduced and a single tacking suture put in to hold the medial retinaculum to the patella. A check is then made that the patella tracks normally in the new intercondylar groove. If it does not, osteophytes may need to be trimmed from the edge of the patella. If the lateral retinaculum is too tight then a lateral retinacular release may need to be performed. The wound is closed in layers and the knee placed in a back slab splint. There is no evidence that continuous passive movement after surgery either reduces blood loss, decreases pain or improves the overall outcome, but it is commonly used. The key to success is good postoperative physiotherapy aimed at building up the power of the quadriceps then regaining full extension and at least 90° of flexion. Total knee replacement does not give immediate pain relief in the same way as a total hip replacement. The patient also needs to do a great deal of work over the next 6 months to regain strength and range of movement in the knee. This needs to be clearly explained to the patient before embarking on the surgery.

Complications of total knee replacement

Total knee replacement is subject to wound breakdown if care is not taken with the anterior incision. If the wound does break down then the knee replacement is likely to become infected.

Tourniquet damage is well described, especially in the elderly. The tourniquet may fracture atherosclerotic plaques in the femoral vessels and, if left on too long, may cause nerve damage. If tourniquet time is more than 1 hour in the elderly, the tourniquet should probably be released and then reinflated after 10 minutes.

Tourniquets can also cause burns if alcohol-based skin preparation solution is allowed to seep down into the tourniquet padding (Fig. 23.35).

Damage to the vessels behind the knee can be avoided by making the cuts on the tibia with the knee flexed and being very careful not to let the saw cut too deep.

The retractor on the lateral side of the knee must be used with care if damage to the lateral popliteal nerve is to be avoided.

If the knee is put in too loose it may be unstable and require bracing.

The infection risk of total knee replacements is around the same as total hip replacements, somewhere below 2 per cent. The risk of infection can be reduced using three doses of prophylactic antibiotics specifically to cover *Staphylococcus*.

The incidence of deep vein thrombosis after total knee replacement appears to be high, but few of these cases produce any clinical symptoms. The overall death rate after total knee replacement is low (less than 1 per cent, and the death rate from pulmonary embolus even lower). There is, therefore, no evidence to support the use of thromboprophylaxis in total knee replacement, either chemical or mechanical.

Some total knee replacements fail to mobilise quickly particularly if physiotherapy resources are not good or the patient lacks motivation. After 2 weeks a manipulation under anaesthetic may need to be performed to release any adhesions. This must be done with great care to avoid breaking the femur.

Total knee replacement does not produce immediate relief of pain but if severe pain persists the possibility of aseptic or septic loosening must be considered. The joint should be aspirated and fluid sent for culture. If a trial of antibiotics does produce relief of pain then the diagnosis of septic loosening is most likely and a revision should be considered.

Aseptic loosening of total knee replacements probably occurs in a similar way to the hip, with particulate wear stimulating an inflammatory response. Special implants are available for revision but tissue should be sent at the time of surgery for histology and bacteriology. The problems of wound healing after a revision are considerably increased, as is the risk of infection and stiffness.
The Tibia

Fractures of the tibial shaft can occur after repetitive loading (stress fractures) or following a single major traumatic event. The tibia is a subcutaneous bone on its anteromedial margin and so any significant displacement of the fracture is likely to result in an open injury. This skin over the tibia is also a notoriously poor healer, and therefore the open fracture of the tibia is an especially challenging problem for the trauma surgeon.

Mechanism of injury

The mechanism of injury is particularly important with respect to the energy involved, likely contamination of the wound and subsequent problems with healing.

Stress fractures

Stress fractures are particularly common in the tibia, particularly in runners. The patient initially complains of pain during exercise, then pain during and after exercise, and finally pain at all times. On examination there may be little to find except for the fact that the tibia may be tender to percussion. Initially the X-ray may be normal but after some weeks a faint haze of callous may form locally over the site of the invisible fracture. This X-ray, if combined with a history of continuous pain, is also characteristic for osteosarcoma. Careful imaging with MRI or CT scan should be able to distinguish these two diagnoses.

Low-energy direct blow fractures to the tibia

The tibia may be broken by a direct blow such as a bumper injury to a pedestrian. Despite the low-energy nature of the injury the skin and soft tissues may be damaged over the fracture, so the fracture may be technically open. If the fracture is a simple transverse fracture or a small butterfly fragment the fracture may be stable under compression. In this case nonoperative treatment will be best. If, however, there is a large butterfly fragment the fracture is likely to be unstable and treatment in plaster may lead to unacceptable shortening. Because of its subcutaneous position the tibia is ideally suited to the use of an external fixator (Fig. 23.36), except that the tibia is slow-healing bone and external fixators on the whole delay healing rather than stimulate it. Nevertheless, an external fixator offers a viable option where facilities for internal fixation are limited, or where it is felt that the damage to the skin and soft tissues over the bone makes the risk of internal fixation too high.

Operative technique for unreamed intramedullary nailing

The patient is placed supine on a fracture operating table and the tibia set either vertically with the femur horizontal or horizontally with the femur vertical with the tibia above the rest of the table. Either way, the opposite leg must be put in a different position so that the image intensifier facilities as the complication rate of this operation is high even in experienced hands.

Operative technique for unreamed intramedullary nailing

The patient is placed supine on a fracture operating table and the tibia set either vertically with the femur horizontal or horizontally with the femur vertical with the tibia above the rest of the table. Either way, the opposite leg must be put in a different position so that the image intensifier facilities as the complication rate of this operation is high even in experienced hands.

Management of stress fractures

This condition can prove very difficult to manage. It may occur at a crucial phase in an athlete’s training programme and at some stage, preferably sooner rather than later, it is going to become clear that training for the next few months, or indeed that season, is over. This can be very difficult for an athlete to accept, but until it is the condition is unlikely to settle. One problem may be the boredom that sets in if the significant proportion of the day, which was previously devoted to sport, is now to be spent resting. The alternative is to devise forms of exercise which are as strenuous and as time-consuming as the original activity, but which do not stress the tibia. For runners the nearest sport is cycling, a more remote possibility swimming. As the fracture is incomplete, it should not require any extra protection.

It may occur at a crucial phase in an athlete’s training programme and at some stage, preferably sooner rather than later, it is going to become clear that training for the next few months, or indeed that season, is over. This can be very difficult for an athlete to accept, but until it is the condition is unlikely to settle. One problem may be the boredom that sets in if the significant proportion of the day, which was previously devoted to sport, is now to be spent resting. The alternative is to devise forms of exercise which are as strenuous and as time-consuming as the original activity, but which do not stress the tibia. For runners the nearest sport is cycling, a more remote possibility swimming. As the fracture is incomplete, it should not require any extra protection.

Low-energy direct blow fractures to the tibia

The tibia may be broken by a direct blow such as a bumper injury to a pedestrian. Despite the low-energy nature of the injury the skin and soft tissues may be damaged over the fracture, so the fracture may be technically open. If the fracture is a simple transverse fracture or a small butterfly fragment the fracture may be stable under compression. In this case nonoperative treatment will be best. If, however, there is a large butterfly fragment the fracture is likely to be unstable and treatment in plaster may lead to unacceptable shortening. Because of its subcutaneous position the tibia is ideally suited to the use of an external fixator (Fig. 23.36), except that the tibia is slow-healing bone and external fixators on the whole delay healing rather than stimulate it. Nevertheless, an external fixator offers a viable option where facilities for internal fixation are limited, or where it is felt that the damage to the skin and soft tissues over the bone makes the risk of internal fixation too high.

Internal fixation can be performed using either a plate or an intramedullary nail. A plate cannot be fixed on the anteromedial border of the tibia because it is subcutaneous. If there is any soft tissue defect then a careful plan will need to be made with the plastic surgeons to ensure that cover of the fracture and plate can be obtained. This may mean rotating a musculocutaneous flap. A plate cannot be applied if cover cannot be obtained. Some surgeons apply bone graft to all tibial shaft fractures which are plated because of their reputation for poor healing.

The tibia is well suited to intramedullary nailing (Fig. 23.37), especially using the newer type of unreamed nail. Fixation can be obtained without unduly disturbing the fracture. Proximal and distal locking provides control of axial compression and gives rotational stability. A nail allows immediate mobilisation of the patient, although with the unreamed nail they should probably remain partial weight-bearing on crutches for the first 6—8 weeks. The technique can apparently be used without undue risk of infection even in open fractures provided that there is no significant contamination or major soft-tissue damage. The operation should only be performed by an experienced team with excellent X-ray image intensifier facilities as the complication rate of this operation is high even in experienced hands.

Operative technique for unreamed intramedullary nailing

The patient is placed supine on a fracture operating table and the tibia set either vertically with the femur horizontal or horizontally with the femur vertical with the tibia above the rest of the table. Either way, the opposite leg must be put in a different position so that the image intensifier facilities as the complication rate of this operation is high even in experienced hands.

A final check is made using the image intensifier to ensure that all screws are passing through the nail and engaged on both cortices (Fig. 23.38). A check is also made of the distal circulation. Postoperatively, sensation should be checked and the patient put under observation to ensure that circulation to the foot is maintained and that a compartment syndrome is not developing. The operation and immediate postoperative period should be covered with prophylactic antibiotics. The patient can start mobilising the next day but should remain on crutches until the fracture starts to unite. If the patient cannot be trusted to be careful then it may be wise to put on a plaster gaiter to protect
Management of the severely crushed tibia

In the high-energy injury to the tibia or where there are has been severe crushing, the fracture may be highly unstable, contaminated and surrounded by damaged soft tissues which cannot cover the fractures (Fig. 23.39). The patient will need resuscitating and a check made for other injuries. The neuro-vascular status of the foot distal to the fracture will also need to be checked. Where possible, Polaroid photographs should be taken and then the fracture site wrapped in sterile saline swabs. The management of this fracture is going to be by a team approach but the continuous re-exposure of the fracture for each member of the team to inspect should be avoided as this will increase the overall risk of infection. The first decision which will need to be made is whether the limb is salvageable at all or whether an early amputation will provide the quickest return of the patient to active life. In the case of land mine injuries, the damage appears to be more severe the further distal one goes and the decision on amputation can be a simple one. In isolated injuries of the tibia, however, the decision will depend on the age of the patient and the function of the distal limb. If the patient is elderly or the distal limb’s sensomotor supply is compromised then serious consideration must be given to whether the unit has the expertise to provide this patient with a sensate and functional foot and union of the tibia. The worst possible scenario is to find that the limb is not salvageable after a year of heroic effort. By then the patient’s morale will be sapped and amputation is unlikely to lead to a rapid return to independent living. In contrast, an early amputation followed by rapid rehabilitation through a limb-fitting unit might have allowed return to work within 6—8 weeks.

Complications of tibial fracture and their management

Loss of circulation to the foot

This is the most important complication and treatment must be started immediately. If the limb is angulated it should be put straight immediately in case the cause is merely kinking vessels to the foot. If this does not produce an immediate improvement in circulation and the patient is young enough for a repair of the vessels distal to the trifurcation to be a possibility, then arrangements need to be made immediately for surgery with an arteriogram on the table. In some units a temporary stent is inserted to start reperfusion of the foot before stabilisation of the fracture is attempted. In other units the fracture is first stabilised. Otherwise there is a risk of disrupting the vascular repair when stabilising the fracture. Hardware which may prevent the fracture significantly prolongs the warm ischaemic time of the foot so it is decided to stabilise the fracture first then this must be done as quickly as possible. When circulation returns to the lower limb there is a high probability of developing a compartment syndrome. Fasciotomies will usually be required.

Neurological damage to the lower limb

If the soft-tissue damage around the fracture is so extensive that the nerves cannot be repaired then primary amputation should be considered. An insensate limb is unlikely to be of any use to the patient. If the nerves are damaged in continuity, then some recovery can be expected and salvage of the limb should be attempted. In closed injuries it is likely that damaged nerve is in continuity and reasonable recovery can be expected provided that the blood supply to the foot is restored as quickly as possible.

Infection

Infection of closed tibial fractures should be rare but of open tibial fractures is common. All fractures with a puncture wound over them, however small, should be treated as open fractures with contamination. They are all treated in the same way. The skin edges of the wound should be excised and the wound extended so that a clear view of all damaged tissue can be obtained. Any dead and necrotic tissue should be removed and the wound should be washed out with several litres of saline. The wound should be left open and re-inspected at 24 hours. Again, any necrotic or contaminated tissues should be excised and the wound washed out. This process should be repeated until the wound is clean. When this occur delayed primary close can be performed. Throughout this time high levels of intravenous broad-spectrum antibiotics should be used aimed at covering Staphylococcus, Streptococcus and Clostridium. If infection develops when internal fixation is in place then the surgeon is caught on the horns of a dilemma. Stabilisation of the fracture is needed to bring infection under control but foreign material may be acting as a focus for the infection. If a nail is in place then exchange nailing may need to be performed under intravenous antibiotic cover. If a plate has been used then this too may need to be replaced and all infected tissue excised and the wound washed out. An alternative is to change fixation to an external fixator while removing all internal metal ware.

Compartment syndrome

A compartment syndrome may develop at any time in the first 48 hours after the accident or after surgery. The patient usually complains of severe unremitting pain with some numbness in the foot. The foot may be cold but there may still be pulses even though a compartment syndrome is developing. Passive Dorsiflexion of the toes produces severe pain in the leg. There are no reliable investigations for compartment syndrome and if the condition is suspected then the suspicion should be acted on.

Operation note for fasciotomies

The Mubarek fasciotomy is probably the most reliable form as it ensures that all four compartments are decompressed. An anterolateral incision allows the anterior and perineal compartment to be entered through one incision. Care is taken not to damage any nerves running in the fascia. The fascia is divided, first with a sharp knife and then with a pair of scissors, under direct vision. If a compartment syndrome is present the muscle will poult out a deep purple in colour, and if the fasciotomy was performed soon enough the muscle will then pink up. A second incision is then made posteromedially allowing decompression of the superficial and deep posterior compartments. The deep posterior compartment is the most likely site for a compartment syndrome. If any dead muscle is found it should be excised. Even if no dead muscle is found the wound should be left open and re-inspected at 24—48 hours when it will be easier to see whether muscle is dead or viable. At that stage all dead muscle can be excised and closure performed with a split skin graft or with a fasciotomy closure device (Fig. 23.40).

Nonunion

Atrophic nonunion of the tibia is not uncommon. The blood supply to the mid shaft of the tibia is not good and the soft-tissue cover is also minimal. High-energy trauma may strip the periosteum off the tibia and infection may further compromise healing ability. If after 8—12 weeks the tibia is showing no radiological signs of union then delayed union is occurring and may go on to nonunion. If a plate or nail has been used there is a risk that the metalwork will fatigue before the fracture unites. Bone grafting can be used to stimulate callus formation. If an intramedullary nail is already in place then exchange nailing may need to be considered to stabilise the fracture with a new nail which has not yet started to fatigue. Hypertrophic nonunion usually develops if there is too much movement at the fracture site. This is unlikely to occur if internal fixation or an external fixator is used but might occur if a plaster is used to hold the fracture.

Treatment. The fracture site should be opened and the cleft of the fracture cleaned of all fibrous tissue. Consideration should then be given to inserting a reamed nail or putting on a carefully moulded plate to compress the fracture ends and stabilise them. Bone graft should then be
put around the fracture site. The patient should only be mobilised under careful supervision of a physiotherapist.
injuries around the ankle

Minor injuries around the ankle must be one of the commonest presenting conditions in a casualty department. Most of these are minor sprains which only require RICE (Rest, Ice, Compression, Elevation). Nonsteroidal anti-inflammatory drugs may help the pain, reduce swelling and speed rehabilitation. A simple sprained ankle is usually the result of a patient going over on their ankle (an inversion and internal rotation of the foot on the tibia). On examination tenderness is confined, to the lateral side of the ankle and is localised over the ligament. The bone itself is not tender. More serious injuries to the ankle have a pattern characterised by the way in which the injury occurred. The injuries caused by inversion and external rotation of the foot on the tibia occur in a sequence. First, the posterior part of the distal fibula fractures off (Fig. 23.41). If the injury is more serious then the foot continues to rotate and the medial collateral ligament fails or the tip of the medial malleolus is pulled off. At this stage the ankle becomes unstable. Finally, if the force continues further, the posterior capsule fails by ripping off the posterior malleolus of the tibia, completely disrupting the ankle joint (see Fig. 23.42).

If the deforming force on the foot is pure inversion then it is usual for the lateral structures to fail first. There is either a rupture of the lateral ligament or avulsion of the tip of the fibula. If, however, only the ligament is ruptured the X-ray may look normal as there will be no fracture visible and the ankle at rest will lie in its normal anatomical position. If the ankle is stressed while the X-ray is taken, by holding the foot inverted using lead-protective gloves, the full extent of the injury will be immediately apparent on the X-ray (see Fig. 23.43). If the injury is more serious, and especially if there is a medial compression element to the fracture, then a vertical shear fracture may develop separating off the medial malleolus (see Fig. 23.44). Some of the standard forms of fracture pattern are shown in (Fig. 23.45).

Value of the history

The history may be helpful in defining what type of ankle injury is likely. Remember that the fracture may have occurred because the ankle was held stationary while the body continued to move. The patient’s description of the injury may need translating into the actual movements of the foot on the tibia and fibula.

Examination

The neurovascular status of the foot should always be tested first. In an ankle dislocation, the circulation to the foot may be compromised, as is the viability of the skin over the extruded talus. Reduction of the fracture is an emergency, if skin necrosis is to be avoided (see Fig. 23.46).

Palpation should start at the proximal fibular head. The Maisonneuve-type fracture is an external rotation of the foot on the ankle. The fibula rotates with the talus, avulsing the anterior diastasis but fracturing just below the knee at the fibula neck. The fracture is not normally noticed on an X-ray centred on the ankle, and therefore only clinical examination will reveal the tenderness which warns you to look for this fracture. Careful palpation down the full length of the fibula and on to the lateral collateral ligament will reveal whether there is likely to be a fracture of the fibula or a tear of the ligament. Similar palpation of the medial malleolus and deltoid ligament will give information about the medial side of the ankle. It is always worth including the fifth metatarsal head in this examination, as an inversion of the ankle can result in an avulsion fracture of peroneus tertius from the metatarsal head.

Investigation

Two X-ray views of the ankle will be needed. Most fractures are much better seen in one view than another. The posterior malleolar fracture is very difficult to see in the AP X-ray because it is obscured by the talus and the rest of the tibia. The posterior spiral fracture of the fibula is also difficult to see in the AP X-ray as it is hidden by the silhouette of the intact fibula. A very careful check should be made on the AP X-ray to make sure that the talus has not shifted in the mortice (the socket created by the fibula and the medial malleolus). If the joint space between the talus and the medial malleolus is wider than the joint space between the talus and the plafond of the tibia, then the diastasis ligament between the tibia and the fibula is likely to be disrupted or there is an unstable fracture pattern. If this state of affairs is left untreated then early aggressive arthritis of the ankle will result.

Unusual fractures of the ankle

A direct compression force, such as caused by landing on the feet from a height, can drive the talus up into the tibia, destroying the tibial plafond. The principle of management is the same as for any other fracture, reconstruction of a congruent joint surface. However, this can be very difficult to achieve.

Twisting injuries to the ankle in unusual positions such as full plantar flexion may produce a chip fracture of the talus (see Fig. 23.44.7). These fractures can be difficult to see as they can be very posterior and lie hidden behind the rest of the talus in a normal X-ray. A shoot-through view of the ankle joint in full plantar flexion should reveal the injury.

Footballers who use the front of the foot for kicking a ball can develop a prominent osteophyte on the front of the tibia, which can then fracture. The appearance of the ankle joint even before a fracture has occurred can be quite unusual because of the prominent osteophyte.

Management

If the injury to the ankle joint is stable with the foot plantigrade then the fracture can be treated in a simple plaster. This should be split for the first 24 hours to allow for swelling, but can then be closed. A very careful check should be made that the talus is stable within the mortice. If you are dealing with an unstable fracture pattern, then the plaster will need changing regularly to maintain a close fit as the swelling goes down. Regular checks using X-rays will also be necessary to make sure that displacement has not occurred.

It is important to keep the foot dorsifixed in plaster, otherwise a fixed flexion deformity of the ankle may develop within a few weeks. If the fracture pattern is stable then weight-bearing can be allowed, but the plaster will need to be reinforced with a foot piece or an external shoe to protect against wear. If the fracture is unstable then weight-bearing must not be allowed. If you feel that the patient is unlikely to understand or co-operate with this instruction, then a simple solution is to incorporate the knee in plaster fixed to 900. This effectively prevents them getting the foot to the ground, and increases the overall stability of the plaster.

If the injury is of such severity that the ankle joint is unstable and cannot be held in a stable configuration with plaster alone, then open reduction and internal fixation must be considered. Avulsion of the medial malleolus can be reduced and held with a lagged screw, while a vertical shear fracture may require lag screws and a buttress plate. The oblique fracture of the fibula is both more difficult to reduce and more difficult to fix and will require a third tubular plate applied anteriorly or posteriorly with lag screws across. Plates applied directly to the lateral side of the fibula are too bulky and prevent closure of the wound.

Timing of surgery
Unstable ankle injuries produce enormous swelling. If surgery is attempted when swelling is excessive then it will be impossible to close the wounds at the end of surgery, and a simple closed fracture will be converted into a complex open fracture. Surgery should therefore be undertaken within a few hours of the injury before the swelling has become too great. Otherwise the ankle should be elevated and a pneumatic splint used, if available, until the swelling has gone down enough for surgery to be possible. A simple test is to see whether the skin over the ankle is slack enough to create a small pucker with pressure between the fingertip and the thumb. If it is not, then it is too tight for surgery and the wound will not close (Fig. 23.48).

Postoperative care

The normal aim of internal fixation is to create a stable skeleton so that full mobilisation can be undertaken. This is unlikely to be achieved in ankle fractures. The purpose of internal fixation is to create a congruent ankle joint so that early arthritis is avoided. The ankle will still need protecting with plaster, and the patient will need to remain nonweight-bearing for at least 2 weeks and then partial weight-bearing until union has occurred. If a removable plaster is used then early active mobilisation of the ankle joint can be started under the supervision of a physiotherapist, so that stiffness is avoided and swelling is brought down as quickly as possible. Once bone union has occurred and ligaments are felt to be healed an intensive programme of physiotherapy is needed to restore full range of movement in the ankle, and to build up proprioception in the ankle joint. This is carried out using a wobble board (a small platform with a half-ball underneath which requires considerable skill to balance on). Patients should only be allowed to return to contact sport once they have regained full control of the ankle joint as otherwise they will simply repeat the injury.

Ruptured tendoachilles

This injury occurs most commonly in the middle aged. It occurs without warning and is often associated with strenuous exercise such as playing a game of squash. The patient describes hearing a sharp crack behind the heel, and may look around to see if she or he has been struck. There is immediate pain and weakness in the ankle. However, the patient may still be able to plantar flex the foot quite forcibly using the flexor digitorum and flexor hallucis longus. The diagnosis is therefore not as easy to make as might first appear. In a true rupture of the tendon there is swelling and tenderness over the tendoachilles about 3 cm above the heel. If it is possible to palpate deeply, a clear step can be felt in the tendoachilles, especially when compared with the other side. Sometimes the swelling is so great and the patient is in so much pain that it is not possible to feel this step. An alternative injury is a tear at the musculotendinous junction of gastrocnemius much higher up in the calf. Here the tenderness is much less well localised, some 10 cm above the heel and overall the calf is much more swollen. This injury has a completely different treatment and prognosis, and it is therefore important to distinguish between the two. If the patient is laid prone on the examination couch with their feet hanging over the edge, squeezing of the calf produces severe pain in a rupture of the musculotendinous junction, but in a true rupture of the tendoachilles there is little pain but the foot fails to plantar flex on pressure (see Chapter 20 on examination of joints).

Treatment

Treatment of the tear of the musculotendinous junction is immobilisation with the foot in full plantar flexion and non-steroidal anti-inflammatory drugs. As the pain and swelling go down, gentle mobilisation can be started. Healing is quick as there is a good blood supply.

Treatment of the ruptured tendoachilles is a completely different matter. There is a very poor blood supply, and if the ends are not brought into close apposition the tendon will either fail to heal or heal elongated. Either way, there will be a severe weakness of plantar flexion of the ankle. Non-operative treatment consists of putting the leg in plaster with the foot fully plantar flexed and the knee flexed to 90° initially to bring the tendon ends together. After 2 weeks the plaster is reduced to a below the knee plaster and the patient is allowed to mobilise on crutches. Over the next weeks, serial plasters are applied gradually bringing the foot up to a normal plantar grade position over a period of 6 weeks. The patient is then allowed to mobilise gently, but full activity is not allowed for a minimum of 3 months. There is a significant rate of re-rupture. Healing the second time is even slower and the likelihood of a fixed plantar flexion deformity even greater. Surgical treatment can be performed either percutaneously or under direct vision. The tendon ends are sutured together using strong nylon sutures. The stitches are very difficult to insert as the tendon is macerated and stitches tend to cut out unless they are placed very carefully. If the sutures are pulled too tight the tendon tends to bunch up and then it is impossible to close the wound. There is a significant incidence of wound breakdown and some people would question whether wound healing is any faster or the rate of re-rupture any lower in surgical repair compared with nonoperative treatment.
Injuries to the foot

The foot is very susceptible to crush injuries. Even if there are no fractures, the damage to the soft tissues causes swelling and stiffness, and is very slow to heal. Prevention is always better than cure, and in Britain all workers are obliged to wear steel-tipped toe-capped boots if there is a possibility of a heavy object landing on or running over their feet. Degloving injuries occur where there is a shearing force on the foot, such as occurs when a wheel of a vehicle runs over the foot. The injury may appear trivial with no fractures on X-ray and merely a blotchy area of skin over the dorsum of the foot. If this skin is insensate, then it is almost certainly been stripped from its underlying blood and nerve supply. Over the next few days the area will demarcate and necrose. In some cases the degloving is complete at the time of the accident (see Fig. 23.49), and it is clear that amputation is the only option. Minor degloving injuries require excision of all dead tissue and immediate grafting if the foot is salvageable.

Frostbite

The toes are particularly susceptible to frostbite, which may be quite painless initially and may not be noticed by the patient. Once again, prevention is far better than cure, and experienced climbers go to great lengths to make sure that frostbite is not setting in. Once it has occurred demarcation occurs over a period of days and, provided that the tissues do not become infected, simple excision of the necrotic areas can be performed when the boundary between dead and living tissue is clear (Fig. 23.50).

Fractures of the hind foot

The talus

Most of the surface of the talus is intra-articular, and so any fracture needs to be perfectly reduced if osteoarthritis is to be avoided. An extra complication is that the blood supply to the proximal half of the talus travels up the neck of this bone. A fracture across the neck leads to avascular necrosis in the same way as a fracture across the waist of the scaphoid bone. These fractures need early reduction and careful monitoring for the onset of avascular necrosis.

The calcaneum

Patients landing on their heels from a great height are likely to suffer a series of fractures passing through the body, including fractures of one or both heel bones. The bone tends to split and to crush. If the fracture is not reduced then the hind foot is greatly widened when it heals, making shoe fit difficult. The fracture lines commonly extend into the subtalar joint, and lead to pain and stiffness in the subtalar joint (Fig. 23.51). This makes walking difficult, especially on rough ground such as building sites. Open reduction and internal fixation of these fractures are extremely difficult because the anatomy of the fracture is difficult to see on ray and there is commonly massive bone loss in the body of the calcaneum (Fig. 23.52). Wounds in the hind foot are slow to heal and swelling may make closure of the wound difficult anyway. The technique should only be attempted in units with considerable experience and with special equipment for reduction and holding of fractures.

Fractures and dislocations of the midfoot

This injury, sometimes named a Lisfranc fracture, is commonly seen following head-on road traffic accidents where the feet are jammed between the pedals of the car. These injuries are a blend of fractures and dislocations combined with massive soft-tissue swelling. If they are not reduced the arch of the foot is lost and the foot becomes stiff and painful. Reduction is best performed under an image intensifier and Kirschner wires are used to transfix the midfoot to hold fractures and dislocations reduced (Fig. 23.53).

Fractures and dislocations of the toes

These injuries are common, and if they are stable when reduced can be treated symptomatically or with a buddy strapping (tapping the injured toe to the adjacent toe). If the fracture or dislocation is unstable then the toe can be held by transfixing it with a wire driven through from the distal phalanx into the metatarsal head.
Further reading

Education goal

To understand the importance of early diagnosis and aggressive treatment of osteomyelitis and septic arthritis so as to prevent the formation of chronic osteomyelitis and secondary osteoarthritis.
Learning objectives

• To know the importance of having a high index of suspicion for osteomyelitis and septic arthritis in the neonate.

• To recognise the value of blood cultures to isolate an organism before starting antibiotics.

• To learn the importance in giving high-dose intravenous antibiotics.

• To understand the importance of early drainage and washout of joints in preventing secondary arthritis.

• To recognise the common forms of crystal arthropathy.
Acute osteomyelitis

Pathogenesis

Acute osteomyelitis now commonly occurs in three different groups.

1. It can occur in the premature baby, possibly as a result of blood-borne spread of infection from intravenous cannulae or other portals.
2. Secondary to open fractures where there has been inadequate cleaning of a wound or it has been closed before it is clean.
3. Following joint replacement or open reduction in internal fixation of fractures where contamination of the bone has occurred.

Osteomyelitis of the neonate

An infant with acute osteomyelitis will be fretful and pyrexial and will not feed. The only clue to the underlying diagnosis may be the child failing to move one limb. Premature babies on intensive care are particularly susceptible, especially as they will have drips and arterial lines, all of which can act as a source for sepsicaemia. The infection may be remote from the source as the infection spreads through the bloodstream. Unlike osteomyelitis in older patients, the pathogen need not be *Staphylococcus aureus*. It may be *Streptococcus*, *Pneumococcus*, *Haemophilus influenzae* or even *Escherichia coli*. The key to successful treatment is a high index of suspicion leading to early diagnosis by blood culture. High-dose intra-venous antibiotics should be started as soon as possible but not before blood cultures have been taken. If the diagnosis and treatment are delayed, pus may collect either under the periosteum or within the medulla of the bone. The epiphyseal plate may be damaged and it will not be possible to bring the infection under control until the abscess has been drained.

Osteomyelitis in the neonate

- Premature are babies susceptible
- The baby may not move the limb
- Organism may not be *Staphylococcus*
- Antibiotics should be started as soon as cultures have been taken

Antibiotics must be started blind after blood cultures have been taken because if the disease can be sterilised within the first 48 hours of onset, complete resolution can be guaranteed. If, however, the diagnosis is reached more than 48 hours after the onset of symptoms, it should be assumed that there is a collection of pus and therefore surgery to drain this pus should be considered. Flucloxacinil should be given at a daily dose of 250 mg/kg in the very young child. Ampicillin 150 mg/kg should also be considered because it has a better spectrum against *H. influenzae*. If the child fails to settle rapidly, it must be assumed either that the organism is not sensitive to the antibiotic being used or that there is a collection of pus present which requires drainage.

Operation

**Drainage of pus**

Under general anaesthetic, the skin is opened over the most tender red area. The incision is carried down to the periosteum and when this is opened it is usual to find pus expressed at high pressure. This pus should be sent for culture. If no pus is found it is probably worth drilling through the cortex to make sure that there is no pus in the medullary cavity (**Fig. 24.1**).
Osteomyelitis in open fractures

Any fracture which connects to a wound in the skin must be managed as an open fracture. The haematoma around the fracture acts as a perfect culture medium if any organisms succeed in colonising it. The key to avoiding this situation is to open the wound, fully wash out the haematoma and remove any dead or contaminated tissue. The fracture should then be stabilised and the wound left open. The wound should then be checked every 24—48 hours until it is clear that all dead and contaminated tissue has been removed and clean granulation tissue is forming. Then, and only then, can delayed primary closure (DPC) be attempted.

Osteomyelitis in open fractures

• All open fractures are contaminated
• Wash out and remove dead tissue
• Leave wound open
• Only close once wound is clean
Osteomyelitis in association with orthopaedic implants

Orthopaedic procedures should always be performed in sterile conditions, preferably in an operating theatre with laminar flow. At least three doses of prophylactic antibiotics should be used, the first given 1 hour before the procedure starts, the second 8 hours later and the third 8 hours after that. There is no evidence that continuing antibiotics beyond this reduces the risk of infection. There is, however, good evidence that prolonged use of antibiotics increases the risk of producing multiple antibiotic-resistant staphylococci (MARS). Any organism introduced into the operative field effectively turns the exposed bone into an open fracture. The most likely organism will be *S. aureus* and therefore an antibiotic with good activity against this organism should be used. Flucloxacillin has excellent activity against *Staphylococcus*. If *Streptococcus* is a possibility, then penicillin should be added.

Preventing infection of orthopaedic implants

- Strict operative discipline with laminar flow
- Three doses of antibiotics starting 1 hour before surgery
- Reopen and wash out suspicious wounds and persisting haematomas

Features which suggest that an orthopaedic operation has become infected

Postoperatively, many patients have a pyrexia in the first 24 hours but it rarely goes above 38°C. If this pyrexia persists or the temperature goes above 38°C then a careful check should be made for a source of infection. This may be the lungs, urine or the wound itself. If a wound is infected it may appear red and swollen, and may start discharging old blood (Fig. 24.2). A persistently discharging haematoma is infection until otherwise proven. The patient should be taken back to theatre, the wound opened and deep samples taken for histology and bacteriology before any antibiotics are given. The wound should be carefully washed out and all dead tissue excised. Infection is more likely to occur in patients who are immunocompromised. The most common cause for this is diabetes or steroids.
Chronic osteomyelitis

Once osteomyelitis is established it is almost impossible to eradicate. The intraosseus blood vessels thrombose and the bone infarcts. Pus lifts the periosteum. If the process continues the pus ruptures through the periosteum, tracks into the soft tissues and may even discharge through the skin remote from the initial site of infection. The bone may die and form a sequestrum. The new bone formed by the periosteum which has been lifted is known as an involucrum. Once there is dead bone the infecting organisms have a permanent site where they can survive beyond the reach of the body’s immune system or of antibiotics. Any time that the patient’s resistance to infection is reduced, the infection can break out again and produce a septicaemia. Brodie’s abscess is a chronic abscess walled off in sclerotic bone. This can remain dormant for many years.

Treatment of chronic osteomyelitis

All dead tissue needs to be removed. If there is a fracture, this will need to be stabilised. If there was previous fixation which has become infected then this will need replacing. The dead bone is very sclerotic and extremely difficult to remove without causing a new fracture. It is also very difficult to be certain that all dead bone has been removed. If it is not, then the infection will recur. The introduction of the Ilizarov fixator and modern distraction techniques allow much more radical excision with a real prospect of reconstructing a functioning limb.

Chronic osteomyelitis

• Excise all dead tissue
• Take deep cultures
• Give appropriate antibiotics
• Reconstruct limb
Discitis of the spine

In the elderly, infection of the intervertebral disc can occur spontaneously. It may arise from haematogenous spread from a urinary tract infection through the lumbar plexus and commonly involves Gram-negative organisms. The infection is low grade and insidious in onset. The patient complains of increasingly severe back pain which is also present during the night, not just in the day during activity. The patient may have a low-grade fever and the white cell count and erythrocyte sedimentation rate (ESR) may be raised. The diagnosis can be difficult to make on X-ray because degenerative changes present in the elderly spine may make the characteristic signs of collapse of the disc space difficult to spot. However, if the diagnosis is considered, careful scrutiny of the X-rays may show a soft-tissue shadow swelling in the prevertebral space with destruction of the adjacent vertebral body endplates. Needle aspiration under image intensifier will allow the organism to be identified and its sensitivity determined. Treatment with the appropriate antibiotic, initially intravenously and then orally, should cure the condition.
Tuberculous osteomyelitis

Tuberculous osteomyelitis is rare and occurs following haematogenous spread from the primary focus in the lung or in the gut. In the spine it is usual for two adjacent vertebral bodies to be involved (Pott’s disease). The vertebrae collapse but the posterior structures remain intact, so the spine angulates into a kyphos. An abscess forms, which may put pressure on to the spinal cord or the nerve roots, but which also tracks forward in the prevertebral space. From there it follows fascia, and in the case of low thoracic or lumbar tuberculosis may follow the psoas muscle from its original origin to its insertion in the lesser trochanter of the femur. There the pus may track through the subcutaneous fat and discharge through the skin. There is little inflammation because the abscess cavity is remote from the point of discharge so it is a ‘cold’ abscess.

In the developed world, tuberculosis is again on the increase in patients who are immunocompromised either because of diseases such as acquired immunodeficiency syndrome (AIDS) or because they have been immunosuppressed. The organism is becoming increasingly resistant to standard antibiotics such as rifampicin. The failure of some patients, such as drug addicts, to comply fully with the treatment regime, further increases the risk of spread of antibiotic-resistant tuberculosis.
**Septic arthritis**

Arthritis caused by sepsis is a rare but important surgical emergency. Some organisms such as *S. aureus* may have a collagenase, which actually dissolves the articular surface. If the joint is not sterilised within 24—48 hours, irreversible damage will occur to the articular surface, which will inevitably lead to aggressive arthritis and even ankylosis (fusion) of the joint. Pus in the joint may interfere with the nutrition of the articular cartilage, which has no blood supply itself but derives nutrients from the synovial fluid. In acute arthritis the rapid accumulation of pus leads to a sharp rise in intra-articular pressure. This is extremely painful for the patient, but also tamponades the blood vessels in the capsule. This is the main blood supply to both the femoral head and the humeral head, and so avascular necrosis will occur if the pressure is not quickly relieved.

**Epidemiology**

Septic arthritis occurs most commonly in children but can also occur in adults whose resistance to infection has been reduced, such as diabetics, and can also occur after surgical intervention, such as arthroscopy. The onset is sudden with extreme pain in the joint. The patient may have rigors and will certainly feel shivery and generally unwell.

**Examination**

The joint may be red, hot and swollen, and held in the posi-tion of comfort (see Table 24.1). However, the most characteristic feature is the quite extraordinary amount of pain experienced by the patient when any attempt whatsoever is made to move the joint. If the joint moves even 10° the patient cries out with pain. If this sign is present, then both diagnosis and treatment run hand in hand. The pressure in the joint needs to be relieved without delay and the organism needs to be identified. Needle aspiration of the joint will provide fluid for microscopy and culture and start the decompression of the hip. In the child this will need to be done under a general anaesthetic, and is most easily performed using an imageintensifier. If pus is found in the joint then the best treatment is to proceed immediately to a complete decompression of the joint and wash out either through the arthroscope or by open arthrotomy. It is important that organisms are washed out of the joint as quickly as possible to prevent collagenase from damaging the articular surface. It is equally important that the pressure within the joint is reduced to normal to prevent avascular necrosis and to allow normal nutrition of the articular cartilage. Intravenous antibiotics should also be given as the patient is likely to be septicaemic (Fig. 24.5). The initial antibiotic should be chosen according to whether the organism identified at microscopy is Gram-negative or Gram-positive. The antibiotic can be changed later when the sensitivity is known.

**Late diagnosis of septic arthritis**

In immunocompromised patients the symptoms of septic arthritis may not be so florid, and initially the diagnosis may not be suspected. If it is likely that septic arthritis has been present for several days, then it is unlikely that the infection can be brought under control without a synovec-tomy, and the prognosis for the joint is poor. It should be splinted in a position of best function, as a painless arthrodesis will be the best outcome that can be hoped for. The position of function is not the same as the position of comfort, and therefore the joint will need careful splintage. After acute septic arthritis there is usually bony ankylosis. This provides a stable painless limb, but if the ankylosis is not solid, or if the joint has fused in a poor position, a formal arthrodesis may need to be performed once the infection has been brought under control. This operation will need to be covered with antibiotics, as it may produce a further recurrence of septicaemia.
Tuberculous arthritis

Tuberculous arthritis can be of slightly more insidious onset than acute septic arthritis, but nevertheless the pressure within the joint causes severe pain. The joint is held in the position of comfort but the redness and swelling may not be so pronounced. However, there is marked wasting of the muscles around the joint. The child will be very unwilling to move the joint, and the muscles around the joint may be in tight spasm, preventing it moving. This leads to the characteristic feature of ‘night cries’. When the child finally falls asleep the muscle spasm decreases and the joint moves. The child awakes with a characteristic cry of pain.

The treatment once again is decompression of the joint and identification of the organism as soon as possible, then treatment with the appropriate antibiotics. Synovectomy may well be useful, especially if the diagnosis is delayed (as is usual). In tuberculosis the ankylosis is usually fibrous and therefore unstable. Once the infection is brought under control there may then be a place for carrying out a formal bony arthrodesis with the limb in the position of function.
Tuberculous tenosynovitis

This is a rare condition. If it occurs in the hand a soft ganglion appears which seems to be multilobulated (the compound palmar ganglion). If this is drained surgically the characteristic finding will be of a synovitis with a synovial effusion full of fibrinous ‘melon-seeds’. The treatment is as for tuberculous septic arthritis.

Crystal deposition disorders

Gout, pseudogout and hydroxyapatite deposition are three types of crystal deposition in joints and around joints, and can cause pain and inflammation. In the long term they may actually cause destruction of the joint. They can be confused with infection.

Crystal deposition disorders

Type: Crystal deposited:
• Gout • Monosodium urate crystals
• Pseudogout Calcium pyrophosphate
• Chondrocalcinosis • Hydroxyapatite

Gout. Normally the patient is unable to metabolise purine normally. This leads to hyperuricaemia and orate crystal deposition in the joints. The condition is very common in men hut may be seen in women after the menopause. Most cases are congenital. Secondary causes can be divided into those resulting from overproduction of uric acid or failure of excretion. Myeloproliferative disorders may lead to tissue breakdown and overproduction. Any form of renal failure may prevent excretion.

Presentation. The patient suffers sudden attacks of acute arthritis and/or tendonitis as a result of monosodium urate crystals being deposited in the joint in tendon sheaths or in tophi. The patients may also be prone to renal calculi. Any minor trauma or a bout of drinking alcohol may precipitate an attack. This normally occurs in the first metatarsal phalangeal joint of the big toe, the ankle, the finger joints and the olecranon bursa. The joint becomes hot and extremely tender. The skin over it is tense and glassy. If the joint is aspirated birefringent crystals can be seen under polarised light. Those confirm the diagnosis. Chronic gout leads to degenerative changes in the joints. Tophi may form on the extensor surfaces of joints and in the ears.

Diagnosis of gout

• History — previous attacks, acute-onset arthritis
• Examination — hot, red, painful site
• Investigation — birefringent crystals in joint aspirate
• Differential diagnosis — septic arthritis

The differential diagnosis is septic arthritis. The patient will usually have had an attack before and will therefore know the diagnosis, but otherwise aspiration of the joint and the finding of crystals rather than pus will give the diagnosis. The X-rays are compatible with an erosive arthritis.

Treatment. The treatment is resting the joint and anti-inflammatories. Allopurinol can be used as a prophylactic agent hut must not be started during an acute attack. When it is started, a anti-inflammatory should be given at the same time, as otherwise it may actually cause an acute attack.

Pseudogout. Pseudogout involves the deposition of calcium pyrophosphate crystals. It is part of the normal ageing process of a joint. However, patients can develop an acute arthritis resembling gout. It normally occurs in large joints such as the knee. On X-ray the articular cartilage and menisci can be seen to be calcified. Once again, the diagnosis is made by finding birefringent crystals in the synovial fluid. An attack can be treated by aspirating the joint and injecting corticosteroid.

Hydroxyapatite deposition. Hydroxyapatite crystals can also be deposited in a joint, in a bursa or in a tendon sheath. They most commonly give problems in the shoulder, where they can be seen on ray as a small area of radio-opacity.

Treatment. The treatment of gout can be divided into the management of an acute attack and the prevention of future acute attacks in patients with an underlying metabolic disorder which predisposes them to further acute attacks.

Treatment of an acute attack of gout

• Analgesia
• Nonsteroidal anti-inflammatories
• Rest
• NOT allopurinol

Hyperuricaemia which is leading to acute attacks.
• Treatment. Allopurinol.

Management of an acute attack. The treatment is symptomatic with analgesia, nonsteroidal anti-inflammatories and rest. Check that any predisposing factors such as diuretics are stopped if possible.

Prevention of further attacks. Regular treatment with allopurinol should bring down the levels of uric acid in the blood and so reduce the chance of further attacks. However, allopurinol should not be started during an acute attack as in the short term it may exacerbate the condition rather than improve it. For the same reason patients need to be warned, when starting antimetabolism drugs, that an acute attack
may be precipitated.

This is a rare condition. If it occurs in the hand a soft ganglion appears which seems to be multilobulated (the compound palmar ganglion). If this is drained surgically the characteristic finding will be of a synovitis with a synovial effusion full of fibrinous ‘melon-seeds’. The treatment is as for tuberculous septic arthritis.

Education goal

• To understand that the majority of malignant tumours in bone is secondaries, and that a significant part of their management is palliative.
Learning objectives

• To understand the nomenclature of tumours in the musculoskeletal system.

• To learn the cardinal features of the history, examination and investigations which distinguish benign tumours from malignant ones.

• To learn the importance of making sure that the approach for the biopsy does not compromise further management of the tumour.
Introduction

Benign tumours of the musculoskeletal system are common and frequently show up as an incidental finding on an X-ray taken for other reasons. Metastases in the skeleton are also common, particularly from carcinoma of the breast, the prostate and the kidney. Primary malignant tumours of the musculoskeletal system are rare, apart from those arising from the marrow such as multiple myeloma and lymphoma.

Tumours are named after the tissue from which they have arisen. They can be identified from their shape and their staining. Benign tumours are given the suffix ‘oma’ and malignant tumours ‘sarcoma’ (see Table 25.1).
Benign tumours

Many of the benign tumours appear to have been present from birth and to grow with the child. They may be multiple, suggesting a problem in development, and if they are truly benign they stop growing when the child stops growing.

Osteochondromas are outgrowths of the bone, which may look much smaller on X-ray than they feel on clinical examination. This is because the outgrowth of bone has a large cartilage cap over it. Growths within the bones such as enchondromas may weaken the bone so that it fractures. The benign tumour is then diagnosed on X-ray with a pathological fracture running across it (Fig. 25.1).

Where possible, benign tumours should be left alone. There are, however, three indications for surgical intervention in a benign tumour (Table 25.2).

1. If there is doubt about diagnosis and a biopsy is needed to determine whether the tumour is, indeed, benign or malignant. In this case surgery should be planned as if the tumour is malignant, and an approach made which allows either complete excision of the tumour or an incision which will not interfere with further surgery later, if a massive implant or amputation is required.

2. If the bone is so weakened that a pathological fracture has occurred or is likely to occur. In this case the contents of the tumour can be curetted out and the cavity filled with chips of bone harvested from elsewhere in the patient.

3. If the bony protuberance is so prominent that it creates a cosmetic deformity or interferes with muscles or joints, so that the limb cannot function normally.
Distinguishing between benign and malignant tumours

This can be very difficult in the growing child, and is best handled with a team approach among the surgeon, radiologist and pathologist.

History

Malignant tumours are usually painful. Benign tumours are not. The pain of malignant tumours is very characteristic. Its most noticeable at rest, particularly at night. The site and the age of the patient will also give clues to the likely pathology.

Examination

A lump which has been present for a long time is unlikely to be malignant. Unfortunately, some benign tumours can turn malignant, so a sudden change in size or increase in tender-ness in what was previously thought to be a benign tumour should raise suspicions.

Investigations

X-rays

Benign tumours have well-circumscribed margins and may even have a thin rim of sclerosis around a lyric lesion. Malignant lesions do not have clear margins. A subtle, but important, sign is periosteal lifting over the site of the lesion (Fig. 25.2). This indicates inflammation and can be a clear sign of malignancy.

Periosteal lifting can also occur over a stress fracture and if there is underlying infection, so both these possibilities must be borne in mind when making a differential diagnosis.

Osteochondroma

These benign tumours are common and frequently multiple. The commonest site is in the femur or the tibia around the knee. There are commonly on a bony pedicle which grows away from the epiphyseal plate and which is covered in a large cartilage cap (Fig. 25.3). If they are large they can interfere with the function of the knee. Occasionally they become malignant and if they become painful the possibility of malignant change should be considered.

Osteoid osteoma

These benign tumours occur in children, adolescents and young adults. They are commonest in the femur and tibia but can occur elsewhere, even in the spine. They are unusual as benign tumours in that they produce a constant aching pain, which is most noticeable at night and is sometimes relieved by aspirin. They can be very difficult to see on plain X-ray where they may look like an area of slight sclerosis (Fig. 25.4). However, on tomography it may be possible to see the characteristic radiolucent centre. Osteoid osteomas also show up very hot on radioisotope scans. Surgical excision relieves the pain but they can be difficult to find at surgery so careful preparation is needed.

Chondromas

As their name suggests, these tumours are made up mainly of cartilage and are common in the hands and the feet. The medulla of the bone may be scalloped out (enchondroma) and there may be cortical thinning which may produce a pathological fracture. The condition of multiple enchondroma is called Oller's disease. Malignant change is not common but when many chondromata are present this risk is increased.

Fibroma

These appear as well-circumscribed lyric lesions in the cortex of bone. They can be difficult to distinguish from fibrous dysplasia, which usually has new bone within the lyric lesion. Another dysplasia, which can cause confusion with a tumour, is the aneurysmal bone cyst. This is an expanding lyric lesion most commonly found in the ends of growing long bones.

Osteoclastoma or giant cell tumour

These benign tumours are filled with undifferentiated spindle cells and multinucleate giant cells (Fig. 25.5). They are commonly found in the epiphysis of a bone, lying close to the epiphyseal plate. The cortex over the tumour may be destroyed and there may be periosteal elevation. They can be treated by block excision but, unfortunately, they are commonly closely associated with a joint. If they are rapidly growing or recur after excision they may be malignant and require more aggressive treatment.
Metastatic tumours

A pathological fracture through a metastatic tumour may be the first clue that a patient has malignant disease. Indeed, the primary may never be found. In other cases metastatic bone disease occurs some time after treatment of the primary tumour. The commonest source of metastases in bone is tumours of the breast, the prostate and the kidney. In patients who are suspected of having metastases, a radioisotope bone scan may show up lesions which are nor yet symptomatic, and which may not even be visible on X-ray (Fig. 25.6).

The management of metastases is excision, where these are isolated and relatively slow growing. In the majority of cases radiotherapy and/or chemotherapy can be used to slow the rate of growth of the lesion. If more than 50 per cent of the cortex is eroded over more than 2 cm then it is considered that the long bones are liable to imminent pathological fracture. Under these circumstances it is best to stabilise the bone before it breaks. In the femur, the tibia or the humerus, a prophylactic intramedullary nail can be used to support the bone. Even where a fracture has already occurred, stabilisation and radiotherapy will relieve the patient’s pain, allow them to remain mobile and may even allow the fracture to heal.

Before embarking on stabilisation of a metastatic lesion, it is always worth taking an X-ray of the whole bone and of the other long bones. It may be that other bones need fixing at the same sitting or that there are so many metastases that stabilisation of one will make no difference to the patient’s quality of life. Patients with multiple metastases may have a high serum calcium and this will need checking before embarking on a general anaesthetic. The risk of pulmonary embolus is also high, and patients need to be warned of this when giving their consent for surgery.

Primary malignant bone tumours

These are very rare indeed. The commonest of this rare group is the osteosarcoma. These tumours have very variable histology and occur either in adolescents or in the elderly secondary to Pager’s disease. The tumour is metaphyseal (usually the tibia or the femur) and is easy to confuse with a stress fracture or with an infected haematoma. If the diagnosis is suspected, the tumour should not be biopsied. The patient should be referred to a team of doctors who are com-petent to undertake the surgery, the radiotherapy, the chemotherapy and the counselling of the patient.

Imaging

Characteristically, there is periosteal lifting (Codman’s trian-gle) and ‘sun-ray’ spicules of new bone within the tumour. Magnetic resonance imaging (MRI) and computerised tomo-graphy (CT) scan may be helpful in determining the true extent of the tumour within the medulla (Fig. 25.7).

Treatment

The choice of treatment depends on the histological grading of the tumour, the age of the patient, the presence or absence of secondaries and the wishes of the patient.

If there is no evidence of secondaries, and it is technically possible, an amputation may be the treatment of choice with chemotherapy used to destroy micrometastases. Alternative-ly, radiotherapy and chemotherapy to shrink the lesion fol-lowed by a massive joint replacement may carry a higher risk of recurrence but may be cosmetically and functionally much more acceptable. If massive joint replacements are to be used in growing children, then designs need to be used which allow for lengthening of the limb as the child grows. Massive allografts using bones and joints from cadaver donors have limited long-term success, and have problems with rejection and the possibility of transmission of infection.

prognosis

Survival is dependent on the histological grading and the degree of spread, but in cure rates of around 50 per cent can be achieved.

Chondrosarcoma

This tumour commonly occurs in the pelvis, ribs or proximal long bones in middle-aged people. The tumour is lytic with ill-defined boundaries and has speckled calcification within its substance (Fig. 25.8). The grade of malignancy is very variable and is closely linked to the prognosis. Low-grade tumours have a survival rate of 75 per cent at 5 years, while high-grade tumours have a survival rate of less than 10 per cent over the same period.

Fibrosarcoma

These tumours occur most commonly in the metaphysis or diaphysis of the tibia or femur, but may also arise in soft tissue. They metastasise to the lungs and the 5-year survival rare is around 30 per cent.

Synovial sarcoma

This is a highly malignant tumour which metastasises through the blood supply, bloodstream and lymphatics. Five-year survival rare is low whatever treatment is attempted.

Ewing’s tumour

This tumour is commonest in childhood and arises in the midshaft or metaphysis of long bones. The child may present with pyrexia and have a high erythrocyte sedimentation rare, so the condition can be confused with osteomyelitis. Radio-logically, there may be multiple layers of subperiosteal new bone producing an ‘onion skin’ arrangement. Although the tumour is highly malignant, aggressive treatment with chemotherapy and radiotherapy has started to produce some survivors (see Fig. 25.2).
Summary

Bone tumours are rare. Most of them are secondaries. Tumours which appear to be primary bone tumours should only be investigated and treated at specialist centres. The quality of life of patients with bone secondaries can be improved dramatically with internal fixation followed by radiotherapy. Pain will be reduced and mobility maintained.

Jaffe, H.L. (1972) *Metabolic, Degenerative and Inflammatory Diseases of Bones and Joints*, Lea and Febiger, Malvern, PA.
**Educational goal**

To understand the presentation and underlying pathological process of the common metabolic and degenerative disorders affecting bone and articular cartilage.
Introduction

Bone is a living structure. It is continuously being broken down by osteoclasts and built up again by osteoblasts. It has a blood supply and a nerve supply, and is therefore subject to diseases and problems just like the rest of the body. Perhaps because of its relatively low rate of turnover it is unusual for a primary bone tumour to occur, but bone is a common site for secondaries. Similarly, bone infection is rare but when it does occur it is very difficult to eradicate.

Articular cartilage has no blood supply at all. It receives its nutrition from synovial fluid. Its powers of healing are therefore very limited. Once damage occurs, repair is difficult if not impossible. Further breakdown is inevitable, slowly at first, then more rapidly.
Disorders of joints

As mentioned above, the articular cartilage has no blood supply. It is nourished by the synovial fluid, the nutrients being produced by the synovial membrane. The nutrients diffuse through the joint, speeded by the movement of that joint.

Osteoarthritis (Fig. 26.1)

This is the common pathway for all diseases which damage the articular cartilage. The patient complains initially of pain on movement, and over a period the joint becomes stiffer and stiffer, gradually fixing in the position of maximum comfort. The muscles around the joint tend to waste and weakness sets in, further hampering the patient’s mobility.

Eventually the joint may actually collapse, the limb shortens and the joint may lose its normal alignment.

Examination

On inspection the joint may be slightly red and there may be swelling of the soft tissues, combined with muscle wasting. The limb is held in the position of comfort and may even be deformed. There may be some heat over the joint, and careful examination usually reveals at least a small effusion (although it can be very large). The osteophytes around the joint may be palpable and the joint line itself is often tender to palpation. Movement will be markedly limited and crepitus may be both palpable and audible. In osteoarthritis, the knee tends to fall into varus (bow legs), while in rheumatoid arthritis the knee falls into valgus (knock knees). The hip tends to flex into internal rotation, and the limb may actually shorten if there is bone loss.

Treatment

The early treatment of osteoarthritis is aimed at treating the pain and disability. Nonsteroidal anti-inflammatories may help with the pain. Physiotherapy should help to maintain mobility. It is said by some that weight loss improves symptoms. Walking sticks and household aids including a seat in the shower and handles around bathroom fittings may help the patient to maintain independent existence.

Once these nonoperative measures are no longer adequate, joint replacement should be considered in the hip, knee and the shoulder, as replacement in these joints now has good long-term results. Even so, in a young active patient, an arthrodesis should always be considered as an alternative. It is strong. It should give complete pain relief and can always be taken down and replaced with an artificial joint if necessary. Arthrodesis should only be considered when a single joint is affected, otherwise it transfers extra load on to already compromised joints.

Aetiology

Primary osteoarthritis develops spontaneously without any apparent predisposing cause.

Secondary osteoarthritis. This is the final common pathway after damage to the joint from some other cause. This may be traumatic, sepsis or inflammatory arthritis. Even repeated bleeds into a joint (as occurs in haemophilia) will cause breakdown of the articular cartilage, and multiple attacks of gout or pseudogout will have the same effects.

Underlying pathology of osteoarthritis

Articular cartilage is a complex structure made up of collagen and proteoglycan molecules which are highly hydrophilic and create the turgor pressure of the articular cartilage which gives it its strength and resilience. The joint surface itself is lubricated by a film of fluid squeezed out of the articular cartilage by the pressure applied. The first signs of osteo-arthritis appear to be some softening of the articular cartilage (or at least loss of this turgor pressure) followed by a break-down in the smooth surface. Microcracks appear in the articular surface (fibrillation) and pieces of the articular cartilage start to break off. These small fragments are mopped up by the macrophages in the synovium but this produces an inflammatory response. At the same time it appears that some form of repair mechanism is going on. This repair mechanism does not seem able to replace the articular cartilage in the load-bearing area of the joint. Instead, there is new bone formation and fibrocartilage laid down around the edge of the joint. This ring of new bone may be visible on the X-ray as osteophytes. The bone arcades lying immediately beneath the articular cartilage and which supported it now become more sclerotic, perhaps because of the increasing load coming on to the bone. The synovial fluid appears to break through the cartilage to create cysts in the subchondral bone. Finally the articular cartilage is completely worn away (eburnation) and there is direct articulation bone to bone. Pain may serve a protective function because in those joints lacking pain perception (Charcot’s joints) the disintegration of the joint is both more rapid and more severe. Eventually the bone itself breaks down and the joint collapses completely.

Cardinal features of osteoarthritis on X-ray

These include:

- loss of joint space;
- subchondral sclerosis;
- osteophytes;
- cysts.

Radiological features of osteoarthritis (Fig. 26.2).

These include:

- joint narrowing;
- osteophyte formation;
- subchondral sclerosis;
- cyst formation.
Rheumatoid arthritis

This is much rarer than osteoarthritis and occurs in a younger age group. Indeed, it can occur in children, when it is called Still’s disease. The disease is usually symmetrical and starts in the small joints of the hands and feet. Women are more commonly affected than men. As each joint becomes involved, it becomes red, stiff and painful. After a time the disease burns out in an individual joint, but the damage is done and secondary osteoarthritis now sets in.

History

Characteristically the patient complains of feeling generally unwell and the painful joints are most painful and stiff early in the morning when the patient first gets up. This is in contrast to osteoarthritis where the joint is usually most painful in the evening after a long day’s activity.

Examination

The skin over the joints is red and glassy. The soft tissues are swollen and in the late stages the joints may be subluxed or even dislocated. The skin may be hot to touch and the swelling of the soft tissues is often as much synovial thickening as a synovial effusion. The joint therefore feels doughy rather than having a simple effusion. The bones do not usually have palpable osteophytes. Normal movement is markedly diminished but the joint may be grossly unstable as the ligaments around the joint may have stretched, or the joint surface itself may have collapsed.

Treatment

The bulk of treatment for rheumatoid arthritis is nonoperative. Nonsteroidal anti-inflammatories, analgesics and immunosuppressants, including steroids, are routinely used, combined with splints and with physiotherapy. If these measures fail then surgery needs to be considered. In the early stages where there is massive synovitis but relatively little damage to the articular cartilage as yet, a synovectomy may slow the course of the disease and reduce damage to ligaments and tendons. However, the procedure is not easy to perform and the results are not impressive. Once the joint surface has been destroyed then joint replacement may be the only option. Arthrodesis does not work well in rheumatoid arthritis as the bone is soft and other local joints are involved by disease. Paradoxically, joint replacement works well in rheumatoid arthritis and can be used in the hip, knee, shoulder, elbow and even the metatarsal phalangeal joints. However, fusion of the wrist remains the best solution for severe rheumatoid arthritis of this joint.

Pathology

A pannus of inflammatory tissue spreads from the margin of the joint, across the articular cartilage, creating inflammation in the joint and destroying the articular cartilage. The bone around the joint becomes osteoporotic, possibly because of hyperaemia, and because of disuse. In the late stages the joint may collapse completely.

Charcot’s joints — neuropathic joints

Any joint which has lost its nerve supply seems to be susceptible to a particularly aggressive form of arthritis. The condition was originally described with tertiary syphilis but can in fact occur whenever the sensory supply to a joint is affected. There is massive joint destruction combined with new bone formation producing a very disorganised joint in a patient who is complaining of surprising little pain. Once seen it is never forgotten.

Nonspecific seronegative arthritis

Not all arthritis is either osteoarthritis or rheumatoid arthritis. Acute onset of pain in joints can occur secondary to a viral infection or indeed for no known cause. The treatment is symptomatic with anti-inflammatories, splints and physiotherapy.

Chondromalacia patellae — anterior knee pain

This condition occurs in adolescents, particularly girls, and may initially be brought on by a blow to the knee. The patient complains of severe pain in the knee which is worse going down stairs and if they are obliged to sit still for any length of time. After this period of rest any attempt to move the knee is extremely painful and may cause them to collapse. On examination there is surprisingly little to see. There is no redness or swelling and there may be very little thickening of the synovium and no effusion. Range of movement is good but there may be crepitis from the patella. The synovium around the patella is tender to palpation.

This condition can also be caused by maltracking of the patella but in the majority of cases there is no obvious cause to be found.

Luckily, the condition is usually self-limiting and treatment is symptomatic using nonsteroidal anti-inflammatory, splints and physiotherapy and trying to keep the patient as mobile as possible within the limits of pain.
Diseases affecting bone

Paget’s disease

This condition seems to involve a dramatic increase in both osteoclasts and osteoblasts in the bone. The bone starts to remodel far too rapidly. The patient complains of bone pain, and over a period of years the bone may gradually change shape, producing a characteristic bowed tibia and an enlarged skull. One bone may be involved in isolation, or several bones can be involved at the same time. The condition becomes increasingly common with age, affecting as much as 10 per cent of the very elderly. The X-ray findings of the bone are quite characteristic. The abnormal bone may suffer a pathological fracture. This fracture can be difficult to manage because the bone is deformed and because any attempt to pass a nail down the medulla may produce significant loss of blood. The cortical bone is also extremely hard and it can be very difficult to make drill holes for screws. Surgery on pagetic bone should be approached with great caution by both surgeon and anaesthetist (Fig 26.2 and Fig 26.3).

Osteoporosis

This condition is becoming increasingly common in the Western world in the elderly but especially in postmenopausal women. It is believed to be related to a fall in oestrogen. The remodelling activity of the bone appears to fall away but osteoblastic activity falls more rapidly than osteoclastic, so there is a gradual thinning of the cortex and trabecular pattern of the bone. The bone gradually weakens until trivial trauma leads to a fracture. The common sites for a fracture are the neck of the femur, a crush fracture of the lumbar or thoracic spine, the head of the humerus and the distal radius. The fractures heal normally but can be difficult to hold with internal fixation because the bone is so soft and spongy.

Rickets/osteomalacia

The failure of bone osteoid to mineralise is called osteomalacia. In children, the disease is called rickets. The cause is a deficiency in vitamin D or in its metabolism. Vitamin D is produced in the skin when exposed to sunlight. It is also absorbed in the diet and is fat soluble. If the patient has a malabsorption syndrome, then vitamin D deficiency may occur. In the body vitamin D is converted to 25-hydroxycholecalciferone in the liver, then to 1,25-dihydroxycholecalciferone in the kidney. In children who lack vitamin D, either because of diet or because of an inbuilt error in metabolism, the costochondral junctions enlarge to form the ‘rickety rosary’. The skull develops frontal bosses and the long bones bend, especially the lower third of the tibia. The child is also small. Serum calcium and phosphate are normal but alkaline phosphatase is usually raised. In adults bone deformity is not so marked but the patient may complain of marked muscle weakness. Lytic lesions may appear in the bone called Looser’s zones. These are particularly common in the pelvis and may cause a pathological fracture.

Hyperparathyroidism

If for any reason there is excessive production of parathormone there is increased osteoclast activity which leads to lytic lesions in the bone, similar to those seen in osteomalacia. These are called ‘Brown tumours and fractures may occur through these. The osteolytic lesions are particularly characteristic in the terminal phalanges and the alveolar margins of the jaws. The patient’s serum calcium is raised and serum phosphorus is lowered with the alkaline phosphatase slightly raised. The treatment is to manage the underlying endocrine condition but fractures should be treated as normal and will heal well.

Ankylosing spondylitis

This progressive disorder has some features in common with rheumatoid arthritis. It is much more common in men than women and starts with the central joints of the body. The ligaments around the joints calcify and then ossify, freezing the patient into their deformed position (Fig. 26.4). The tissue antigen HLA-B27 is very common in patients who have ankylosing spondylitis but is rarely found in the normal population. It is therefore diagnostic.

History

The condition starts in early adult life, and starts with painful stiff joints.

Examination

Reduction of chest expansion is an early physical sign.

Investigation

As mentioned, the HLA-B27 antigen will be positive. The erythrocyte sedimentation rate may be slightly raised and X-rays of the sacroiliac joints show early obliteration with ankylosis. An X-ray of the spine may show ossification of the spinal ligaments (bamboo spine; Fig. 26.5).

Treatment

Early treatment with anti-inflammatories and physiotherapy can reduce the disability. In cases where gross flexion of the spine has occurred an osteotomy can be performed but this is not without risk of causing paraplegia. If the disease includes the hip joints then total hip replacement will help.

Introduction

Children’s orthopaedics is different from its adult counter-part because growth is still taking place. This can work for or against the child and surgeon. On the positive side there are great powers of remodelling and recovery (Fig. 27.1). Conversely, a growth plate injury or congenital shortening of a limb will produce progressive deformity (Fig. 27.2).

The understanding of children’s orthopaedics is helped by a knowledge of its terminology (Table 27.1 gives examples).

Many orthopaedic conditions are congenital, i.e. present at birth. Some are immediately obvious, for example the absence of a limb; others such as cerebral palsy or developmental dysplasia of the hip may not be clinically detectable at birth but declare themselves later. In addition, some acquired conditions arise against a background of genetic susceptibility, for example immune deficiency predisposing to infection. Finally, children present great variation within the spectrum of normality (e.g. gait pattern), while others have conditions such as postural abnormalities which are self-limiting. These may cause great concern to a family. Clinical assessment and explanation must be just as thorough as for a child with an obviously severe condition.

Figure 27.3 presents a helpful system for treating orthopaedic conditions in childhood.

The term ‘orthopaedics’ (straight child) originally referred to correction of deformity in children. The speciality generally has expanded beyond all recognition and this includes shortening.

Not only has deformity to be addressed, often with sophisticated technology for investigation and treatment, but the children’s orthopaedic surgeon is concerned with a much wider range of musculoskeletal disease, along with closer involvement in the general care of the child in the community. The role of the orthopaedic surgeon may be primary or secondary, according to the overall needs of the child.
Normal variants and self-limiting conditions

The range of normality in the development of the musculoskeletal system is wide (Table 27.2). At all ages the appearance of a child's limbs or spine includes the components of rotation, angulation and joint laxity. When these are added to the natural clumsiness of a developing youngster it is not surprising that parents may be concerned whether their off-spring is normal. Therefore, all consultations must be thorough and sympathetic.

Common reasons for referral are intoeing, bow legs (Fig. 27.4), knock-knees and flat feet (Fig. 27.5). None can be judged in isolation. For example, intoeing (foot progression angle) is the result of the various torsional and angulation components within the femur, tibia and foot.

For example, the child in Fig. 27.6 is normal. The condition is symmetrical and symptomless, the joints are supple and there is no evidence of skeletal dysplasia or systemic disease such as neurological or metabolic condition.

Conversely, the child in Fig. 27.7 is abnormal. There is asymmetry and evidence of a systemic disorder (rickets).

Self-limiting conditions (Table 27.3) are outside the definition of normal variance because they do not fulfil the 'five Ss' rule. They include postural deformities such as calcaneo valgus (Fig. 27.8), moulded baby syndrome ( plagiocephaly, infantile scoliosis, tight hip adductors), metatarsus varus (Fig. 27.9) and 'growing pains'. Asymmetry, stiffness and symptoms may be present. The conditions usually correct spontaneously or with minimal treatment such as stretching exercises.
Congenital disorders

These may be intrinsic malformations within a developing structure (e.g. limb deficiency) (Fig. 27.2), or the result of extrinsic influences, for example postural (Fig. 27.6), neuro-muscular (Fig. 27.10) or a malformation elsewhere (Fig. 27.11). Regularly, however, we do not know why a congenital abnormality (e.g. talipes equino varus) has occurred.

Nowadays, diagnostic ultrasound can detect musculoskeletal abnormalities in utero. This technology is creating both opportunities and difficulties in the management of an unborn child. Whatever the cause, a significant abnormality diagnosed prenatally or at birth can be devastating to a family. Support and advice from a wide range of experts may be required.

Malformations of the limbs and spine

Musculoskeletal structures develop alongside other body systems. By the 12th week of intrauterine life the spine and limbs are formed, the upper limbs slightly ahead of the lower. Examples of how embryological structures can stray from the path of normal development are shown in Table 27.4.

Because the various organs are developing concurrently, the causes of malformation may affect more than one system. Therefore, when presented with a limb anomaly one should consider associated abnormalities in, for example, the cardiovascular, urogenital or nervous system.

However, in most cases the children are usually otherwise normal and develop and function well. They are regularly well motivated and do not admit to any disability in spite of obvious physical abnormality. These aspects have to be understood when considering treatment.

In the majority of cases there is no obvious cause, such as thalidomide. Occasionally a genetic (especially in skeletal dysplasia) or syndromic association [e.g. thrombocytopenia, absent radius (TAR syndrome)] is possible.

Congenital malformations

Failure of formation

These cases may present as multiple complex abnormalities (Fig. 27.12) or fit recognisable patterns of deformity (Fig. 27.13). The defects may be classified as transverse [e.g. con genital amputation through a limb] or longitudinal (e.g. femoral deficiency (Fig. 27.13) or radial club hand (Fig. 27.14)). A longitudinal deficiency may be florid [e.g. tibial dysplasia (Fig. 27.15)] or subtle [e.g. congenital pseudoarthrosis of the tibia (Fig. 27.16)]. The limb beyond the defect may be normal (Fig. 27.17) or abnormal (Fig. 27.2).

Femoral deficiency. This ranges in severity from a short femur to total absence. Treatment varies accordingly.

A short femur may be amenable to lengthening. The commony associated coxa vara may require correction before-hand by valgus osteotomy.

More profound degrees are beyond the limits of surgical leg equalisation. However, children usually function well in an extension prosthesis (Fig. 27.18). Indeed, there is a debate whether a child with a congenitally short limb is better served by complex leg equalisation surgery with its regular complications and joint stiffness or by early mobilisation in an extension prosthesis.

Fibular deficiency (Fig. 27.2 and Fig. 27.17). In this condition the tibia is short and bowed anteriorly, often with an overlying skin dimple. The fibula is wholly or partly absent. The foot is in equino valgus and commonly shows deficiency of the outer rays. The condition also affects the whole limb. There is mild femoral shortening and genu valgum and often the cruciate ligaments are absent.

Treatment is dominated by the overall predicted shortening and the state of the foot. A child with marked shortening and a deformed residual foot is best served by a Syme’s amputation at about 1 year. If the foot is normal, it is reasonable to consider correction of the equino valgus deformity and equalisation of leg lengths. This may require a combination of lengthening of the affected tibia and a shortening procedure, for example epiphysiodesis on the normal side.

Tibial deficiency (Fig. 27.15). The tibia is wholly or partially absent. The foot is in equino varus and, in contrast to fibular deficiency, may be augmented (e.g. polydactyly or diplodopia).

Reconstruction of the foot is usually unsuccessful except in mild cases. If the tibia is absent a ‘through the knee’ amputation is indicated. If there is a tibial remnant a good option is to fuse the fibula with this and fit the child with an extension prosthesis. It is thereafter usually preferable to amputate the foot to allow better fitting of the prosthesis.

Congenital pseudoarthrosis of the tibia (Fig. 27.16). This is a subtle longitudinal defect causing anterolateral bowing in the lower tibia. The condition may be associated with neurofibromatosis or fibrous dysplasia. The deformity regularly progresses to a beastly fracture for which treatment is difficult and prolonged. The whole armamentarium of the fracture surgeon can be involved including intramedullary fixation, traditional and advanced grafting techniques (e.g. vascularised fibular graft and the Ilizarov method). Even then the pseudoarthrosis may not heal and amputation becomes inevitable in a minority of cases. The prepseudoarthrosis and the treated pseudoarthrosis should be braced until skeletal maturity.

Congenital pseudoarthrosis of the clavicle (Fig. 27.19). This defect of the midshaft of the clavicle is probably related to the development of the subclavian artery as it occurs on the right side unless there is dextrocardia.

The main problem is cosmetic, although there may be discomfort. If treatment is undertaken the options include excision of the defect with repair of its periosteal sleeve or fixation and grafting.

Infantile coxa vara. There is a defect of ossification in the femoral neck, leading to a varus deformity usually requiring corrective osteotomy.

Failure of separation

Syndactyly (fingers and toes) (Fig. 27.20). Three types are described, simple (soft tissue only), complex (bones involved) and acrosyndactyly (digits joined at their tips). Syndactyly as a regular component of syndromic conditions (e.g. Apert’s syndrome, constriction ring). Where possible fingers should be separated, although the techniques are demanding and involve flaps and skin grafting. Separation of toes is rarely
indicated.

Radionulnar synostosis. The fused radius and ulna are shorter than their counterparts. Abduction of the shoulder effectively mimics pronation. Therefore, a forearm fixed in neutral rotation or slight supination can be compensated by the shoulder and this allows virtually normal hand function. A forearm fixed in pronation cannot be thus compensated and in such cases a rotation osteotomy to bring the hand to the neutral or slightly supinated position may be indicated.

Tarsal coalition. The usual patterns are calcaneonavicular (Fig. 27.21) or talocalcaneal fusions by cartilaginous or bony bars. There may be pain as well as stiffness, particularly in eversion, and the condition is also known as peroneal spastic flat foot. There may be an associated ball and socket ankle joint. The calcaneonavicular bar can be demonstrated by plain radiographs, whereas computerised tomography (CT) best visualises the talocalcaneal bar. If conservative measures (e.g. analgesics, orthotics) fail, excision of the bar may be indicated. If degenerative changes ensue, arthrodesis may ultimately be required.

Vertebral and scapular anomalies. Vertebrae and ribs may be fused with resultant scoliosis and/or chest wall deformity. Regularly, there are associated abnormalities within the spinal column (e.g. diastomatomyelia) and elsewhere (e.g. urogenital and cardiac systems).

Klippel–Feil syndrome. This comprises multiple congenital abnormalities in the cervical spine leading to a characteristic short, stiff neck and a low hairline. Torticollis, facial asymmetry and webbing of the neck may be apparent.

Sprengel shoulder. This is due to a failure of normal descent of the scapula which remains high and small (Fig. 27.22). There may be a bony tether, the omovertebral bar, between scapula and spine, which is also prone to anomalies.

Treatment is largely for cosmetic reasons. Excision of the superomedial portion or displacement osteotomy of the scapula is a better option than attempts to reposition the whole bone.

Gigantism

A whole limb (Fig. 27.23) or part (Fig. 27.24) can be affected. The condition may be idiopathic or associated with neurofibromatous or a vascular malformation. The gigantic part is distressing for the child and family. Procedures such as debulking and growth arrest are usually unsuccessful. The best results are from amputation, where this is a realistic option.

Polydactyly

Extra digits can be an isolated abnormality, part of a pattern of limb malformation (e.g. tibial deficiency with diplodia) or syndromic, as in chondroectodermal dysplasia (Ellis—van Creveld syndrome) which consists of short-limbed dwarfism, dysplastic nails, hair and teeth, polydactyly and congenital heart disease.

Extra digits usually require removal. It is sometimes difficult to know which digit to sacrifice (Fig. 27.25).

Skeletal dysplasias

These generalised disorders of the skeleton are often genetically determined. They may affect the whole or part of a bone. In some, for example osteogenesis imperfecta, the condition is a generalised disorder affecting connective tissue.

They characteristically produce skeletal deformities and abnormal stature. Although uncommon, they pose complicated problems in management. Their detailed description is out with the scope of this book but it is possible to summarise them along with suitable examples.

They can be categorised into major groups shown in Table 27.5.

The diagnosis is from clinical data, especially comparing the patient’s measurements with standard growth charts, radiographs (typically a skeletal survey) and further tests (e.g. biochemical). In some cases the diagnosis can be made by ultrasound.

Osteogenesis imperfecta (OI). This relatively common dysplasia (incidence 1:20 000 births) is caused generally by an abnormality of collagen type I and thereby all connective tissues are involved. The joints are loose, bones bend and break, teeth can be abnormal (dentinogenesis imperfecta, DI) and there may be neurological and gastrointestinal problems. The care of these children as with many other dysplasias becomes multidisciplinary. In severe types the children are unable to walk through weakness and deformity. Other methods of locomotion must be used (e.g. bottom shuffling, crutches, wheelchairs).

Four broad types of OI are described but it is not always possible to thus classify a patient.

• Type 1(a) — the classic form; blue sclerae, autosomal dominant inheritance and the mildest clinically. Children and adults can be reasonably active with precautions. A neurological problem is premature deafness.

• Type II — lethal perinatal form.

• Type III (Fig. 27.26) — severe deforming type. Autosomal recessive. Multiple fractures. The children rarely achieve walking. DI is common.

• Type IV — as for type 1 but the children are less active and the sclerae are normal. DI is common.

The diagnosis of OI is usually possible from clinical data and radiographs. These can show classical appearances in the limbs, spine and skull (osteopenia, deformities, vertebral collapse and Wormian bones in the skull). However, there are borderline cases which pose great difficulties, especially if the differential diagnosis includes nonaccidental injury. There is yet no test which will unequivocally confirm the diagnosis of OI.

Treatment depends on the individual and the severity of the condition. Any advice must be given within the context of what goals are achievable.

Much can be done through occupational therapy, orthotics, seating and general paediatric care.

The orthopaedic surgeon can help with deformity correction and intramedullary stabilisation of long bones using rods or wires. These can prevent recurrent fractures and help those children who are strong enough to stand and walk.
The value of treatments to increase bone strength (e.g., bisphosphonates) remains unproven.

Osteopetrosis. The bones are dense, hard and brittle. The milder tarda form is autosomal dominant; the severe congenital type is recessive. Death may occur from lack of bone marrow. Distortion of the orbits may cause blindness. Bone marrow transplantation can be successful.

If fractures need fixation, special instruments are needed to overcome the hard bone.

Hereditary multiple exostoses (diaphyseal aclasis) (Fig. 27.27). This is a relatively common, autosomal dominant dysplasia. Cartilaginous-capped exostoses occur at the metaphysis and the osteochondromas grow with the child and stop growing at maturity. The lumps may cause mechanical or cosmetic problems which justify their removal. There may be differential growth disturbances in the forearm or leg leading to ankle, wrist and elbow deformities. Distortion of growth plates may cause, for example, genu valgum. All of these deformities may require surgical correction.

Malignant change in an osteochondroma (chondrosarcoma) is possible, usually after skeletal maturity. The combination of pain and/or enlargement is an indication for further investigation.

Disorders of the epiphyses. Multiple epiphyseal dysplasia can be autosomal dominant. It causes irregular epiphyses which, in the hip can be confused with bilateral Perthes' disease. The hips and knees are prone to early degenerative change.

In spondyloepiphyseal dysplasia the vertebrae are also affected and there may be instability of the atlantoaxial joint.

Disorders of the metaphyses. These result in short stature and deformities such as genu varum which require correction (Fig. 27.28).

Achondroplasia. This is the commonest cause of short-limbed dwarfism (Fig. 27.29). The inheritance trait is autosomal dominant, although many cases arise as new mutations.

The limbs are short with wide metaphyses, there is lumbar lordosis, the forearm bulges and the nasal bridge is low. Trunk height is maintained but spinal stenosis is common.

Cleidocranial dysostosis. This generalised dysplasia includes partial or complete absence of clavicles, ossification defects in the skull, abnormal dentition and a wide symphysis pubis. The absence of clavicles allows the shoulders to be brought together in front of the chest (Fig. 27.30).

Storage diseases. In the mucopolysaccharidoses, the intermediate metabolites of the partial degradation of glycosaminoglycans are stored in various tissues including bone marrow and connective tissues.

The specific enzyme defects responsible for the various types of storage disease (e.g., Hunter's disease, Morquio's disease) are becoming well known. Bone marrow transplantation can be successful in certain types.

The clinical manifestations include short stature, limb deformities, coarse features, stiff joints, expanded bones, mental retardation and carpal tunnel syndrome.
Congenital deformities

Developmental dysplasia of the hip (DDH)

This term is more accurate than the older congenital dislocation of the hip (CDH) because it includes dislocation along with other less severe forms, all of which have in common a dysplasia or natural shallowness of the acetabulum. The femoral neck is usually anteverted.

There is a wide spectrum of presentation of DDH from birth to adult life. The condition can manifest as a neonate with clinical hip instability (Fig. 27.31), an infant with limited abduction (Fig. 27.32), a limping toddler (Fig. 27.33), a child or adolescent with dysplasia (Fig. 27.34), or an adult with established degenerative change (Fig. 27.35).

Incidence

This is highest in the neonate where environmental factors such as breech presentation, transient ligamentous laxity and the skills of examiners can influence the rate of detection of instability.

The incidence depends on the criteria by which the diagnosis is made. The rates of detection of neonatal instability in some series approach 20 per 1000 births, whereas the incidence of late presenting dislocations (after the age of 3 months) is generally in the order of 0.5—1 per 1000. The inference is that many cases will stabilise spontaneously and this creates a dilemma for the surgeon as to which cases should be treated.

Aetiology

Many factors are related to DDH (Table 27.6). A family history of DDH increases the risk up to 30 times. The condition is five times more common in girls, possibly related to hormonal factors producing joint laxity. The left side is affected more commonly than the right.

Breech presentation, especially the extended position, first-born children and caesarean section are associated with increased neonatal instability, possibly through restricted foetal movement.

A foot deformity or torticollis should also alert the examiner to possible associated DDH. Finally, there may be hip dislocation or dysplasia in association with neuromuscular disease syndromic conditions and skeletal dysplasia.

Diagnosis

Neonate. The clinical examination is only part of the general examination. All newborn babies should be screened for hip instability by a skilled examiner using the Barlow and Ortolani tests (Fig. 27.31). The baby should be relaxed and the hips flexed to 90 degrees. It is possible to reduce a dislocated hip by abduction and gentle forward pressure (Ortolani) or dislocate an unstable hip by adduction and gentle backward pressure (Barlow). In both cases a soft clunk is felt as the hip reduces or dislocates.

The specificity of clinical neonatal examination is 100 per cent (no false positives). However, its sensitivity is much lower; even skilled examiners are unable to eliminate late diagnosed cases.

Ultrasoundography is a valuable test. It is more sensitive than clinical examination and can detect not only displacement of the femoral head but also varying degrees of dysplasia. Therein lies its weakness for it tends to overdiagnose the condition and thus subject babies to unnecessary treatment. Also, it is very difficult to deliver universal ultrasound screening to communities where the population is mobile, the time in hospital is short, and obstetric and imaging services may be geographically separated.

Radiography can be helpful in the neonate provided care is taken in positioning the patient. However, X-rays are not generally reliable until approximately the age of 3 months (Fig. 27.36).

Infant. The hips should be examined as part of routine developmental checks, looking in particular for asymmetry, such as an extra thigh crease, shortening of a limb or limitation of abduction (Fig. 27.32).

Child. The child limps, the affected leg is externally rotated, there is an increased lumbar lordosis, and there is regularly an extra thigh crease and limited abduction. However, the signs may be subtle (Fig. 27.33) and easily misinterpreted as part of normal development in an unsteady toddler. A bilateral case is more difficult to diagnose because the gait is symmetrical. Indeed, the condition may be missed until late in childhood.

Adolescent. Pain is the usual feature and an X-ray will reveal dysplasia and possible subluxation.

Adult. Pain is again the usual complaint and X-rays may now show degenerative change as well as dysplasia (Fig. 27.35).

Treatment

Although the details of treatment vary at different ages the principles are the same (Table 27.7) and should all be considered before deciding which one is appropriate for an individual case. The objective is a stable congruous reduction through gentle methods so that the fragile growth plate is not damaged. Such an event (avascular necrosis) is a major complication and usually results in shortening, coxa vara and a greater trochanter, which is high because its growth plate is not affected.

Infant. Traction and surgery are not indicated. The hips can usually be reduced (Ortolani) and should then be held in a harness or splint (Fig. 27.37) for about 8 weeks. A harness allows movement but requires more supervision, and out of expert hands carries a significant failure rate. A splint contains the hips better but thereby carries a risk of avascular necrosis.

A baby, for example, aged 6 months would usually require preliminary traction followed by closed reduction augmented by soft-tissue release (psoas and/or adductor).

An arthrogram is often helpful to define the abnormal soft tissues and confirm a satisfactory reduction.

Toddler and young child. Although it is still possible to achieve reduction by closed methods it becomes more likely that, with age, open reduction along with femoral or innominate osteotomy will be required.

Open reduction. This is usually undertaken through the anterior approach. The iliac apophysis is split. The psoas is divided near its insertion.
The capsule is opened and excess trimmed. The ligamentum teres and soft tissues in the acetabular floor are removed. The transverse ligament is divided. The intumted labrum (limbos) may also need to be cut in a radial fashion to allow entry of the femoral head. Reduction can then usually be achieved. However, in the majority of cases it is necessary to complement the reduction with a realignment femoral or innominate (Salter) osteotomy. If reduction is impossible because of a high dislocation, femoral shortening along with realignment is necessary. Postoperatively, the child is held in a cast for 6—8 weeks and then mobilised.

In later childhood, dislocations can still be treated by the combination of open reduction, femoral osteotomy and acetabuloplasty. However, the older the child the more difficult and unrewarding the surgery becomes, especially in bilateral cases.

Adolescent or young adult. Those presenting with a painful dysplastic hip may require surgery. A realignment of the joint through pelvic or femoral osteotomy is only appropriate if there is a congruous hip joint. Otherwise (i.e. sub-luxation) the acetabulum has to be augmented by other means, for example shelf arthroplasty.

Special cases. DDH associated with neuromuscular disease, syndromic disorders or skeletal dysplasia requires special thought. In such cases (e.g. arthrogryposis, spina bifida) surgery is likely to fail through redisplacement or stiffness. Therefore, it may well be in the child’s overall best interests to leave the hip joint alone and restrict one’s surgery by treating major limb malalignment by corrective osteotomy.

Coxa vara

This is a descriptive term that describes a decrease in the angle between the femoral neck and shaft. Many conditions can produce this deformity but three general categories are recognised.

• Congenital — this is present at birth and results in shortening of the leg. It is often associated with femoral deficiency.
• Developmental (infantile) — coxa vara develops in early childhood and progresses with growth. The cause is likely to be related to defective enchondral ossification in the metaphysis. Corrective osteotomy may be required.
• Acquired — this group includes cases where the deformity is due to a metabolic disorder (e.g. rickets), trauma (e.g. avascular necrosis in the treatment of DDH) and infection.

Congenital deformities of the feet

Congenital talipes equinovarus (club foot)

If ever there was a condition which exemplified ‘Beauty and the Beast’ this is it. The deformity can present over a wide spectrum of severity. At one end there are postural forms which respond easily to simple treatment; at the other there are severe fixed deformities which resist treatment and behave in a beastly fashion.

Incidence. This is generally quoted as one—two cases per 1000 babies.

Aetiology. Although the majority of cases is idiopathic, the condition can regularly be related to factors such as posture, heredity and associated conditions like neuromuscular disease (Table 27.8 and Fig. 27.38).

The risk of club foot is increased 20-fold if a first-degree relative has the condition, and there are examples of racial prevalence, for example among Polynesians. The most difficult club feet tend to be in association with neuromuscular, syndromic or dysplastic conditions.

Clinical features. The baby must be fully examined because of the links between foot deformity, hip disorder and other conditions. The diagnosis of club foot is usually obvious. The hindfoot and forefoot are in equinus and varus (Fig. 27.39). However, the stiffness varies from case to case and it is important to assess whether the deformity is likely to be postural or fixed (Fig. 27.40). Mild postural cases may be corrected above the plantigrade position, whereas a severe fixed deformity fails well short of this.

Pathological anatomy. In fixed deformity the navicular dislocates medially and downwards off the head of the talus, whose neck likewise becomes deformed in the same direction. The front of the os calcis goes medially under the talus, whereas the back of the os calcis is high and lateral, with tethers between it and the fibula. Several tendons are tight (tendo achilles, tibialis posterior, flexor hallucis longus, flexor digitorum longus) and there are contractures of joint capsules and ligaments. Debate continues as to which of the changes in club foot are primary and which are secondary.

Treatment. This depends on stiffness. Mild cases will respond to stretching, whereas fixed deformities will probably need surgery.

The parents must be given careful explanation of the condition. They should understand that club foot alone does not prevent a child walking, and even in the untreated case function can be good (Fig. 27.41). However, the foot cannot be made normal. It usually ends up smaller and stiffer and the calf is thinner. Finally, parents must realise that relapse can occur and, therefore, follow-up until maturity is necessary.

Most babies with significant congenital talipes equinovarus (CTEV) undergo stretching and strapping, usually supervised by a physiotherapist. Alternative methods include serial casts or splints.

Surgeons generally advise nonoperative treatment for 3 months when it is likely to be clear whether soft-tissue surgery is needed. If so, persisting with stretching and splintage is unlikely to remain effective. Indeed, persistent or over-vigorous stretching may cause a breach in the midfoot to produce a rocker bottom deformity which is very difficult to treat.

Primary surgery. This can be undertaken at 3 months, but most surgeons prefer to wait until after 6 months of age. In infants who are handicapped in other ways, and whose prognosis for walking is unclear, it is wiser to wait even longer.

The operation depends on the severity of the condition. The structures to be considered for division or lengthening are tendons (achilles, tibialis posterior, flexor hallucis longus, flexor digitorum longus), joint capsules (ankle, subtalar, calcaneocuboid, talonavicular, navicolucneiform) and ligaments (talofibular, calcaneofibular, talotibial, peroneal sheath, plantar fascia).

The surgical approach depends on what are to be divided. The posterior route alone will suffice for most cases, whereas a pantalar release will require a more extensive approach (e.g. Cincinnati). Temporary wires may be used to fix reduced joints, especially the talonavicular. In very severe cases (e.g. arthrogryposis, sacral agenesis) soft-tissue surgery alone will not correct the deformity. In this event, taloeotomy may be indicated.
Postoperatively, an above-knee cast is applied with the knee at a right angle and the foot as dorsiflexed as the wound and the circulation will allow. The cast is changed at 2—3 weeks when further correction is gained. Difficult cases may need more than one change. Plasters are retained for 8 weeks or so. Thereafter, continuing splintage and supportive footwear may be needed according to severity.

**Secondary surgery.** Recurrence of deformity (relapse) is, unfortunately, common in severe cases and bony surgery is ultimately necessary. However, most surgeons try to avoid such surgery in patients under the age of 5 years. Meanwhile, repeat soft-tissue release and/or transfer of the tibialis anterior tendon may hold the foot, at least temporarily.

Later on, collateral release (division of medial structures combined with calcaneocuboid fusion), wedge tarsectomy, triple arthrodesis, supramalleolar osteotomy and the Ilizarov technique are possible salvage operations.

**Congenital vertical talus**

This is a rare condition, 100 times less common than club foot (Fig. 27.42). The hindfoot is in equinus with the talus vertical.

The navicular is dislocated on to the neck of the talus and the combination gives the appearance of a rocker bottom foot. However, unlike the deformity caused by over-correction of club foot, the talus and os calcis retain a normal relationship.

The condition is regularly associated with neurological disorder. Surgical correction is usually required and involves complex reconstruction of the foot.

**Congenital elevation of the fifth toe**

The little toe is hypoplastic and sits upon its neighbour. Surgical correction is usually undertaken for cosmetic and/or shoe-fitting problems.

**Curly toes**

The third and fourth toes are usually affected and flexed at their distal interphalangeal joints. The condition may correct spontaneously and surgery (normally flexor tenotomy) should be delayed until after the age of 3 years, as for symptomatic toes.

**Congenital abnormalities of the knee**

**Patella**

There is a number of congenital conditions involving the patella, which may be absent or hypoplastic in association with the nail—patella syndrome. Other features of the syndrome include hypoplasia and splitting of the nails, elbow abnormalities and bony spurs on the ilium. The patella may be bipartite and confused with a fracture; the separate ossicle is usually superolateral. There may be congenital dislocation of the patella, which is small and fixed to the lateral femoral condyle; a fixed flexion deformity of the knee and genu valgum will be noted.

**Discoid meniscus**

The lateral meniscus is almost always involved, and there is either a complete discoid meniscus of normal mobility or the anterior and lateral attachment is deficient resulting in hypermobility. The latter type causes problems of locking and pain. Surgery is often required but where possible meniscal pre-serving techniques should be used because total meniscectomy invariably leads to degenerative change.

**Congenital dislocation of the knee**

The joint is hypo extended with the tibia displaced forwards on the femur. Mild cases are postural and related to malpresentation (e.g. extended breech). They can be treated by simple splintage or exercises. More severe ones involve quadriceps contractures, which require surgical release (quadricep plasty).

**Congenital deformities of the fingers**

**Camptodactyly**

This is a nontraumatic flexion deformity of the little finger at the proximal interphalangeal joint. Most cases are better left alone as function is usually normal.

**Clinodactyly**

This is a curvature of a digit in the radioulnar direction. It may be associated with other syndromes.

**Kirner’s deformity**

This affects the little finger in which there is radial and palmar curving of the distal phalanx.

J. Kirner. German physician, described this deformity in 1927.
Introduction

Injury or disease affecting the developing skeleton may lead to growth abnormality or deformity. The effects of damage to the growth plate are particularly troublesome. In this chapter, fractures and joint injuries are not discussed. Although most of the conditions described are generally considered to be acquired, they may arise against a background of genetic susceptibility.
Osteochondritis

This loosely defined term embraces three pathological processes involving epiphyses of larger bones or even the whole of a small bone, e.g. in the carpus or tarsus.

The processes are avascular necrosis affecting epiphyses normally under compression, chronic strain injuries to traction epiphyses and osteochondritis dissecans, which is a stress fracture through articular cartilage with or without involvement of subchondral bone. The individual conditions are usually referred to anonymously (Table 28.1).

Avascular necrosis (AVN)

The causes of osteochondritis presenting as AVN are obscure and theories include interruption of arterial supply through trauma, coagulopathy, venous hypertension or disorders of epiphyseal cartilage.

Legg—Calve—Perthes (LCP) disease

This is a mysterious and poorly understood condition. The capital femoral epiphysis undergoes an early stage of infarction, progressing to collapse and fragmentation, followed by healing (Figs 28.1, 28.2, 28.3, and 28.4). The whole process takes several years (Fig. 28.2) and involves part or all of the epiphysis.

Various classifications of the radiological changes have been used, e.g. Catterall, Salter—Thompson, Herring. Unfortunately, they are prone to interobserver error and it is difficult from a single set of X-rays to be sure of the stage or extent of the disease. Moreover, radiological classifications do not reliably relate to the age of the child or the clinical features. For example, a child, especially if young, with whole head involvement may have good movements and very little disability. The condition is relatively benign in the majority of children and does not lead to severe disability or arthritis in adult life. All of these uncertainties make it difficult to select those children who might benefit from treatment in both the short and long term.

Clinical features. The condition can occur between the ages of 3 and 12. It is more common in boys and more frequent in children of low birth weight or those who had a constitutional delay in growth. There is a family history in 12 per cent of cases and the condition may be bilateral in 20 per cent. Synchronous involvement is rare and when seen the diagnosis of multiple epiphyseal dysplasia should be considered.

The usual presentation is pain and a limp. These can be mild and intermittent so the onset may be difficult to define. The pain is usually in the hip region but, like slipped upper femoral epiphysis (SUFE), can be referred to thigh or knee. Therefore children with knee pain should always have their hips examined and X-rayed if there is any suspicion of disease therein.

In LCP disease, flexion is usually maintained but the hips lose abduction and internal rotation. The thigh is usually thinner than the normal side and the Trendelenburg test frequently positive. In spite of these clinical features the children usually remain active and regularly have to be restrained.

The diagnosis is confirmed by radiographs. Magnetic resonance imaging (MRI) or bone scans may be helpful in the very early stages.

Treatment. The goal is to achieve a congruous joint. The majority of cases will not regain their previous normal shape (spherical congruity) but heal as an oval head (aspherical congruity). However, providing the head matches the socket, the hip is likely to do well in the long term. Where there is a mismatch (aspherical incongruity) the hip does badly.

It is generally agreed that hips should be exercised and kept as mobile as possible, thereby aiming to prevent adduction or flexion deformity and encourage remodelling to a congruous joint. If adduction deformity develops, a period in abduction splintage should be considered.

The role of open surgery, e.g. femoral or innominate osteotomy, is controversial, especially in the younger child. It is difficult to prove that surgery will be beneficial in the long term. In the short term, operations designed to achieve containment of the femoral head may cause damage to the growth plate, usually make a limp worse and may cause incongruity and stiffness. Therefore, if a surgeon cannot feel sure of achieving a congruous joint (an arthrogram may help in the assessment) a better alternative to osteotomy is a shelf-type procedure to augment the acetabulum and thereby give the femoral head.

In summary, LCP disease is generally benign with a good long-term prognosis. The hip should be kept mobile to avoid deformity and encourage congruous healing. Children who are younger and with partial head involvement do better and the role of operations remains controversial. We still do not know how to select accurately those children who will benefit from surgery in the long term.

Freiberg’s disease

This affects the distal epiphysis of the second metatarsal and is generally very troublesome. If simple treatment, such as insoles, fails it may be necessary to consider osteotomy or even excision of the metatarsal head.

Kohler’s disease

This benign condition affects the tarsal navicular. This normally does not ossify until the fourth year of life and thereby confusion may occur. Kohler’s disease presents with pain which is usually not bad enough to warrant more than symptomatic treatment. Radiographs show a flattened navicular (Fig. 28.5) and a comparison view of the other foot is indicated to ensure that one is not dealing with a normal ossification pattern. The children can be advised on activity within the limits of their symptoms and the navicular usually remodels to normality.

Keinbock disease

This affects the carpal lunate and causes troublesome pain and stiffness. It usually affects older teenagers and young adults. The lunate flattens and fragments thereby disturbing the proximal row of the carpus. It is a difficult condition to treat with no reliable surgical option. Various procedures include replacement of the lunate, shortening of the ulna, proximal row carpectomy or even arthrodesis of the wrist.

Panner’s disease

The capitellum becomes flattened and the elbow stiffens. There is no satisfactory operation for the condition but fortunately good elbow function is usually maintained.
Traction or strain injuries

These can occur wherever powerful muscles are attached to bone. In children ligaments and tendons are generally stronger than bone and acute or chronic traction injuries manifest by signs of avulsion. Examples of acute traction injuries include rectus femoris at the anterior—inferior iliac spine and hamstrings at the ischial tuberosity.

The classical chronic traction injuries are recognised eponymously. They are:

- Osgood—Schlatter’s disease (tibial tubercle; Fig. 28.6);
- Sinding Larsen disease (distal pole of patella);
- Sever’s disease (posterior epiphysis of os calcis).

The treatment of all these injuries is rest. Unfortunately many of the affected children are keen athletes and the lesions are the effects of excessive demands on an immature skeleton. It is often unrealistic to impose a total ban on sport; a more practical approach is to advise activity within the limits of the symptoms with the likelihood that the conditions will settle as the skeleton matures.

Osteochondritis dissecans

In this condition, a piece of articular cartilage, with or without the underlying subchondral bone, becomes unstable and may detach into the joint, thereby forming a loose body. The mechanism is acute or chronic trauma.

Common sites include the medial femoral condyle, talus and capitellum. Loose bodies cause pain and locking whereas an unstable fragment may cause discomfort when the joint is stressed.

The lesions may be present on plain X-rays but can also be well demonstrated by MRI.

In general an expectant approach is adopted, unless a troublesome loose body needs removal.
Slipped upper femoral epiphysis

This is a shear failure through the hypertrophic tone of the upper femoral growth plate (physis). The capital epiphysis slips backwards and downwards. SUFF is uncommon. For example, a family doctor in Britain is likely to see only one case in a working lifetime (Table 28.2). Although the condition is classically described in a very overweight (Pickwickian) child, it can occur in a tall or muscular child. Conversely, the physis can be weakened by injury or disease, e.g. renal failure, radiotherapy, hyperthyroidism. Thus no type of body build can be considered safe from SUFF (Fig. 28.7).

Classification

The condition can be graded according to the degree of slippage as measured in the lateral X-ray. However, such classifications are prone to inconsistencies in measurement owing to differences in positioning and interobserver error. Moreover, they do not relate easily to treatment. There are better classifications, e.g. those of Dunn or Loder (Table 28.3) which complement each other. The former relates presentation to treatment, while the latter usefully defines slips according to whether the child can walk unaided (stable) or requires crutches (unstable). A stable hip would therefore correspond to an early chronic (Fig. 28.8) and an acute on chronic (Fig. 28.9) or late chronic slip with the growth plate open (Fig. 28.10) would be likely to be unstable.

Clinical features

Boys and girls are more or less equally affected but girls tend to get the condition earlier, e.g. ages 9—14 as opposed to 11—16. A girl who has reached menarche is virtually immune. Although the classically overweight picture is commonly seen, no body habitus is exempt. As the severity and speed of slippage varies, so does the classical presentation. An early chronic (stable) slip may be the cause of mild intermittent pain which is ignored or missed, whereas an unstable acute on chronic or late chronic slip may result in catastrophic loss of function in the limb.

The diagnosis of early slips is usually delayed because this relatively rare condition is not suspected or the symptoms are minor. Pain is classically felt in the groin and thigh but may be referred to the knee. Any child with knee pain should have the hips examined and if necessary X-rayed.

The backward and downward displacement of the epiphysis causes the lower limb to adduct, externally rotate and extend. The hip thereby shows apparent shortening with loss of abduction, internal rotation and flexion.

Investigations

The diagnosis is confirmed on the lateral radiograph but the features are regularly seen on the anterior—posterior view. A computerised tomography (CT) scan can help in defining whether the growth plate is open (Fig. 28.11). Blood tests are usually unhelpful unless there is a suggestion of metabolic or endocrine disorder, e.g. renal failure or hyperthyroidism.

Treatment

The child should be placed on protected weight bearing or even bed rest and traction prior to surgery. The choices for treatment are fixation in situ or realignment, either by reduction of the slip or osteotomy (Table 28.4). When the growth plate is open one should fix in situ if at all possible (Fig. 28.12) because realignment through the growth plate carries a significant risk of AVN. The treatment of unstable slips is thereby controversial. However, an extreme slip either acute on chronic or late chronic may be impossible to fix in situ and reduction before fixation may have to be considered, notwithstanding the risks involved (Fig. 28.13). Postoperatively the child should be on protected weight hearing for 6 weeks and followed up until both growth plates are fused. The family should be warned of the risk of slippage on the contralateral side (20 per cent). Any evidence of this through symptoms or X-rays demands fixation of that side as well. Routine prophylactic pinning of the opposite side is normally reserved for those children at special risk, e.g. renal failure, hypothyroidism.

Complications

Avascular necrosis

This is serious and disabling. It may occur as the result of an acute on chronic slip or may be caused in the course of treating an unstable slip (Fig. 28.14). Part or all of the head may be involved and the condition does not usually manifest itself radiologically until several months after treatment.

Chondrolysis

This is a poorly understood condition possibly related to autoimmune causes, whereby the hip joint stiffens and narrows. Chondrolysis is not related to the severity of slippage and indeed can occur after prophylactic pinning of the contralateral hip.

Treatment is to prevent contracture and keep the hip mobile while healing occurs.

Osteoarthritis

Although osteoarthritis is a common effect of SUFF, it is generally a forgiving complication. Hips generally function well in the long term and only a minority will require, for example, a hip replacement.
Infection of bone and Joint

Osteomyelitis and septic arthritis remain a significant cause of morbidity in paediatric practice. Prompt and adequate treatment is needed to reduce the risk of complications. In some parts of the world tuberculosis is still a serious problem; indeed there are signs it may be on the increase in the Western hemisphere.

Bone and joint infection is usually described in terms of acute, subacute or chronic. No age is exempt from any type. Although there are classical forms of presentation at different ages, skeletal infection can pose great problems in terms of differential diagnosis. For example, trauma or sickle cell crisis can be confused with acute osteomyelitis, benign or malignant bone tumours can mimic subacute or chronic infection (Fig. 28.15) and other causes of inflammatory joint disease, such as juvenile arthritis or irritable hip syndrome, have to be distinguished from septic arthritis (Fig. 28.16).

Thus, bone and joint infection may present in many guises, from an acute life-threatening condition to a painless deformity manifesting many years after an unrecognised infection damaged the growth plate.

The treatment of skeletal infection is based on the following principles:

- rest;
- elevation;
- surgical drainage;
- antibiotics;
- nutrition.

In every case, all must be considered although not all may need immediate implementation. For example, an early osteomyelitis may not require surgical drainage or, in another case, antibiotics should be withheld until adequate surgical clearance has removed infected, dead tissue and provided specimens for culture and sensitivity. It is also vital to remember that when surgeons are considering which antibiotic to give or whether a bone should be explored, the importance of resting and elevating a limb, along with correction of nutritional deficiency, including anaemia, must not be forgotten.

The cause of skeletal infection is usually haematogenous spread from without the body or from a septic focus within. In acute osteomyelitis the metaphysis is the common site. Involvement of epiphysis or diaphysis is more often seen in subacute or chronic infections.

Acute infections

Septic arthritis

The hip and knee are the commonest joints affected but the principles of management apply to any joint.

It is difficult to distinguish between septic arthritis of the hip and osteomyelitis of the upper femur. The growth plate and metaphysis are intracapsular and an early osteomyelitis can rapidly progress across the metaphysis directly into the joint. In practice, especially in the neonate, osteomyelitis and septic arthritis of the hip should be considered a single entity.

The usual cause of septic arthritis in any joint is haematogenous spread but direct inoculation can occur, e.g. penetration of the hip during femoral venepuncture. Neo-nates, the immunosuppressed and children with sickle cell disease are more susceptible.

Bones and joints can be involved as part of septicaemia, e.g. meningococcal. Diagnosis is often delayed in the seriously ill child where attention is directed towards the septicaemia.

Clinical features. The diagnosis is straightforward when there are typical signs such as tenderness, reluctance to move a limb (pseudoparalysis) and fever. In superficial joints an effusion can be demonstrated and the joint is warm. In the hip, ultrasonography is useful to show an effusion. Plain X-rays show this as widening of the joint space (Fig. 28.17) and in severe cases there may be a septic dislocation of the hip.

Treatment. Blood should be taken for blood count, erythrocyte sedimentation rate (ESR) and C-reactive protein. The joint should be aspirated. If pus is obtained or there is any doubt, open surgical drainage and decompression of the joint is indicated. In the hip, this is most easily done through an anterior approach. A section of capsule is excised to ensure free drainage and the joint copiously irrigated. Once material has been taken for culture, intravenous antibiotics are commenced. The guidance of a microbiologist is recommended.

If the hip was subluxated or dislocated a hip spica should be applied to keep it reduced. Otherwise bed rest is appropriate until the signs of infection, combined with blood tests, are seen to be settling. In this regard it is easier to monitor and treat a superficial joint, e.g. knee. Pus in a joint is destructive. If treatment is delayed chondrolysis occurs. In the hip, this is followed by avascular necrosis of the femoral head and ultimately limb shortening due to dislocation (Fig. 28.18). A hip thus affected may come to arthrodesis or trochanteric arthroplasty in which the unaffected greater trochanter is placed in the acetabulum to stabilise the hip. Minor damage to the growth plate may not show until late after the infection (Fig. 28.19).

Osteomyelitis

As with septic arthritis, the usual cause is haematogenous spread to the metaphysis and most frequently involves the most rapidly growing ends of long bones. There is often a history of antecedent trauma and osteomyelitis may follow a subperiosteal haematoma. The initial inflammatory reaction is followed by an abscess which tracks laterally to lift the periosteum. This deprives the cortex of its blood supply and it may die; a sequestrum. Subperiosteal new bone produces the involucrum (Fig. 28.20). Pus may continue to rupture through the involucrum via cloacae and reach the skin (Fig. 28.21a and b).

Clinical features. Classically, the child is ill with signs of septicaemia. There is local tenderness erythema and increase in local temperature. In severe cases the whole limb is swollen, tender and hot, making localisation difficult. Radiological appearances in osteomyelitis are normal in the early stages, although a bone scan may be helpful.

Treatment. Once pus is formed it must be surgically released. In the genuinely early case (history less than 24 hours) treatment with antibiotics can be started after blood cultures are taken. Provided there is a prompt response (24–48 hours) surgery may be avoided. This approach may also be justified in early severe cases where generalised swelling and tenderness of the whole limb makes localisation difficult. In such cases it is advisable to take blood cultures, commence resuscitation and intravenous antibiotics, and wait 24–48
hours when localising features will develop to direct the surgical approach.

When surgery is required the periosteum is incised and any subperiosteal abscess drained. If there is no subperiosteal abscess, the bone should be drilled to drain any intraosseous pus. Postoperatively the limb should be rested in a cast. Prolonged antibiotic therapy is necessary (at least 6 weeks) because it can be very difficult to eradicate the condition permanently: ‘once an osteomyelitis, always an osteomyelitis’.

Apart from chronicity, other possible late effects of osteomyelitis include overgrowth of the limb due to stimulation of the growth plate or deformity due to growth plate damage (Fig. 28.22a and b).

Acute infection can affect the spine in childhood. It is often not suspected in a toddler or child who may be generally well; backache, stiffness and a limp are alerting signs. X-rays show disc space narrowing and an MRI scan will highlight the inflamed area. A CT-guided biopsy will probably show infected tissue but it is common that culture is negative or inconclusive. Rather than exploring and draining the spine it is usually worthwhile to treat these children with a spinal brace and broad-spectrum antibiotics whereupon the infection usually subsides, with or without spontaneous fusion between affected vertebrae.

Subacute and chronic infections

The epiphysis is a relatively common site. The diaphysis can also be affected. The clinical features are much less marked than with acute infections and diagnosis is often delayed. Radiographs may show a sclerotic wall around a cyst or in many cases sclerosis may be the only feature. A bone scan may be helpful to distinguish from quiescent harmless bone lesions. In cases where sampling a lesion may be difficult because of its anatomical location or lack of clear definition on radiographs a conservative approach with antibiotics may be indicated. If there is no response, biopsy is indicated to exclude a tumour.

Irritable hip

This is also known as transient synovitis or observation hip. It is essentially a diagnosis of exclusion — most importantly from septic arthritis. It is a common condition in which the child, usually between 4 and 8 years old, presents with pain in the hip of variable severity, reluctance to weight bear and a limp. The cause is usually unknown but there may be a history of preceding trauma or a viral infection. The clinical features vary from a well child with minor loss of movement to the unwell child with a low-grade fever and marked stiffness.

Systemic examination may reveal lymphadenopathy or other evidence of a viral infection, such as a rash. Radiographs are normal or may show slight widening of the joint space. The blood count is normal and the ESR may be minimally raised. The presence of fever, effusion and marked stiffness would be an indication to investigate as a septic arthritis. This would only apply to a minority of cases. The great majority settles with bed rest followed by mobilisation as the hip becomes comfortable.

Skeletal tuberculosis

This may present as chronic arthritis (Fig. 28.23) or osteomyelitis.

In the spine it usually involves the adjacent parts of the bodies of two vertebrae. The disc is relatively resistant to tuberculosis but eventually undergoes avascular necrosis although it may sequestrate. Abscesses can spread in various directions by stripping the vertebral ligaments. In the lumbar region, a paravertebral abscess may enter the psoas sheath to appear in the femoral triangle. Clinical features include general malaise, backache and stiffness. The principal complications of spinal tuberculosis are paraplegia and deformity. Paraplegia may occur early or late in the disease. Early paraplegia is usually due to mechanical pressure on the cord from granulation tissue, pus, sequestrated disc material or oedema; ischaemia can also be a cause. Late paraplegia is usually associated with stretching of the spinal cord over an angular deformity, resulting in ischaemia. The usual deformity in spinal tuberculosis is a kyphosis due to collapse of the vertebral bodies. As with other forms of skeletal tuberculosis, treatment should be with appropriate antibiotics. However, it has been shown that, although conservative treatment is effective, there is a risk of a deterioration in the kyphosis and that this is most likely to occur in children and when several vertebrae are involved. Radical anterior débridement and spinal fusion will usually prevent any progression of the deformity.
Neuromuscular orthopaedics

In neuromuscular conditions such as polio, spina bifida, cerebral palsy and the muscular dystrophies, imbalance of muscles and the effects of gravity can result in deformity. Orthopaedic surgery has a valuable role in properly selected patients. However, it is important to remember that surgery is only an incident in the continuing care of these patients. The support of parents, other medical specialists, therapists, orthotists and teachers is essential for good results. The care of these children should be delivered in a co-ordinated way, usually through a paediatrician or general practitioner.

Polioymielitis

This is usually due to infection by one of three types of poliomyelitis virus, although other members of the entrovirus group can cause clinically and pathologically indistinguishable disease. Effective vaccination has been present for almost 40 years but the disease has not been eliminated from certain parts of the world. The virus enters the oropharyngeal route, passing via the alimentary lymph nodes to enter the circulation with an incubation period of 6—20 days. One or 2 per cent of patients develop neurological disease as the virus affects the anterior horn cells, particularly in the cervical and lumbar enlargements (as well as parts of the brain including the medulla). Weakness in a muscle is in proportion to the number of motor units destroyed. Up to 60 per cent of units have to be damaged before weakness is clinically detectable. Muscles innervated by the cervical and lumbar enlargements are most commonly affected and paralysis is twice as common in the lower than in the upper limb. Orthopaedic surgery is not indicated in the acute or convalescent stages although careful physiotherapy in the convalescent stage is helpful to work individual muscles to maximum capacity without letting normally working muscles become hypertrophied. Paretic muscles must not be over-exercised and contractures in paralysed muscles must be stretched out before exercising them.

In the chronic stage which can be as much as 2 years after onset of the disease, orthopaedic surgery may be indicated. Joint deformities will largely be dictated by the muscle groups affected, although certain patterns of deformity, such as flexion contracture of the knee and hip and calcaneus of the hindfoot, are common. Patients with a weak quadriceps and a flexion contracture may develop ‘knee—hand’ gait in which the hip supports the knee which cannot be locked into extension. In severe cases patients have to crawl and the pattern adopted is a guide to the muscle groups affected. When all muscles acting on a joint are paralysed it will become flail and unstable. It is surprising that such joints rarely show degenerative changes. When the paraspinal muscles are affected a scoliosis may develop. A disused lower limb grows shorter than normal and leg-length discrepancy is common.

If surgery is to be undertaken in poliomyelitis, it should be preceded by a full assessment, including muscle charting. If orthoses are being considered, it is important to be certain these will be appropriate in the patient’s home environment.

The surgical options in polio include:

• tendon transfer to augment or replace weak muscles;

• release of contractures by soft-tissue release and/or corrective osteotomy. The knee—hand gait can often be abolished by extension osteotomy of the distal femur which allows the knee to lock in extension. However, in some cases a contracture may help the patient and the surgeon must be circumspect about releasing it (Fig. 28.24);

• stabilisation of flail joints by arthrodesis;

• spinal fusion and instrumentation for scoliosis;

• leg equalisation surgery.

Cerebral palsy

This is classically a nonprogressive injury to the developing brain that usually occurs in the neonatal period. There are several potential causes such as anoxia, intracerebral haemorrhage and infection. There is a strong association with prematurity. In such cases it is debatable whether the neurological damage is due to a naturally impaired brain or caused during delivery. Severe neurological impairment may also be part of syndromic or genetic conditions. Finally there may not be any obvious cause for a child’s neurological condition. On rare occasions such a child presenting as ‘cerebral palsy’ may respond to dopamine treatment.

Cerebral palsy is often not apparent at birth and may only be suspected as an infant fails to reach milestones or shows evidence of altered muscle tone. For all of these reasons it is important to try and accurately assess the cause and scale of neurological impairment, be it cerebral palsy or otherwise. The skills and armamentarium of the paediatric neurologist are usually required for this.

In cerebral palsy there are various patterns of disability depending on the type and distribution of the motor disturbance (Table 28.5). It is also helpful to grade the condition according to function which should include intellectual ability and whether there is epilepsy (Table 28.6). The commonest type of disturbance is spasticity which tends to affect flexors rather than extensors. Orthopaedic surgery can only have limited goals in cerebral palsy as it deals with peripheral effects rather than the central problem. Moreover, the orthopaedic surgeon is usually part of a large team involved in the care of the child.

The aim of surgery should be to improve function and facilitate the care of these patients by correcting or prevent-ing deformity. Regular physiotherapy to stretch contractures (Fig. 28.25a and b) and supervise the use of orthoses is essential (Fig. 28.26). Realistic goals must be set. It has to be explained that results can be unpredictable and disappointing especially in dystonic cases. The immediate postoperative care may be hampered by difficulties with nursing and skin problems due to pressure from casts. Rehabilitation is usually prolonged.

The goals and scope of treatment are usually determined by the anatomical distribution and functional ability as follows.

Hemiplegia

The children walk independently and the hip is not at risk. The common problems in the lower limb are equinus or internal rotation. Equinus usually requires physiotherapy, an ankle/foot orthoses (AFO) and frequently elongation of the tendo achilles (ETA). Severe internal rotation can be due to femoral torsion and an external rotation osteotomy may be justified.

The upper limb in hemiplegia is often badly affected. Surgical options to improve function significantly are sadly few but some help can also be given to improve the cosmetic appearance of the hand.
Duchenne dystrophy is inherited as a sex-linked condition and only boys are affected. They are not usually diagnosed until after walking, which is delayed. They may present as toe walkers or show difficulties with mobility. For example, when getting up from the floor they use their hands on their thighs to push themselves up into the erect position. They often have thick calves (pseudohypertrophy) and the Achilles tendons are tight. The clinical features plus a raised creatine phosphokinase (CPK) confirm the diagnosis.

Total body involvement

The children are usually very impaired mentally as well as physically. However, in some, whereas the physical disability may be severe the child can be intellectually bright. There are usually difficulties with incontinence, feeding, nutrition and epilepsy.

The orthopaedic goals in such cases can be summarised as follows.

- **Spine.** Scoliosis is likely and should be anticipated. Early curves can be treated by postural exercises, seating supports and braces. More severe curves require surgical stabilisation to prevent them progressing to unmanageable deformities.

- **Hips.** These are at risk of dislocation because of adductor and psoas spasm. The joints should be monitored clinically and radiologically. Preventive measures include exercises, abduction splints and seating adaptation. If the hip is displacing early surgical options include adductor release of femoral osteotomy (Fig. 28.28 and Fig. 28.29). In late dislocations which are painful and pose severe nursing or seating problems, the combination of open reduction, femoral osteotomy and acetabular augmentation may be necessary.

- **Seating.** Proper seating is important and is a major factor in maintaining posture and minimising deformity (Fig. 28.30). If hips, knees or ankles pose problems in achieving good seating and transfers usually because of flexion deformities, then soft tissue releases will have to be considered.

- **Communication skills.** The child should be in the school best suited to his or her particular needs and potential. Computers and electronics can help parents and teachers in this regard.

Spina bifida

Unfortunately, most children with spina bifida have profound lower limb weakness and sensory loss (Fig. 28.31). They regularly need multidisciplinary help from paediatricians, orthopaedic surgeons, neurosurgeons, therapists and orthotists.

However, not all spina bifida produces severe disability (Fig. 28.32). Occult forms may cause subtle changes in neurology as a child grows. If a lower limb deformity, weakness or urinary symptoms develop it is advisable to seek neurosurgical help as, with growth, there may be tethering of nerve roots or other pathology such as a syrinx which can be amenable to surgery.

In severe cases the extent of disability depends on the level of the lesion. In the majority there is some upper motor neuron involvement as well as the classical lower motor neuron lesion. Spasticity may therefore complicate the motor and sensory loss.

The lack of protective sensation means that minor cuts and abrasions may pass unnoticed and lead to infection. Once this involves bone it is extremely difficult to eradicate. Patients and carers must therefore adopt a daily routine of foot inspection and must always try to protect skin. Surgery to the foot in spina bifida is largely to achieve a plantigrade foot which can be fitted with an orthosis and moulded footwear to avoid areas of pressure.

Flexion contractures at hip or knee can be treated by soft-tissue release and/or osteotomy. External rotation of the tibia may cause the medial side of the foot to drag along the ground. This can be helped by internal rotation osteotomy of the tibia. Spina deformity is common in higher level lesions and usually takes the form of a kyphosis. This can be controlled with a brace but spinal fusion and instrumentation may be necessary (see Chapter 20).

Muscular dystrophy

The details of the many types of muscular dystrophy which vary in severity and age at presentation are beyond the scope of this book. However, a short discussion of a severe and classical type, namely Duchenne dystrophy, exemplifies the diagnostic and therapeutic approaches, which may be applicable throughout the spectrum of the muscle dystrophies.

Duchenne dystrophy is inherited as a sex-linked condition and only boys are affected. They are not usually diagnosed until after walking, which is delayed. They may present as toe walkers or show difficulties with mobility. For example, when getting up from the floor they use their hands on their thighs to push themselves up into the erect position. They often have thick calves (pseudohypertrophy) and the Achilles tendons are tight. The clinical features plus a raised creatine phosphokinase (CPK) confirm the diagnosis.

The condition is sadly progressive. The children usually come off their feet in late childhood or early teens and die in late adolescence or early adult life. At present there is no cure but gene therapy holds some hope for the future.

Treatment is multidisciplinary and aims to keep the children as mobile as possible and prevent deformity. Imobilisation after any surgery must be for as short a time as possible. Walking can be prolonged by percutaneous lengthening of the Achilles tendons and orthoses.

The spine is particularly liable to deformity. This may be lessened by bracing and seating. However, it regularly pro-gresses beyond these measures. Whereupon surgical stabilisation is worthwhile, otherwise the deformity may become very severe and the management difficult and unpleasant for the child during his or her final years. The timing of spinal surgery is important. It should be done before the vital capacity has deteriorated to a dangerous level.
**Torticollis (wryneck)**

This is frequently related to neurological or muscular conditions. The causes of the abnormal neck posture can be summarised as:

- **cervical** — congenital and acquired conditions of the cervical spine, painful or otherwise;
- **pharyngeal** — usually infection, e.g. tonsillitis;
- **ocular** — squints or visual field defects;
- **intracranial** — posterior fossa tumours;
- **muscular** — contracture of the sternomastoid;
- **habitual** — no obvious organic cause.

The classical type is due to contracture of either or both anatomical heads of the sternomastoid muscle ([Fig. 28.33](#)). The cause of contracture is usually unknown. It can follow a sternomastoid tumour, which is probably a traumatic lesion sustained during delivery and usually resolves without long-term effects ([Fig. 28.34](#)).

Treatment is usually by surgical release of the contracture followed by physiotherapy and exercises to re-educate the child back to normal posture and movement.
Spinal deformity

Scoliosis

This is a lateral curvature of the spine but is usually accompanied by a rotational deformity as the spinal column starts to buckle and shorten. In the thoracic region the rotation throws the ribs into prominence producing the cosmetically deforming rib hump (Fig. 28.35a and b) whereas in the lumbar region the same degree of curvature may not be so noticeable. A curve is described as structural fixed when there is loss of mobility in the involved segment. This usually occurs because of alterations in the shape of the vertebrae and adaptive changes in soft tissues. A curve is mobile when normal flexibility is preserved; such curves are often described as postural although strictly speaking the terms are not interchangeable. A postural curve is secondary to the position of the body, one of the commonest causes being leg-length inequality. Curves are also described on the basis of their anatomical site and whether they are primary (major) or secondary (compensatory) to the primary curve in an attempt to maintain spinal balance.

The causes of scoliosis are summarised in Table 28.7.

Idiopathic scoliosis

Idiopathic scoliosis is the commonest type and is usually considered in three sub groups.

Infantile idiopathic scoliosis may be related to sleeping position. It is usually noted between birth and the age of 1 year. It is often a component of the 'moulded baby syndrome' (plagiocephaly, tight hip adductors, scoliosis, foot deformities). The curves are usually convex to the left and are more common in males. The great majority resolve without treatment but approximately 10 per cent progress and pose difficult problems. Serial examination and radiographs are important to detect progressive cases. Measurement of the rib—vertebra angle difference (Mehta) is helpful in predicting which cases are likely to progress. Treatment is initially by bracing but if unsuccessful there is an indication for anterior release of the affected spinal segments.

Juvenile idiopathic scoliosis. This occurs between the ages of 3 years and puberty. The distinction between juvenile and early adolescent curves is ill defined. However, juvenile curves frequently progress and early bracing is advisable.

Adolescent idiopathic scoliosis is the commonest form and occurs at puberty. It is slightly more common in girls and usually convex to the right. A number of different patterns of curve has been described depending on site and distinguishing between the major and compensatory curves. Appreciation of the patterns is important in assessing the extent and level of spinal fusion. In general, treatment is required for all curves that are progressing.

The following are important factors in assessing progression.

- Sex. Progression is more common in girls.
- Age. Progression is more likely when there is potential for skeletal growth. Curves presenting before menarche have more potential for progression. Ossification of the iliac apophysis (Risser's sign) is helpful in assessing skeletal maturity.
- Curve pattern. Double curves are more likely to progress than single thoracic curves which in turn are more likely to progress than lumbar curves.
- Curve magnitude. Progression is more likely with curves over 300.
- Other factors. Patients with slender spines are more likely to progress.

Clinical features. The above features related to curve progression must be noted. In addition, a history of pain or neurological symptoms makes it important to exclude other causes of scoliosis such as a spinal tumour. On examination, the site, flexibility and cosmetic effects of the curve are noted, as well as spinal balance, i.e. is the head centred over the natal cleft? A neurological examination should be carried out, skin blemishes, e.g. café au lait patches, should be sought and any leg-length discrepancy measured. The curve can only be assessed accurately by radiology (Fig. 28.36).

Treatment. Idiopathic scoliosis can only be treated by bracing and surgery. In general, curves which measure less than 30 degrees should be managed nonoperatively with regular clinical and radiological assessment. Earlier intervention should be undertaken in those curves with a worse potential. Once there is clear evidence of progression bracing is used for curves between 30 degrees and 45 degrees. There are two main types of brace. The Milwaukee incorporates anterior and posterior struts that support a neck ring and suboccipital pads. The Boston brace is an underarm device constructed from a pelvic module fitted with individualised pads to correct lumbar and thoracolumbar curves. Since it can be worn under clothes it is more acceptable than the Milwaukee but is not suitable for high curves.

Surgery is generally indicated when:

- bracing is likely to be ineffective because
  - the curve is too large, i.e. >450
  - the site makes it difficult to brace, e.g. high thoracic or true double thoracic curve,
  - the curve is fixed;
- the curve is deteriorating in a young child;
- there is loss of spinal balance;
- the cosmetic appearance needs correction.

The surgical procedures to correct, stabilise and fuse the spine include anterior release, and anterior and posterior instrumentation techniques (Fig. 28.37). Spinal cord monitoring is usually employed during such surgery that aims to produce a balanced, corrected, stable spine with a minimum of fused segments.
Congenital scoliosis

This is usually due to a failure of formation, e.g. hemivertebra (Fig. 28.38) or failure of segmentation, e.g. a bar. Mixed patterns can occur and the anomalies may be single or multi-ple. Associated abnormalities are diastomatomyelia, and cardiac and renal malformations. A unilateral unsegmented bar with a contralateral hemivertebra at the same level along with thoracolumbar anomalies are associated with partic-ularly severe curves. In general, early fusion in situ should be undertaken for curves that are progressing or likely to progress. On occasions, other procedures may be appropriate such as hemivertebra excision or growth arrest operations.

Neuromuscular scoliosis

Many neuromuscular conditions such as cerebral palsy, spina bifida, polio and muscular dystrophy can cause a scoliosis. Characteristically a long, C-shaped thoracolumbar curve is found. Left untreated, severe deformities can occur with reduction of respiratory function and great difficulties in nursing. Early bracing is valuable, surgical stabilisation is often necessary and strong internal fixation is necessary to allow early mobilisation.

Tumours

Turnouts involving the vertebrae, e.g. osteoid osteoma or the neural elements, may present as a scoliosis. Any child presenting with significant back pain should be investigated and a bone scan is a useful screening test.

Other conditions

Other conditions associated with scoliosis include infections, disc prolapse, spinal injury and skeletal dysplasias such as neurofibromatosis, Marfan’s syndrome and osteogenesis imperfecta.

Kyphosis

A kyphosis is normally present in the thoracic spine but more than 45degree is considered to be excessive. The deformity may be idio-pathic or occur as a result of:

• congenital abnormalities such as anterior bony bar;
• developmental delay, e.g. cerebral palsy;
• vertebral collapse, e.g. infection, osteoporosis, sickle cell disease (Fig. 28.39a—c).

There is a spectrum of idiopathic scoliosis. In Scheuermann’s disease, the kyphosis is associated with radiological changes such as irregular vertebral end plates, apparent narrowing of the disc space and wedging of one or more vertebrae. These changes make the kyphosis more rigid than the less severe postural round back in which radiographs are normal. Apart from the cosmetic deformity, Scheuermann’s disease may be associated with back pain, especially after skeletal maturity and, in severe cases, brace treatment and occasionally fusion may be justified.

Biomechanics

Biomechanics is a subject of immense complexity and it is especially difficult for surgeons because graduate engineers often fail to appreciate the abysmal ignorance of mathematics which hampers surgeons in this field. (Sir John Charnley)

Despite this sobering thought from Sir John Charnley, all surgeons who deal with injuries of the musculoskeletal system require a basic understanding of biomechanics. It is the science of the action of forces, internal or external, on the living body and dictates how accidents and overloading produce tissue damage. Effective treatment regimes, surgical or nonsurgical, to restore the mechanical properties of injured structures must be based on knowledge of the fundamentals of biomechanics.

Dynamics

Dynamics is the study of the motion of bodies and forces that produce the motion. There are three subtypes:

- **Kinematics** is the study of motion in terms of displacement, velocity and acceleration without reference to the cause of the motion.
- **Kinetics** relates the action of forces on bodies to their resulting action.
- **Kinesiology** studies human movement and motion.

The guiding principles by which forces act on bodies are encapsulated in Newton’s three laws. Statics is the study of the action of forces on bodies at rest and is governed by Newton’s first law; if a zero net external force acts on a body, the body will remain at rest or move uniformly. Thus, the sum of the external forces applied to a body at rest equals zero. Newton’s second law relates to acceleration. The acceleration $a$ of an object of mass $m$ is directly proportional to the force applied to the object $F ma$. Newton’s third law states that for every action there is an equal and opposite reaction. This allows us to analyse the action of forces on the whole body, or limbs, and resolve them.

Biomaterials

The effect of externally applied loads on a particular structure, such as a ligament or tendon, and the resulting internal effects and deformations induced in these structures is the study of biomaterials. The basic terminology is given in Table 29.1.

All materials will eventually fail if sufficient load is placed upon them. If you clamp the medial collateral ligament including its bony attachments and pull it apart (a tensile test) then you would be testing a structure whose properties are defined by a load—deformation curve (Fig. 29.1a). If the experiment were modified to include only the ligament then you would be testing it as a material resulting in a stress—strain curve (Fig. 29.1b).

In Fig. 29.1b the first part of the curve (toe-in) occurs as the natural wavy pattern (crimp) of the fibres is eliminated. As the stress increases the fibres lengthen proportionally, the slope of this line representing Young’s modulus $E$. As the strain increases beyond physiological loads increasing numbers of fibres are injured until the highest stress is recorded immediately prior to failure of the ligament.

It is therefore apparent that if a single load in excess of the ultimate failure load of a structure is applied then it will fail. An example of this occurs when a football player is tackled from the side. The knee is forced into valgus and the medial collateral ligament is loaded in tension. If the load exceeds the ultimate failure load it will rupture completely. If the load is below this then a partial rupture may occur.

If the ligament is partially ruptured and the player manages to continue playing, a second injury of similar magnitude results in complete rupture of the ligament. This brings us to the concept of fatigue failure. Figure 29.2 depicts the relationship between load and the number of stress cycles required to produce failure in a structure. As the applied load diminishes the number of cycles tolerated by the structure increases. Once the load reaches physiological levels then, theoretically, the structure will remain intact however many cycles are applied — the fatigue endurance limit.

The principles outlined in the above example are applicable to all constituents of the musculoskeletal system: bone, tendon, ligament and muscle. Whilst the units will vary between tissue types the patterns will also vary within one tissue depending on the direction of the applied load, and this property is called anisotropy. For example, bone has a very high failure load in compression but a relatively low failure load in tension. So far, the principles described could equally well be applied to an inert structure. The challenge of biomechanics is apparent when one considers the multitude of other factors that affect the structural properties of living tissues. Age has a profound influence on both mode of and loads to failure. In growing skeletons the junction between ligaments/tendons and bone is weaker than the ligament itself, and failure typically occurs here. In mature skeletons the failure usually occurs in the midsubstance of the ligament. The failure load of all structures peaks in early adult life and declines thereafter. Ligaments, tendons and muscles are all more compliant (less stiff) at higher temperatures and circulating hormones, particularly sex hormones, can affect the structural properties of soft tissues from one day to the next.
**Diagnosis of sports injuries**

The first question that a surgeon must ask himself or herself is whether the extent of the injury is in keeping with the description of the mechanism of injury. In other words, was this normal tissue that was injured because of an abnormal load applied to it, either a single high load or many cycles of low load? In this situation successful resolution of the injury and avoidance of the abnormal load should prevent recurrence. However, if a relatively normal load resulted in injury then the tissue was probably abnormal and the underlying abnormality is the main concern.

All of these points serve to emphasise the importance of good history taking and careful clinical examination. They still form the cornerstone of diagnosis in all branches of medicine but especially with injuries to the soft tissues.

**Arthroscopy versus imaging**

The principle of using the arthroscope and specialised imaging techniques to diagnose pathology is to be decried. The arthroscope should be used to confirm and treat pathology identified by the surgeon from the history and clinical examination. If the signs and symptoms elicited are not sufficient to establish a diagnosis, then an arthroscopy will not advance matters. For example, arthroscopic confirmation of a torn anterior cruciate ligament is a wasted procedure: the knee is either clinically and/or functionally unstable, or it is not; there is nothing to be gained by looking at it.

The careful clinical assessment of the functional stability of an injured ligament is far more valuable than expensive imaging techniques, such as magnetic resonance imaging (MRI) or computerised tomography (CT) scans, which can be very misleading. No one would consider buying a second hand car from a picture as you cannot tell how well a car goes merely by looking at it. The old rust bucket may look fit for the scrap heap but will drive surprisingly well, whereas the ‘top of the range’ model with all the extras will not even start! In the same way, tissues that appear to be damaged on scans may ‘drive’ perfectly well and normal looking tissues may be functionally useless.

Nevertheless, in some situations when a diagnosis is in doubt or there is an unusual presentation of pathology, then arthroscopy and MRI have their place. Identification of meniscal and ligament damage in the knee is 85 per cent accurate using both these techniques and is invaluable in selected cases.
Skeletal muscle

The contractile elements of skeletal muscle are derived from myoblasts. Each muscle is composed of several muscle bundles which in turn contain muscle fibres, the basic unit of contraction. A muscle fibre is an elongated cell and is composed of myofibrils (1-3 μm in diameter and 1-2 cm long) which are collections of sarcomeres. Each sarcomere is composed of thick filaments (myosin) and thin filaments (actin) arranged in an overlapping pattern that allows the filaments to slide past each other. The force generated by a muscle is proportional to its functional cross-sectional area. A muscle contraction is concentric when the muscle fibres shorten and the tension within the muscle is proportional to the externally applied load. During an eccentric contraction the muscle lengths (pays out) and the internal force is less than the external force. The latter have the greatest potential for high muscle tension and injury. During an isometric contraction tension is generated but the muscle does not shorten.

Muscle fibres are divided into two types: fast twitch and slow twitch. Slow twitch fibres are highly vascularised, and contract slowly and aerobically. They are used in endurance (low-load, high-frequency) activities. Fast twitch fibres contract more quickly and powerfully but they do so at the expense of efficiency and are anaerobic such that they fatigue quickly. The distribution of fast and slow twitch fibres is genetically determined but may be influenced by selective training. Endurance training, typically increases the aerobic capacity of the slow twitch fibres by increasing the number of mitochondria and capillary density. Strength training involves using higher loads at lower repetitions and leads to an increased number of myofibrils as well as hypertrophy of fast twitch fibres.

Muscle injury

During physical activity up to 70 per cent of the cardiac output may be diverted to muscle blood flow. It is easy to see that whenever a muscle is injured significant bleeding is an inevitable complication. The injury may be direct, from a blow compressing the muscle against the underlying bone, or it may be indirect due to excessive distraction of the muscle ends. The latter may result in partial or complete rupture of the muscle.

When bleeding occurs within a muscle the clinician must distinguish between intramuscular bleeding, i.e. contained within a muscle sheath, and intermuscular bleeding. Intramuscular haematoma is a more serious injury and the resultant swelling usually persists beyond the first 48 hours, and is accompanied by significant tenderness, pain and impaired muscle function. If the swelling reaches a critical level then an acute compartment syndrome may result (vide infra).

With an intermuscular haematoma the dispersal of blood within the facial plains means that after an initial period of increased pressure there is a relatively rapid reduction in pressure and swelling with return of muscle function. Typically, superficial bruising may be visible some distance from the site of injury 24—48 hours later.

A number of factors predisposes muscles to rupture:

- inadequate warm-up prior to exercise;
- fatigue;
- previous injury, resulting in:
  - incomplete recovery of muscle strength,
  - inelastic scar tissue impeding muscle elongation and joint motion,
  - loss of muscle proprioceptive feedback;
- eccentric loading;
- muscle spanning two joints.

The principles of treatment for any soft-tissue injury, and particularly for muscle injuries, can be remembered using the acronym RICE.

- Rest
- Ice
- Compression
- Elevation

Treatment should minimise the amount of bleeding within the tissues, and cessation of activity as soon as possible after the injury will allow the fibrin scaffold to develop on the damaged capillaries. A sportsman injured during the course of a game presents the surgeon with a delicate judgement. The injured player may be able to continue playing but the importance of the current match must be weighed against the increasing distance from the site of injury 24—48 hours later.

The application of ice and compression vasoconstricts and tamponades the blood vessels, whilst elevation of the limb hampers the player’s activity and improves venous drainage.

After 48 hours of this regime a more accurate assessment of the extent and nature of the injury can be made. Inspection and palpation of damaged muscle is usually sufficient to diagnose the majority of injuries. In cases of complete muscle rupture the surgeon must decide whether exploration and apposition of the muscle ends is required. If some continuity of the musculotendinous unit can be demonstrated, for example active extension of the knee when a quadriceps rupture is suspected, then surgery is not required.

Complications of muscle injury

A small proportion of large muscle haematomas will fail to be reabsorbed. The walls of the cyst become endothelialised and aspiration is of no benefit. Resection of the cyst is then required with particular attention to haemostasis to prevent recurrence.

Healing deep intramuscular haematomas, most commonly of brachialis and vastus intermedialis, may lead to the formation of bone rather than fibrous tissue, a process known as myositis ossificans (MO). This condition should be suspected if pain, swelling and restricted motion persist despite adequate rehabilitation. Over-vigorous passive stretching of the muscle in the early phase of rehabilitation may precipitate MO and should be avoided. Plain radiographs demonstrating hazy callus formation confirm the diagnosis. Surgery for symptomatic cases must not
Compartment syndrome

Compartment syndrome is a condition in which high pressure within a closed space bounded by fascia and/or bone reduces capillary blood perfusion below a level necessary for tissue viability with subsequent neuromuscular dysfunction. Acute compartment syndrome is a surgical emergency and is dealt with more comprehensively elsewhere in this book. Chronic compartment syndrome affects athletes and results from the vascular engorgement of muscles during exercise superimposed on muscles hypertrophied by prolonged train-ing. The anterior and deep posterior compartments of the tibia are most commonly affected, but the lateral compartment of the thigh and forearm compartments may also be affected. The symptoms of a rapidly worsening ache or cramping pain felt in the affected compartment char-acteristically occur at the same time after the start of training. In the same way that a patient with vascular insufficiency will describe cessation of symptoms upon ceasing the activity, so will the symptoms recur if activity is resumed, usually after a shorter interval. Clinical examination with the patient at rest is usually unhelpful, and examination after the patient has exercised may be equally uninformative if a deep muscle compartment is involved. The diagnosis can be made by using intracompartmental pressure monitoring whilst the patient exercises. The resting pressure is often 15—20 mmHg (normal 0—5 mmHg) and may rise with exercise to >100 mmHg. This abnormal elevation will often persist for 15 minutes or more after stopping the exercise. Treatment should aim to correct any abnormalities in the patient’s gait or training methods, but subcutaneous fasciotomy of the involved compartments has a good success rate.

Assessment of muscle function

The inability of a patient to perform a satisfactory voluntary muscle contraction should lead the surgeon to consider a potential site of injury anywhere from the cerebral cortex to the muscle. All too often the focus is on the muscle itself, forgetting the neural networks that are required to empower the muscle. The patient may voluntarily or involuntarily inhibit the activity of the muscle because of pain; the central or peripheral nervous system may be damaged or diseased or there may be a more generalised hereditary condition such as Duchenne’s muscular dystrophy. Whilst it is important for the surgeon to consider all possible causes of muscle dysfunction, this chapter will confine itself to the assessment of muscle function in athletes.

Muscle power is graded on the Medical Research Council scale:

- grade 0 — no movement;
- grade I — only a flicker of movement;
- grade 2 — movement with gravity eliminated;
- grade 3 — movement against gravity;
- grade 4 — movement against resistance;
- grade 5 — normal power.

It is useful in diseased states, but almost all sportsmen have muscle function in grade 5 and still complain of weakness! Tests for muscle function in this situation are divided between functional tests that quantify the ability of a muscle to perform a specific task and objective tests of muscle strength. One example of a functional muscle assessment is the single leg hop test. This tests principally the quadriceps power of an injured knee compared with the control knee. From a single leg stance the athlete jumps as far as he or she can and the distance is recorded. This is then expressed as a percentage of the distance achieved by the control leg. Inevitably, this test requires good function in several other muscle groups as well as the joints above and below the knee. It is therefore less applicable in the comparison of results between patients, but is useful as a means of monitoring one patient’s recovery following injury or surgery. Objective tests of muscle strength, such as grip strength using a hand-held dynamometer, are readily performed but the results are often subject to great variation. Furthermore, the relationship between results and functional outcome is often not as close as we would wish. Task-specific outcomes such as running figures of eight for assess-ment of the lower limbs and performing activities of daily living for use with the upper limb are more time-consuming but have the advantage that the task can be tailored to meet the requirements of the individual.

Proprioception

Full recovery after injury to muscles and joints requires not only their anatomy to be restored but also the neuromuscular reflexes that control their motion. The word proprioception is derived from the Latin word ‘pro prius’ meaning self or own. It describes a process whereby an individual is aware of the position and movement of a joint. However, it is a rather vague term and its components are usefully considered under three headings.

- Static joint position sense (knowing where the limb is held in space), signalled by slow adapting Ruffini receptors found mainly in the superficial layers of the fibrous capsule of joints.
- Kinesthetic sense (detection of displacement and or velo-city) detected by fast adapting Pacinian corpuscles located in the deeper layers of the joint fibrous capsule.
- Unconscious closed loop afferent/efferent neural activity required for reflex activity and regulation of muscle stiffness. This component is signalled by Pacinian and Ruffini receptors but also by Golgi tendon organs (slow adapting) and muscle spindle receptors (fast adapting).

These receptors occur at multiple sites in the body and there is a complex, and poorly understood, interplay between their signals in producing functional stability of joints. Joint stability is maintained by the static mechanical restraints such as the articular geometry and ligaments, as well as a dynamic element provided by the muscles. The relative importance of damage to the neuromuscular, or proprioceptive, feedback in maintaining stability of an injured joint has only recently received much attention. Damage to anatomical structures and the resultant change in stability of a joint is relatively easy to assess, whereas techniques for measuring the loss of neuromuscular reflexes that provided functional stability were only developed more recently.

It is now well established that injury to a joint can impair the function of all three of the components of proprioception. This impairment may be improved by rehabilitation programmes that specifically address the restoration of sensory feedback from injured joints. Reconstructive surgery, which one would expect to address only the static mechanical restraints of an injured joint, also improves the proprioception of the joints. Rehabilitation programmes that aim to improve neuromuscular control begin by re-establishing joint position sense and kinesthesia followed by dynamic joint stabilisation by using activities that produce sudden alterations in joint position necessitating reflex neuromuscular control. The final phase of these programmes addresses functionally specific activities for return to the chosen sport.

Whilst the importance of neuromuscular components in maintaining functional stability of joints is universally accepted, the exact role of each
of the components is poorly understood and the relationship between loss of neuromuscular reflexes and functional instability is not absolute.
Tendon

Tendons attach muscle to bone and are composed of dense, regularly arranged fascicles, or groups of collagen bundles. The fascicles are surrounded by an epitenon and are closed within the paratendon (tendon sheath). The predominant cells are fibroblasts producing mostly type I collagen (85 per cent dry weight of tendon). Tendons transmit load from muscles to the bone and the collagen fibres tend to orientate themselves along stress lines. The collagen laid down in a healing tendon initially has a haphazard arrangement but when subjected to physiological strains the orientation returns to normal, with restoration of the mechanical properties of the tendon.

Tendon pathology may be divided into three types:
- paratendinitis;
- paratendinitis with tendinosis;
- pure tendinosis.

Paratendinitis is inflammation of the investing paratenon and may be diagnosed by eliciting tenderness around the full circumference of the tendon, the site of which does not move with the underlying tendon (Fig. 29.4). It is an extremely painful condition. Paratendinitis usually responds well to anti-inflammatory medication, local physical therapies such as friction massage and ultrasound, and occasionally an injection of local anaesthetic and corticosteroid into the paratenon (not into the tendon itself). If the paratendinitis becomes chronic it may be necessary to strip surgically the injured paratenon from the tendon.

Tendinosis is a more sinister condition both to diagnose and to treat. It is usually asymptomatic and is present in an increasing proportion of all tendons with advancing age. The term covers a wide variety of pathological processes: hyaline degeneration, a decrease in the normal cell population and alterations in the matrix.

Treatment for tendinosis is difficult and patients should be warned against the likelihood of a ‘quick fix’. Physical therapies aimed at improving the blood supply to the degenerate areas are only moderately successful. Rehabilitation programmes should start with complete rest and only progress within the limits of pain. More recently the emphasis has been on eccentric loading and enhanced proprioceptive feedback to improve tendon healing. Surgical treatment for tendinosis is controversial but a distinction should be made between surgery to remove aggravating mechanical factors, for example subacromial decompression of the rotator cuff tendon, which has a good success rate, and surgery to the tendon itself which is less rewarding. However, encouraging results have been obtained after percutaneous, longitudinal tenorrhaphy of the Achilles tendon, although the risk of precipitating tendon rupture is always present.

Tendon rupture

Rupture is the end point of tendinosis in that there is histological evidence of degeneration present within every tendon that has ruptured. It seems that closed injury cannot rupture a normal tendon, failure always occurring at the musculotendinous junction in this instance.

The principles of treatment of a ruptured tendon are similar to those for treating fractures, namely to restore anatomy and maintain it whilst healing occurs. Tendon ends need to be apposed in order to minimise the gap that must be bridged by fibrous tissue. The larger the gap the greater the volume of scar tissue which has inferior biomechanical properties. A large tendon gap also decreases muscle strength by lengthening the musculotendinous unit and reducing the efficiency of its contractions.

All tendons will heal, and indeed this healing may to some extent be impaired by surgery. The surgeon must therefore be clear that benefit will ensue from his or her surgical intervention. The next point to remember is that the strength of any type of surgical repair will only ever be a small fraction of the strength of the intact tendon. Whilst the initial biomechanical properties of a repair may be improved by placing multiple sutures into the tendon ends, this apparent advantage is outweighed by the adverse effect on the vascular regeneration required to produce tendon healing.

Plantar flexing the ankle usually brings the tendon ends together after rupture of the Achilles tendon. Failure to produce tendon apposition may account for the relatively high rate of tendon re-rupture and weakness of calf muscle power in nonoperatively treated patients. In several instances the tendon ends can never be apposed by closed means; examples of this include rupture of the distal insertion of the biceps tendon on to the radial tuberosity and tears of the rotator cuff tendon. Surgery is then required to restore the anatomy whilst preserving the blood supply wherever possible. One advantage of surgical repair of a ruptured tendon is that a graduated rehabilitation programme to maintain muscle function and joint range of motion can be started within a week of surgery.
Ligaments

Ligaments transmit tensile forces across the joint, define the motion limits of the bones with respect to each other and guide the relative movements of bones within the motion limits. Their ultra structure is similar to that of tendons, the principal difference being that they have a higher elastin content which ensures that joint stability is not entirely rigid. The principles of examination of an injured ligament can be applied to any joint that is readily palpable by direct comparison with the uninjured limb:

<table>

</tr>
<tr>
<td>3</td>
<td>Significant increase in joint laxity with no end point.</td>
</tr>
</tbody>
</table>

Arthrometers have been developed to quantify the amount of joint laxity and are most commonly used after cruciate ligament injury in the knee. However, as they only measure the static stability and do not take into account the dynamic stabilisers of a joint, the correlation between arthrometric estimation of joint stability and the functional instability remains poor.

The stability of joints varies enormously from one individual to the next. Women’s joints tend to be more lax than men’s and all joints become stiffer as we grow older. Connective tissue disorders such as Ehlers—Danlos syndrome or Marfan’s syndrome should be excluded in patients with hyperlaxity. A patient should be assessed for generalised ligamentous laxity using the criteria of Wynne-Davies:

- Elbow hyperextension;
- Knee hyperextension;
- Foot dorsiflexion of more than 45 degrees;
- Thumb can be bent back to touch volar forearm surface;
- Fingers can be hyperextended to parallel forearm.

The principles of treatment for ligament injuries are as for tendon injuries. However, ligament injuries are quite commonly multiple, and because of their close proximity to joints the effect on joint motion is more pronounced.
Bursae

Sandwiched between tissues that slide past each other, bursae decrease the frictional forces present. They are endothelial-lined cushions and normally contain little fluid. If they are overloaded they can become inflamed, swollen and very painful. Although the appearances can mimic sepsis, a pathogenic organism is rarely isolated in cases of closed injury. Common sites for bursitis to develop are:

- olecranon;
- psoas tendon;
- greater trochanter;
- iliotibial band;
- prepatellar;
- infrapatellar;
- retrocalcaneal.

Avoidance of the aggravating mechanical factors and a short course of anti-inflammatories is usually sufficient to control symptoms. Intractable cases require aspiration and steroid injections and, more rarely, excision of the indurated bursal wall.
Stress fractures

Bone is a dynamic structure and, unlike the scaffolding of a building, it adapts to the stresses placed upon it according to Wolff's law. Plain radiographs will chart the activity of a limb, the osteopenia of a nonweight-bearing foot or the thickened metatarsal shafts of an army recruit. Fractures of bone may be due to a single high load or cyclical low loads leading to a stress fracture.

Any repetitious activity, particularly endurance training, is a risk factor for the development of stress fractures. Diagnosis should be suspected from the patient's history, particularly if there has been a recent change in the training pattern, different footwear, a new playing surface or a sudden increase in intensity. Pain and tenderness are often poorly localised and radiographs may be normal in the early phase. Bone scintigraphy, or MRI if it is available, is the investigation of choice to demonstrate the earliest changes of marrow hypervascularity and trabecular microfracture (Fig. 29.5).

A common theme for treating these conditions is the necessity for a reduction in weight-bearing, particularly high-impact activity, for healing to occur. This disruption to the athlete's training regime requires counselling but, more importantly, a satisfactory replacement activity must be found to keep up the athlete's supply of endorphins! Cycling, with the pedal held under the heel, is the ideal substitute for runners, whilst swimming is less well tolerated.

Two patient subgroups should be identified: children and women. Children often present late with vague symptoms and the radiological changes to the growth plate may be difficult to interpret. The contralateral limb should be X-rayed to provide a control. Female athletes appear to be at increased risk of developing stress fractures. There appears to be a complex interplay between dysmenorrhea, exercise and decreased bone density, particularly if an eating disorder is superimposed.

The distribution of stress fractures amongst runners is: tibia 49 per cent, tarsals 25 per cent, metatarsals 9 per cent, femur 7 per cent and fibula 7 per cent.

The majority of fractures can be treated nonoperatively without great risk, but femoral neck stress fractures must be carefully assessed. There are two types: a tension fracture, which begins as a cortical defect on the superior aspect of the femoral neck, and the compression type, which appears as a haze of callus around the inferior cortex. Failure to recognise these fractures may result in displacement of the fragments with the subsequent risk of osteonecrosis, malunion and nonunion. Internal fixation with multiple screws should be considered in cases where symptoms are not controlled by reduction in weight-bearing.

Stress fractures of the pelvis occur about the ischium, but the ilium and sacrum may be involved. The tarsal navicular and metatarsal stress fractures are the bane of the armed forces owing to marching, but particular care must be taken of the base elf fifth metatarsal fracture as it has a high rate of delayed union or nonunion. Stress fractures are not confined to the lower limb and may occur in the ribs, clavicle, acromion, olecranon and metacarpals (Fig. 29.6).
Lower leg pain

Lower leg pain is a common complaint in athletes who have recently changed their footwear or have increased the intensity of their training. The main diagnoses to be considered are stress fracture of the tibia, chronic compartment syndrome, medial tibial periostitis and tibialis anterior syndrome. The term ‘shin splints’ is unhelpful and should be avoided.

Stress fracture of the tibia

Stress fractures are not uncommon in the tibia, particularly in long-distance runners. The patient initially complains of pain during exercise, then pain during and after exercise, and finally pain at all times. On examination there may be little to find except that the tibia may be tender to percussion. Initially the X-ray may be normal but after some weeks a faint haze of callous may form locally over the site of the invisible fracture. This X-ray picture, if combined with a history of continuous pain, is also characteristic for osteosarcoma. Careful imaging with MRI or CT scan should be able to distinguish between these two diagnoses.

This condition can prove very difficult to manage. It may occur at a crucial phase in an athlete’s training programme and at some stage, preferably sooner rather than later, it is going to become clear that training for the next few months or indeed that season is over. This can be very difficult for an athlete to accept, but until it is the condition is unlikely to settle. As the fracture is incomplete it should not require any extra protection, and a modification of activity is usually all that is required for healing.

Chronic compartment syndrome

The anterior and deep posterior compartment is most commonly involved. Physical examination is generally unhelpful and a diagnosis is made from the history and intra-compartmental pressure monitoring whilst the athlete exercises. Subcutaneous fasciotomies of the affected compartment provides good relief of symptoms.

Tibialis anterior syndrome

Acute inflammation in the tendon sheath of the tibialis anterior muscle often arises from over-use of the ankle joint, especially running and jumping on hard surfaces. Tenderness is localised to the tibialis anterior tendon with pain on resisted dorsiflexion of the ankle. Increased temperature, swelling and crepitus may be palpated over the tendon sheath. Resolution is usually swift with a short period of non-weight-bearing and rest.

Medial tibial periostitis

The attachment of the investing muscle fascia into the periosteum of the postero-medial order of the tibia may become inflamed. The pain is often poorly localised by the athlete but tenderness is well localised over the distal medial margin of the tibia, particularly over the lower half of the bone. Resisted plantar flexion aggravates the pain and radiographs should be performed to exclude a stress fracture.
Groin pain

A wide variety of pathologies can present with pain in the groin. The surgeon requires a systematic and methodical approach to the diagnosis based on a sound knowledge of the complex anatomy in the region. The history of pain should give clues as to whether the origin is visceral (more constant) or somatic (exercise related). Each surgeon will develop their own system but it is reasonable to separate the pathologies on the basis of the tissue involved.

Muscles

A large number of muscles takes their origin from or traverse the region of the groin. Inflammation of these musculo-tendinous origins or partial tears will produce activity-related pain. The principles of assessment are carefully to localise the point of maximal tenderness and then test the muscles in that area with an isometric contraction. Muscles that frequently cause problems are the proximal insertion of rectus femoris just distal to the anterosuperior iliac spine, the adductor musculature inserting into the inferior aspect of the pubic bone and psoas tendon as it courses over the anterior aspect of the hip joint to the lesser trochanter.

Visceral organs

Visceral pain from pelvic organs may produce groin pain and a careful history will have elicited symptoms of systemic upset. Appendicitis, prostatitis, urinary tract infection and gynaecological disorders should always be borne in mind and dealt with appropriately.

Nerve entrapment

Lumbar spine disease causing entrapment of the higher lumbar nerve roots may produce pain radiating around the buttock to the groin. Less commonly the ilio-inguinal (in the inguinal canal) and lateral cutaneous nerve of the thigh (distal to the anterosuperior iliac spine) may be trapped as they pass through the deep fascia.

Hernia

Male athletes who play sports that involve a lot of twisting and turning are prone to developing the 'sportsman's hernia'. This is really a direct 'prehernia' in that no bulge can be demonstrated either clinically or even with specialist scanning techniques. The hernia is a fatigue failure of the transversalis fascia which only becomes symptomatic because of the repeated stresses placed on it by the athlete. The diagnosis is based on the history and tenderness at the deep inguinal ring. This sign is elicited by invaginating the scrotum with the little finger until the tip can be placed directly over the deep inguinal ring. The examination is uncomfortable and so comparison with the normal side is required. Repair is performed in the standard manner either using a mesh or by reefing the conjoined tendon to the inguinal ligament.

Bone and joint

Osteoarthritis of the hip classically presents with groin pain, and the diagnosis should not be excluded because of normal radiographs. Plain radiographs will usually demonstrate a stress fracture of the femoral neck but if there is still doubt then bone scintigraphy or an MRI will establish the diagnosis.

Osteitis pubis is a well-recognised but poorly understood condition. Pain and tenderness are vaguely localised to the anterior pubic bones and intervening symphysis. Plain radiographs may demonstrate changes of fragmentation of the margin of the pubic bones and patchy sclerosis within the symphysis. The aetiology of this condition is unknown; certainly no pathogenic organisms have ever been demonstrated within biopsies. Treatment is frustrating for both surgeon and athlete as it may require a prolonged period of non-weight-bearing activity. Fusion of the pubic symphysis should be avoided as the results are very poor.
Knee

Ligament injuries of the knee

The four major ligaments of the knee (anterior and posterior cruciate, medial and lateral collateral) maintain its stability and guide its motion. The anterior cruciate ligament (ACL) provides the major restraint to anterior translation of the tibia on the femur, and the posterior cruciate ligament (PCL) to posterior translation. The medial collateral ligament (MCL) resists varus deformation but the lateral collateral ligament (LCL) is the weakest of the four and does little to prevent varus deformity, the majority of restraint coming from the dynamic input of the iliotibial band. All four ligaments work in close harmony and injury to one affects the function of the others. The following combination of injuries is roughly in their frequency of occurrence:

- MCL;
- ACL;
- ACL and MCL;
- PCL;
- PCL and posterolateral structures;
- ACL, MCL, PCL (knee dislocation, rare).

MCL injury

These occur after a valgus injury, commonly during snow skiing. There is pain and tenderness localised to the site of injury, usually the midsubstance or proximal insertion and valgus instability may be elicited. Grade I injuries may be treated symptomatically; grade II—III should be braced with knee motion restricted from 10° to 90° for 3—4 weeks. Athletes should be warned of ‘tweaking’ pains that persist for up to a year following MCL injury.

ACL and ACL-MCL injury

The history of a noncontact athlete who was run-ning and tried to change direction, felt the knee ‘jump’, heard a pop and developed immediate swelling is almost diagnostic of ACL injury. If the knee took 2—3 weeks to settle down and the athlete is left with a feeling of, or experiences, instability then any lingering doubts over the diagnosis can be dispelled. Clinical confirmation comes from increased anterior tibial translation with the knee held in 30° of flexion (positive Lachmann test) and abnormal anterior subluxation of the lateral tibial plateau (positive Pivot shift test). The main indication for surgery is the recurrent episodes of instability that patients experience when changing direction or landing from a jump.

ACL rupture is commonly associated with injury to other structures in the knee. Meniscal tears are present 80 per cent of the time and unstable meniscal tears should be repaired at the time of ACL reconstruction. ‘Bone bruises’ visible on MRI scans represent subchondral oedema and are evidence of impact damage sustained at the time of injury.

All patients with ACL injury should undergo an intensive rehabilitation programme, with special emphasis on hamstring proprioception. The decision making concerning the need for, and technique of, surgical reconstruction is not straight-forward. There is a massive body of literature, but very little science. At present, the major determining factors are the degree of knee laxity and the level of sport to which the athlete wishes to return. The decision is relatively easy at each end of the spectrum; the high-demand athlete with a loose knee probably (but still by no means certain) requires reconstruction, whereas the nonsporting office worker with a fairly stable knee does not need a reconstruction. With patients in the middle ground, who may or may not wish to adapt their sporting lifestyle to accommodate their knee, it is reasonable to adopt a wait-and-see policy, and if functional instability develops then reconstruction can be offered at a later date.

Surgery should be delayed until the swelling and range of motion have improved in order to avoid a painful stiff knee postoperatively (arthrofibrosis). Combination ACL—MCL injuries should be braced for 3—6 weeks to allow the MCL to heal and then have the ACL reconstructed.

Techniques of ACL reconstruction

The child’s ACL usually avulses with a fragment of bone from the tibia. It is relatively simple to fix this fragment back into the tibia either with a bone screw or with sutures passed through to the front of the tibia. The adult ACL tears midsubstance or at the femoral insertion but rarely heals.

Extra-articular reconstructions

These prevent the abnormal anterior subluxation of the lateral tibial plateau by re-routing the iliotibial band around the LCL. Whilst they abolish the pivot shift phenomenon they do not restore normal knee kinematics and the majority of surgeons no longer use them routinely.

Intra-articular reconstruction

Suturing the ends of the ACL back together is only possible in the acute injury, but the long-term stability of the knee is poor and the technique has largely been abandoned. The ACL is therefore replaced with a graft placed through bone tunnels which enter the joint at the sites of attachment. Graft positioning is critical to the success of ACL reconstruction, and ideally the graft should not lengthen or shorten by more than 2 mm when the knee is put through its full range of motion, i.e. it is isometric. Prosthetic grafts are very attractive because of the lack of donor morbidity and their high initial strength. However, the early optimism with their use has been dampened as problems have developed due to particulate debris when the grafts fail. They are usually only used if a viable alternative is not available.

Allografts have no donor morbidity but all methods of sterilisation (to prevent disease transmission) significantly reduce the biomechanical properties and delay the revascularisation of the graft.

Autografts are the most widely employed at present, the two most common ones being the middle third of the patellar tendon with patellar and tibial bone blocks at either end, and the quadrupled semitendinosus and gracilis tendon graft. These may be secured with interference screws within the bone tunnels or via sutures to screws/posts on the external cortex (Fig. 29.7). The surgery may be performed open or with the arthroscope, drilling the tunnels from within the joint. The modern trend for accelerated rehabilitation permits early weight-bearing without braces, and athletes can return to contact sport 6 months after reconstructions.

PCL injury

Commonly sustained during road traffic accidents from a direct blow to the front of the tibia, PCL injuries are much less common than ACL injuries (occurring in a ratio of about 1:10). Examine the patient with both knees flexed to 90° and you will see the tibia sagging back on the
side of PCL injury. The knee of patients who have a femoral shaft fracture should always be examined to exclude injury to the PCL.

Isolated PCL injuries probably do very well if rehabilitated and, as the surgery to reconstruct them is not as well developed as ACL surgery, nonoperative treatment is recommended.

**PCL and posterolateral structures**

These are significant injuries but diagnosis is often difficult, and the loss of posterolateral structures (posterior capsule, popliteus tendon and the popliteofibular ligaments) in addition to the PCL can render the knee unstable. In an athletic individual acute reconstruction is probably to be recommended, but the surgery is complex and the results are not yet convincing.

**Knee dislocation (combination of three or more ligament injuries)**

Thankfully rare and a result of high-energy trauma, knee dislocation is a surgical emergency. Neurovascular injury may occur in 50 per cent of cases despite a normal-looking radio-graph, and vigilance must be maintained at all times with these injuries to avoid catastrophe. Reconstruction of all of the damaged structures is difficult surgery but in experienced hands can lead to a reasonable outcome.
Ankle sprains are one of the most common sporting injuries requiring treatment. The mechanism is usually inversion damaging the anterior talofibular (ATF) and subsequently the calcaneofibular (CF) ligaments (Fig. 29.8). Surgery to repair the ligaments is rarely required; functional bracing with early weight-bearing allows the ligaments to heal whilst main-taining ankle motion.

If the recovery after ankle sprain is slow then chondral damage to the talar dome should be suspected. Bone scintigraphy is the most sensitive investigation and lesions can be treated with arthroscopic débridement.

Recurrent lateral instability of the ankle requires a rehabilitation programme concentrating on restoration of proprioception but if this fails then repair is indicated. A direct repair of the ligament ends is usually possible, otherwise the use of a periosteal flap from the fibula or a free hamstring autograft may be used to reconstruct both the ATF and the CF liga-ments. The use of some or all of the peroneal tendons for reconstruction is best avoided as they are the dynamic stabilisers to inversion.

Posterior impingement of the ankle is practically an occu-pational hazard in ballet dancers. With the ankle in point (forced plantar flexion) the posterior malleolus, the talus and the calcaneum compress the soft tissues causing inflamma-tion. An os trigonum may or may not be present, but the diagnosis is made by reproducing the pain of impingement. With the patient prone, plantarflex the ankle and compress the heel whilst moving the forefoot from side to side. Treat-ment is surgical resection of the soft tissue, or os trigonum if present, via a short medial approach.

Repeated trauma to the anterior joint capsule causes anterior osteophytes (‘footballer’s ankle’) which limit dorsiflexion. These may be resected via the arthroscope.

Forced eversion of the ankle may disrupt the sheath sur-rounding the peroneal tendons allowing them to subluxed anteriorly. The athlete reports a ‘snapping’ sensation with activity and resisted eversion demonstrates the abnormality. Splints are ineffective at keeping the tendons in place so surgery is required to repair the defect in the sheath, supplementing it with a periosteal flap.

Ruptured tendoachilles

Rupture of the tendo achilles (TA) most commonly occurs in patients in their 40s who experience a sharp snap while run-ning or jumping. Over 80 per cent occur during sport, and the athlete describes a feeling of being struck in the back of the heel. On examination there is tenderness and swelling over the TA and careful palpation may reveal a dent in the TA, especially if it is compared with the other side. Paradoxically the patient may still be able to stand using their long toe flexors, although it may be painful. Simmons’ test involves lying the patient face down on the couch with their feet hanging over the edge of the bed. If the calves are squeezed the foot on the normal side plantar flexes but if the TA is ruptured there is no movement. This test is pathognomonic of ruptured TA.

Management

If the tear is at the musculotendon junction high up in the calf then treatment only needs to be symptomatic, but if it is in the middle of the substance of the tendon then the two ends must be brought into close apposition for healing to occur. This can be done by managing the patient in a below-knee plaster with the ankle in full equinus. Serial plasters are may be used to bring the foot up into neutral. After a total of 6—8 weeks the leg is taken out of plaster and mobilisation of the ankle is started. Surgery to appose the tendon ends may be performed through a longitudinal medial incision (open) or via stab wounds (percutaneous) (Fig. 29.9). Accelerated rehabilitation regimes with functional braces are now commonly used. Ankle mobilisation starting 7 days after repair and 3-4 weeks after nonsurgical treatment lowers the re-rupture rate and maintains better muscle function.

Nonsurgical treatment has a re-rupture rate of 6—10 per cent, open repair risks wound breakdown (1—2 per cent) which is a disaster, and percutaneous repair may lead to sural nerve injury. The results of the few prospective randomised trials have unfortunately been inconclusive, so surgeons should stick to what works best for them.
Shoulder

Instability

Glenohumeral dislocation is not difficult to diagnose but athletes are prone to subtle instability due to stretching of the anterior capsular structures. Abducting the shoulder and using the arm above shoulder height are painful. A diagnosis of subacromial impingement is often made because of a failure to elicit a positive apprehension test. Standing behind the athlete, abduct their shoulder to 90°, and then try to pull their elbow posteriorly: if the test is positive they will ask you to stop, not because of pain, but apprehension. In subtle cases of instability you may need to stress the joint by pushing the humeral head forwards with your thumb to reproduce the symptoms.

Treatment should start with a rehabilitation programme to improve proprioception and rotator cuff muscle strength. If there is no improvement after 3 months then a stabilisation is performed by double-breasting the anterior capsule (inferior capsular shift procedure). Athletes with multidirectional instability due to ligamentous laxity should be identified and treated nonoperatively as surgery in these cases is complex and less proven.

Throwing injuries

Throwing involves a number of distinct phases, each with characteristic injuries (Table 29.2). Skeletally immature athletes, despite the same mechanisms of injury, sustain avulsion fractures of the ligament insertions rather than rupture the ligament.
Elbow

Soft-tissue injuries

Rupture of the triceps near its insertion into the olecranon is caused by resisted elbow extension or a fall. The diagnosis is quite often missed as the defect is not readily palpable because of swelling and as gravity can extend the elbow the loss of active extension may not be recognised by the patient immediately. Surgical repair of the avulsion is required for good function.

Avulsion of the biceps tendon from its insertion into the radial tuberosity occurs after violent trauma in young athletes and due to degeneration in older patients. Early reattachment using a small antecubital incision to retrieve the tendon end and a posterior approach to identify the tuberosity usually restores full function.

Nerve entrapments occur at the elbow, commonly the ulna nerve in the cubital tunnel and occasionally the anterior interosseus nerve within pronator teres. Electrophysiology should be used to confirm the diagnosis before surgical release.

Loose bodies

Throwing sports can lead to repeated minor trauma of the elbow which can manifest in loose bodies. The history of intermittent locking is diagnostic and arthroscopic removal is very satisfying for both surgeon and patient.

Epicondylitis

Medial (‘golfer’s elbow’) and lateral (‘tennis elbow’) Epicondylitis are in fact misnomers as inflammation is secondary to the primary pathology, tendon degeneration. The common flexor origin and the extensor carpi radialis brevis are the respective culprits. Anti-inflammatories, oral and locally injected, are usually ineffective and attention should focus on correcting playing style, grip size (tennis racquet) and equipment (light, graphite racquet) before reducing the frequency of playing. Local physical therapies are beneficial but if these measures fail, the degenerate area is excised and the tendon repaired.

Function

Wrist

The wrist connects the radius and ulna to the metacarpals. It should provide a stable, mobile, pain-free platform on which the hand can function. It comprises eight bones — scaphoid, trapezium, trapezoid, capitate, hamate, triquetral, pisiform and lunate. A complex system of intrinsic and extrinsic ligaments maintains the alignment of these bones and co-ordinates their movement, whilst the long flexor and extensor tendons contract across them.

Hand

The hand is a very intricate tool with which the individual can receive information from the outside world and then act upon it. It must be supple, sensate, pain-free and co-ordinated. There are several types of grip. The thumb acts as a post against which the index finger moves for fine pinch (picking up a pin). The little and ring fingers curl into the palm to provide power grip (holding a hammer). The thumb moves to the side of the index finger for key grip and to the tips of the index and middle fingers for chuck grip (holding a pen). All of the fingers curl for hook grip (holding a suitcase).
Assessment

A careful history and examination is as important for the wrist and hand as anywhere else.

History

• General — Is the patient left or right handed? Occupation, hobbies and ambitions? How do the symptoms interfere with these?
• Pain — What is the site of the pain, what makes it better or worse, how long has it been present, does it fluctuate?
• Function — Is the grip weak? Are there problems with fine motor tasks, such as doing up buttons, or coarse tasks, such as opening a jar? Are there clicks or clunks?
• Sensation — Loss of sensation? Tingling? Which part of the hand?
• Injury — The exact nature of the injury: a cut (sharp, blunt, dirty?), a crush, a fall (how far?), a bite, a punch, an avulsion?
• General health — Diabetes? Smoking? Steroids? Cardiac or respiratory problems which may influence the choice of anaesthetic?

Examination

• In the injured patient, are there Airway, Breathing or Circulation problems which should take priority?
• Skin — Are there cuts or bruises? Is there skin loss, and if so are tendons or bone exposed? Are there previous sur-gical or traumatic scars? Are there signs of infection?
• Bones — Is there deformity or tenderness? The precise of tenderness can be diagnostic, for example a tender lunate with Kienböck’s disease or a tender anatomical snuffbox with a scaphoid fracture.
• Joints — Is there deformity or tenderness? Ligament stability should be tested by stabilising the proximal bone and gently stressing the distal. The active and passive range of movement in each joint should be established. A similar restriction in both active and passive movement may be caused by pain or joint stiffness. A discrepancy may be due to tendon rupture, tendon adhesions or a nerve palsy.
• Tendons — Passive tenodesis is a useful screening test: the hand is relaxed and the wrist is moved into flexion and then extension by the examiner. As the wrist extends, the fingers should curl into a neat cascade, and as the wrist is flexed the fingers should open. The function of each individual tendon is established. Flexor digitorum profundus is tested in each finger by supporting the proximal interphalangeal joint and middle phalanx then asking the patient to flex the distal interphalangeal joint. Flexor digitorum superficialis is tested with the examiner holding the other three fingers straight and asking the patient to flex the proximal interphalangeal joint of the remaining finger. Extensor digitorum communis is tested by asking the patient to fully extend the metacarpo-phalangeal joints (interphalangeal joint extension is a function of the intrinsic muscles).
• Nerves — The nerves supplying the hand can be quickly checked. If there is a cut in the palm or finger, the digital nerves should be tested by checking sensation on each side of the finger tip. Two-point discrimination is useful in partial nerve lesions or recovering nerves; two prongs of a paper clip are spread and the patient asked to say whether one or two points can be felt. Normal discrimination in the finger tips is about 6 mm. Tinel’s percussion sign — tapping on a nerve and causing ‘tingling’— is present at the site of nerve compression, a neuroma or at the advancing tip of a recovering nerve. In the unconscious patient or young child, the plastic pen test is helpful. If the nerve is normal then the side of a pen brushed gently across the skin will stick because of the intact supply to sweat glands; if the nerve is divided, the pen will brush off smoothly.

Examining the nerves of the hand

• Circulation — A white or blue fingertip suggests circulation problems. If the finger nail is compressed and then released, the circulation should return in less than 2 seconds. If not, this suggests either systemic hypotension or loss of the local blood supply. With the Allen test, one can tell whether both radial and ulnar arteries are intact. Both are compressed by the examiner’s fingers, the patient squeezes his or her hand to express the blood and then relaxes. The hand will be white. The examiner then releases one artery; if the hand does not ‘pink up’, that artery is occluded or divided. The test is repeated for the other side.

Investigation

• Plain radiographs — The standard views are a posteroanterior and true lateral. Oblique views are helpful particularly for intra-articular fractures and scaphoid fractures. Special views, for example stress views for ulnar collateral ligament injuries of the thumb or a clenched fist view for carpal instability, are sometimes needed.
• Magnetic resonance imaging (MRI) — This can detect, for example, Kienbück’s disease before it is apparent on plain radiographs and gives some indication of the vascularity of a scaphoid fracture.
• Isotope bone scanning — In difficult cases this helps by disclosing the inflammation that accompanies undisconnected fractures or bone lesions such as osteoid osteoma.
• Wrist arthroscopy — This can diagnose tears of the triangular fibrocartilage complex (TFCC), carpal instability and arthritis. Some TFCC
tears are treatable arthroscopically.

• Electrophysiology — For a clinically obvious carpal tunnel syndrome these may not be required; for less clear neurological symptoms these tests detect if and where there is nerve compression.
Basic principles of treatment

Certain principles must be followed when treating conditions of the hand and wrist.

Avoiding swelling and stiffness

The hand swells following injury, surgery or infection (Fig. 30.1); as it swells it tends to fall into a position with the wrist flexed, the metacarpophalangeal joints extended and the interphalangeal joints flexed. This position becomes permanent as the collateral ligaments shrink and the oedematous tissues fibrose. The hand then cannot function properly. To avoid this, one must obey the following three principles.

1. **Elevation.** The hand must be elevated in a high sling or roller towel (Fig. 30.2), care being taken that the venous drainage is not occluded by too much elbow flexion.

2. **Splintage.** The wrist should be splinted initially in the position of safety — the 'Edinburgh' position described by James (Fig. 30.3). Dressings must not be too tight.

3. **Movement.** As many joints as possible of the wrist and hand should be moved as early as possible. Rehabilitation should be planned so that the fewest possible joints and tendons are immobilised.

Anaesthesia

Many procedures on the wrist and hand can be performed using local anaesthesia either proximally (scalene block, axillary block) or more distally (Bier's block, wrist block, digital nerve block or tendon sheath block). In general, if a tourniquet is used for more than about 20 minutes it becomes un-comfortable and so a proximal block or general anaesthetic is preferred.

For a digital nerve block, local anaesthetic is introduced into the palm at the level of the distal palmar crease; this is preferable to surrounding the base of the finger with a potentially occlusive 'ring block'. An alternative is to instil about 1 ml of 2% lignocaine beneath the flexor tendon sheath. This takes a little more time to work than a digital nerve block, but lasts for longer and is equally effective.

Tourniquet

A bloodless field is essential for accurate surgery. A well-padded tourniquet above the elbow, inflated to 75 mmHg pressure over the systolic blood pressure, is usually satisfactory. The time should not exceed 2 hours. An Esmarch bandage or a rubber-tube exsanguinator are effective, but should be avoided for tumour or infection cases lest the pathology is spread systemically. In the finger, a tourniquet can be made by placing a sterile glove on the patient, snipping off the tip and then rolling the glove down to the base of the finger.

Incisions

Incisions which cross a flexion crease may produce an uncomfortable and restrictive contracture. Therefore, surgical incisions should be planned to cut across flexor creases at 45° or to lie in neutral areas, such as the midlateral line of the finger. An alternative is to close a straight incision across a flexor crease with a Z-plasty (Fig. 30.4).

Splints

Splints can broadly be described as resting, static or dynamic (Fig. 30.5). Resting splints are used to immobilise the hand when there is active inflammation, for example after injury, after surgery or during a flare-up of rheumatoid arthritis or infection. Static splints can be used continuously (e.g. for a fracture until healed), serially (e.g. gradually changing the angle of a splint to overcome a joint contracture) or periodically (e.g. a wrist extension splint at night to reduce symptoms of carpal tunnel syndrome). Dynamic splints allow movement of one group of tendons but not the antagonist, for example to protect either the flexor tendons or extensor tendons after repair.
Injuries

Vascular injuries

Vessel division

A partial injury of an artery will not contract and seal itself so it continues to bleed. Bleeding should be controlled with pressure — it is dangerous to use a tourniquet (which can be forgotten) or to clip the vessel blindly (which spoils the chance for repair and can damage the nearby nerve).

Compartment syndrome

Following crush injuries and fractures of the forearm or hand, or prolonged ischaemia from vessel damage, tourniquet or tight dressings, a compartment syndrome can develop. The pressure within the fascial compartments (superficial flexor, deep flexor, extensor, interossei, thenar and hypothenar) rises and occludes the microcirculation which supplies the muscles and nerves. The symptoms are pain, tingling, cold; the signs are tightness, tenderness and swelling of the muscles, and pain on passive stretching of the muscles in the compartment. The main vessels will not necessarily be occluded as their closing pressure is greater than the pressure required to cut off the microcirculation. Any cast and dressings should be released and, if this does not relieve the ischaemia, then a surgical fasciotomy should be performed. Measurement of the compartment pressures can help in a few cases, but should not delay fasciotomy if the clinical picture is clear.

Fractures

Scaphoid

This bone is fractured by a fall on the outstretched hand. The fracture is easily overlooked — it causes little deformity or pain and does not always show clearly on plain radiographs. However, it is notorious for two reasons — it may not unite (particularly in the relatively avascular proximal pole) or it may present later with intercarpal collapse and osteoarthritis. If there is doubt about the diagnosis, the wrist is best immobilised and radiographs repeated 2 weeks later. If there is still doubt, isotope bone scanning or MRI scanning will confirm the diagnosis. Plaster immobilisation is needed for at least 8 weeks; delayed union (e.g. if not healed by about 3 months) may merit bone graft and internal fixation (Fig. 30.6). Some unstable displaced fractures probably need early internal fixation.

Distal radius

This is commonly injured. There are broadly three groups of fracture.

- **Children.** Usually a Salter Harris type 2 physeal injury, with the distal ulna sometimes fractured as well. Manipulation and plaster fixation for a few weeks is usually adequate. Percutaneous Kirschner wires are sometimes needed for unstable injuries.

- **Young adults.** Usually a high-energy injury, with several intra-articular fragments. Perfect anatomical reduction is most likely to give the best result; this may need a selection of techniques, including bone graft, percutaneous wires, internal fixation and distraction with an external fixator.

- **Older adults.** Typically through osteoporotic bone in a postmenopausal female after a fairly minor fall. This is the classic Colles’ fracture. The distal fragment is tilted dorsally and radially; the radius is shortened because of impaction. Reduction is easily achieved by manipulation under regional anaesthesia or haematoma block, but slippage is common and percutaneous wires may be chosen for some.

Metacarpals and phalanges

- Fifth metacarpal neck: usually caused by a punch (hence *Boxer’s fracture*). Up to 600 of flexion at the fracture site can be accepted because of the spare hyperextension in the fifth metacarpophalangeal joint and because the little finger’s function is to flex — a loss of extension is not functionally too important. It is treated with elevation and splintage for a few days and then gentle mobilisation. Surgery is rarely required. The ‘dropped knuckle’ deformity is permanent.

  - Metacarpal shaft fractures: most metacarpal fractures are stable and undisplaced, and need a resting splint for 1—2 weeks followed by careful mobilisation. If spiral, the finger rotates (no longer points to the scaphoid tubercle along with the other fingers when flexed into the palm); if angulated the prominent metacarpal head can be uncomfortable when gripping. Therefore some metacarpal fractures need manipulation and fixation with plates or percutaneous Kirschner wires.

- Phalangeal fractures: whatever the fracture and its management, the fingers must be moved within a few days of injury to avoid stiffness. Most phalangeal fractures are undisplaced or can be manipulated under local anaesthetic into a stable, anatomical position. The hand is splinted and elevated for a few days then the fractured finger is strapped to a neighbouring finger and mobilised. If the fracture is displaced and unstable, or if the joint surface is disrupted, accurate reduction and fixation is needed. Rigid fixation with miniplates and screws allows early mobilisation which prevents stiffness, but unfortunately the soft-tissue dissection required paradoxically can cause stiffness. Therefore, percutaneous wires are generally preferred unless open surgery is needed for reduction.

Ligaments

Carpal instability

No tendons attach to the scaphoid, lunate or triquetral. These bones are called the ‘intercalated segment’, and their position and stability are controlled by the stout ligaments interconnecting them. Damage to these ligaments, usually after a fall on the outstretched hand, causes the bones to rotate abnormally in relation to each other (Fig. 30.7). If the scapholunate ligament is ruptured, the lunate tilts dorsally and the scaphoid flexes forward; on the posteroanterior radiograph the flexed scaphoid looks like a ‘ring’ and the scapholunate gap opens up. Early repair and temporary stabilisation with wires should be considered.

Thumb ulnar collateral ligament

The ulnar collateral ligament of the thumb metacarpophalangeal joint is crucial for stable pinch. It can be torn when the thumb is wrenched radially (‘skier’s thumb’). A relatively stable sprain is splinted for about 3 weeks; an unstable ligament should be repaired; often the adductor pollicis tendon is trapped between the torn ligament and its insertion. The thumb ulnar collateral ligament can also be stretched with chronic
overuse (‘gamekeeper’s thumb’).

**Triangular fibrocartilage complex**

This important structure attaches the base of the ulnar styloid to the ulnar side of the distal radius. It is continuous with the dorsal and palmar capsule of the ulnar side of the wrist. The TFCC stabilises the distal radioulnar joint. It can be torn, leading to instability of the distal radioulnar joint and ulnar sided wrist pain. The diagnosis is confirmed by arthrography or arthroscopy, and some tears can be repaired.

**Dislocations**

**Peri lunate**

A fall on the outstretched hand can cause the lunate to dislocate from the surrounding carpus, or for the carpus to dislocate around the lunate. The scaphoid may also be fractured. Median nerve compression may result. The injury is easily missed on radiographs. Prompt reduction should be supplemented by ligament repair and temporary Kirschner wires.

**Metacarpophalangeal joints**

These can be simple, which reduce easily, or complex, which usually need open reduction through a dorsal approach because the palmar plate (the thickened palmar capsule) is wedged in the joint.

**Bennett’s fracture-dislocation**

This unstable intra-articular fracture of the thumb carpometacarpal joint is difficult to treat with plaster; closed reduction and percutaneous wire fixation for 5 weeks is more reliable.

**Interphalangeal joints**

These are usually easy to reduce and are stable. However, an associated fracture of the condyles, tendon avulsion, palmar plate avulsion or collateral ligament tear may need specific treatment.

**Tendons**

**Mallet finger**

Forced flexion of the distal interphalangeal joint can rupture the insertion of the long extensor tendon. There may be a bone fragment. Closed reduction and splintage in full extension for 8 weeks is preferable to surgery which has a high complication rate.

**Flexor tendons**

Flexor tendon injuries have a poor reputation. Surgery is particularly demanding in Bunnell’s ‘no man’s land’ — other-wise known as zone II — between the metacarpophalangeal joint and distal interphalangeal joint where both flexor digitorum superficialis and flexor digitorum profundus run in an intricate, tight fibrous sheath (Fig. 30.8). The best outcome is probably with primary repair by an experienced surgeon using special sutures under magnification (Fig. 30.9). Rehabilitation must be meticulous to avoid either stiffness or rupture. Various splints and mobilisation protocols have been recommended.

**Extensor tendons**

Extensor tendon injuries generally have a better outcome than flexor tendon injuries. They usually recover well with careful primary suture and splintage for about 4 weeks. There are two sites where special care must be taken.

- Cuts over the proximal interphalangeal joint, if untreated, can lead to a ‘boutonniere’ (buttonhole) deformity because the central slip no longer extends the proximal joint whilst the remaining extensor mechanism hyperextends the distal joint and flexes the proximal joint. Early repair and splintage is therefore important.
- Cuts over the metacarpophalangeal joint, especially following a punch, usually enter the joint and must be thoroughly cleaned.

**Fingertip injuries**

The choice of treatment depends on the type of injury, as well as the patient’s occupation, hobbies and cosmetic demands. Many fingertip injuries will heal when left alone beneath a semi permeable dressing. If more than 1 cm² of skin is lost, a skin graft will speed up the overall time to healing. If the pulp is lost and bone exposed then many techniques are available to cover the bone and maintain the length of the finger. If early return to manual work is important, then shortening through the distal interphalangeal joint is considered (‘terminalisation’). Careful attention to detail is important — trimming the condyles, tailoring well-vascularised skin flaps, burying the nerve ends and completely removing the nail bed. If length, sensation and appearance are important (particularly in the thumb and index finger) then a flap may be preferred: for example, a cross-finger flap or a V to Y advancement flap (Fig. 30.10).

**Replantation**

With microsurgical techniques, it is sometimes both possible and advisable to replant amputated parts (Fig. 30.11). Amputated parts should be wrapped in a sterile cloth soaked in sterile saline, and placed in a plastic bag which is placed in water and crushed ice. Replantation is not always advisable. The choice must always be tailored to the individual injury and the individual patient. A single digit replanted proximal to the superficialis insertion is likely to become very stiff, with imperfect sensation and the prospect of a considerable time off work after the first, and often subsequent, surgery. Amputation is often a better option. The thumb, in contrast, functions well enough even if stiff, and replantation should be considered.

**Replantation**
**Indications:**

- Thumb
- Single digits in children
- Single digits at distal interphalangeal joint level
- Multiple digits
- Hand, wrist, forearm

**Relative contraindications:**

- Single digits in adults
- Crushed, mangled or avulsed parts
- Poor general condition of patient
- Long warm ischaemic time
Infection

Signs include redness, tenderness, swelling (often more apparent on the back of the hand), lymphangitis — streaks of red running up the arm — and lymphadenopathy (epitrochlear or axillary). Many hand infections will settle within 24—48 hours if elevated, splinted and treated with a best-guess antibiotic. As soon as the signs of inflammation have settled, the hand must be diligently mobilised. If pus appears, it must be drained; the wound should be left open, antibiotics changed according to microbiological advice, and the hand splinted in the Edinburgh position and then mobilised as soon as the inflammation settles.

Acute paronychia

This is the most common infection of the hand, often caused by careless nail trimming or picking the skin around the nail fold (Fig. 30.12). After an initial inflammatory phase, pus is trapped beside the nail. The pus is released by incision on to the nail fold and excision of the outer quarter of the nail.

Chronic paronychia

This appears over several weeks (Fig. 30.13). Rather than a consequence of an acute paronychia, it is usually a chronic fungal infection in those with their hands constantly immersed. Microscopical examination of the scrapings and special fungal cultures will confirm the diagnosis. It may resolve if the hands are kept dry and the nail fold is regularly dressed with antifungal ointment. If this fails, the nail fold is laid open.

Pulp space

Otherwise known as a ‘felon’, this causes severe pain in the finger pulp. Pus is trapped between the fibrous septae which bind the specialised fingertip skin to the underlying bone; the bone of the terminal phalanx can also become infected leading to a sequestrum. An abscess should be drained through an oblique incision over the point of greatest tenderness. The differential diagnosis is a herpetic whitlow. This is caused by herpes simplex virus and may be found, for example, in dental workers. Small vesicles appear which then become crusty. Surgery should not be performed; it resolves itself over a few weeks.

Flexor tendon sheath infection

There is little spare space within the tendon sheath; an untreated infection rapidly causes adhesions and even tendon necrosis, leading to a stiff useless finger. The classic signs, described by Kanavel, are a swollen finger held in flexion, with exquisite pain on passive extension and tenderness pre-cisely over the flexor sheath. The usual organism is a Staphylococcus or a Streptococcus. The tendon sheath should be promptly irrigated with normal saline through a fine catheter passed into small incisions over the distal and proximal ends of the sheath. The finger must be moved as soon as the signs of inflammation begin to resolve.

Bites

Serious infection and subsequent loss of function can result from animal or human bites. Human organisms include Eikenella corrodens; animal bites include Pasteurella multocida. Staphylococci are common in both. These organisms are usually sensitive to broad-spectrum antibiotics such as Augmentin. Wounds should be explored under adequate analgesia and a tourniquet. A common injury is over the knuckle when the opponent’s tooth penetrates the metacarpophalangeal joint. The penetration may not be apparent because the four layers (skin, tendon and capsule and synovium) which are injured in flexion close over when the knuckle is examined in extension. The wound must be excised, the joint thoroughly washed out, and the extensor tendon repaired and splinted.

Other infections

Mycobacterial infections

Tuberculosis in the hand may involve the tenosynovium, joints or bone. The most dramatic is a so-called compound palmar ganglion, with synovial swelling both proximal and distal to the transverse carpal ligament. The diagnosis is confirmed by biopsy. Treatment is by synovectomy and prolonged drug treatment.

Pilonidal sinus

A hair implanted in the palm or web space can cause a cyst with recurrent infection (Fig. 30.14). The cyst should be excised.

Orf

Transmitted by sheep, this virus causes red papules which become reddish blue and then grey nodules. The condition resolves after a few weeks.

Palmar space infections

Pus can collect deep to the palmar fascia either side of the septum running down to the third metacarpal. The whole hand is swollen and the palm intensely tender. The infection is drained through a longitudinal incision, great care being taken to avoid damage to the tendons, nerves and blood vessels.

Web space infections

Pus can collect in the potential space surrounding the lumbrical muscles as they pass from the palm, across the deep transverse metacarpal ligament into the extensor mechanism. The swelling in the web space tends to spread the adjacent fingers apart. The pus is drained through a longitudinal incision over the web space, taking care not to damage the nearby neurovascular bundles.
Arthritis

Rheumatoid arthritis

Rheumatoid arthritis is a disease which affects many systems and many joints. It can devastate the wrist and hand. The synovitis destroys ligaments, tendons and joints, producing pain, deformity and loss of function. Zig-zag collapse is typical of rheumatoid arthritis — as one joint deforms in one direction, the next deforms in the opposite (e.g. boutonniere, swan neck, ulnar drift of metacarpophalangeal joints with radial drift of wrist). As the joints deform, the tendons overlying them gain a greater mechanical advantage, leading to greater deformity. Simple activities of daily living, such as thumb pinch and opening jars, stress the weakened ligaments and produce worsening deformity (particularly ulnar drift at the metacarpophalangeal joints).

Assessment

For the hand to function well, it must be placed accurately and firmly in place — the elbow, shoulder and wrist must be carefully assessed as well.

History. What are the patient’s social circumstance, mobility, occupation and general health? These all influence the treatment that is offered. Which particular joints concern the patient? What is the patient’s problem with these joints — pain, instability, weakness, stiffness, appearance? Are there symptoms elsewhere, particularly the shoulder and elbow? What specific functional problems are there?

Examination. Does the patient have a typical pattern of deformity? Are the joints stable or unstable? Is there synovitis in the joints or tendons? What is the active and passive range of movement of each joint? Are these movements painful? Are the tendons intact? Are the muscles weak? Is there a median nerve palsy (from synovitis in the carpal tunnel) or a radial or ulnar nerve palsy (much rarer, from synovitis around the elbow)? Pinch grip and power grip?

Deformities in rheumatoid arthritis

Wrist:
- Radial deviation
- Carpal supination
- Prominent, unstable ulnar head
- Extensor tenosynovitis

Metacarpophalangeal joints:
- Flexion
- Ulnar deviation
- Subluxation, dislocation

Fingers:
- Swan neck
- Boutonniere
- Extensor tendon rupture
- Flexor tendon rupture
- Flexor synovitis

Congenital deformities

| Failure of formation   | Longitudinal absence-radial                  | Longitudinal absence-ulnar (ulnar club hand), longitudinal absence-ulnar (ulnar club hand) | Syndactyly (fingers joined by skin and sometimes bone) | Thumb duplication | Maimaradicaly | Thumb hypoplasia         | Simple rings
| Generalised skeletal abnormalities | Marfan’s, Turner’s, Down’s, etc. |

Nonoperative treatment

Rheumatoid arthritis is best managed with a team comprising the patient, physician, physiotherapist, occupational therapist, social worker and surgeon. Drugs can reduce symptoms and slow progression. Resting splints are helpful during flare-ups. Appliances can help with tasks such as turning on taps or opening jars, which would otherwise strain and damage the lax ligaments. Static splints stabilise and protect lax joints and improve function.

Surgery

The hand can never be made normal but many patients benefit from carefully planned surgery. Surgery must be tailored for each patient. In general, the shoulders, elbow and wrist should be treated before the hand, and reliable operations (e.g. thumb or wrist fusion) should be undertaken before more uncertain operations (e.g. soft-tissue reconstruction).

There are four indications for surgery:

- pain;
- prevention of progression;
- improving function;
- improving appearance.

**Synovectomy of the wrist joint**, metacarpophalangeal joints and interphalangeal joints should be considered if medical treatment has failed to control pain, with minimal joint damage on radiographs. Synovectomy of the flexor tendons may be needed if the patient has flexor tendon rupture, poor active finger flexion, trigger finger or carpal tunnel syndrome. Synovectomy of the extensor tendons (often with excision of the distal ulna) removes unsightly swelling and reduces the risk of rupture.

**Excision of the distal end of the ulna**, often with reconstruction of the associated extensor tendon ruptures, reliably improves pain and function, and prevents extensor tendon rupture.

**Replacement** of the wrist with silicone or metal—polyethylene implants carries a high risk of failure. Replacement of the metacarpophalangeal joints helps pain and appearance, and the implants can last for a considerable time; the extensor tendons, collateral ligaments and intrinsic tendons all need careful reconstruction to overcome ulnar deviation. Replacement of the proximal interphalangeal joint can maintain some movement but there is an appreciable failure rate.

**Fusion** of the radiocarpal joint gives a pain-free, stable platform for the hand. An intramedullary pin with bone graft usually suffices. Fusion of the thumb metacarpophalangeal joint and the finger distal interphalangeal joints can considerably improve function by providing stability and removing pain.

**Tendon reconstruction** is sometimes necessary. A ruptured extensor pollicis longus is treated effectively with an extensor indicis transfer. A ruptured flexor pollicis longus is most reliably treated, if the patient's symptoms need it by thumb interphalangeal joint fusion. Multiple tendon ruptures on the dorsum of the wrist are managed with side-to-side suture to intact tendons, tendon transfer or a tendon graft.

**Swan neck deformity** (Fig. 30.15) is caused by imbalance of the flexor and extensor tendons over the finger, subluxation of the metacarpophalangeal joint, tightness of the intrinsic muscles and failure of the palmar plate of the proximal interphalangeal joint. It may need splintage, manipulation, tenodesis, intrinsic muscle release, lateral band release or even fusion depending on the cause and severity.

**Osteoarthritis**

**Wrist**

The radiocarpal joint may develop osteoarthritis after an intra-articular fracture or infection; it can develop without an obvious cause. If splintage, analgesics and modification of activity fail, then fusion of the wrist at about 20\degree extension with a dorsal plate and bone graft will give a stable, pain-free wrist. Arthritis may develop around the scaphoid after a scaphoid fracture or a scapholunate ligament rupture. If simple measures fail, then bone excision, a limited fusion or total wrist fusion may be needed. The pisotriquetral joint can develop osteoarthritis. There is focal tenderness over the joint and 30\degree supination radiographs show the pathology (Fig. 30.16). If rest, splinting and a steroid injection fail, pisiform excision is helpful.

**Hand**

Osteoarthritis of the hand is most commonly part of a pre-disposition to generalised osteoarthritis, particularly in late middle-aged females. Infrequently it follows joint injury or infection. The proximal interphalangeal joints may be involved (Bouchard's nodes), the distal interphalangeal joints (Heberden's nodes) or the carpometacarpal joint of the thumb. The metacarpophalangeal joints and finger carpometacarpal joints are rarely involved. The symptoms do not correlate well with the radiographs. Occasionally surgery is needed. Fusion of the distal interphalangeal joint removes pain and gives good function. The proximal interphalangeal joint can be fused, but the loss of flexion is a significant hindrance; the alternative of replacement with silastic is unreliable. The basal joint of the thumb usually responds to analgesics, steroid injections and splintage. Excision of the trapezium helps the pain but the thumb is weakened. Filling the space with a rolled-up length of palmaris longus, or suspending the base of the first metacarpal with a sling made from part of the flexor carpi radialis tendon, may improve stability of the thumb.

**Other forms of arthritis**

**Gout** can easily be mistaken for a septic arthritis in the wrist or finger joints. The diagnosis is confirmed by measuring the serum urate and examining the joint aspirate under a microscope. In more chronic forms, tophi are seen beneath the skin and bone can be eroded. Gout can also cause tenosynovitis leading to trigger finger or carpal tunnel syndrome. **Psoriasis** often involves the joints of the hand and wrist. The nails are pitted and bone may resorb.
Dupuytren's contracture

The condition is inherited as an autosomal dominant trait and is more common in males, with age, smoking, pulmonary tuberculosis, epilepsy, acquired immunodeficiency syndrome (AIDS) and alcoholic cirrhosis. It is usually found in those of Anglo-Saxon descent. Myofibroblasts in the palmar fascia proliferate and contract. Initially, there is a nodular swelling in the palm. The overlying skin then puckers. Cords running into the fingers contract causing a flexion deformity of the metacarpophalangeal and proximal interphalangeal joints. The skin over the back of the proximal interphalangeal joints may thicken (Garrod's knuckle pads — Fig. 30.17) and a few patients may have thickening in the penis (Peyronie's disease) or on the sole of the foot (Ledderhose's disease).

Surgery is advised if the deformity is a nuisance or if the deformity is rapidly progressing, especially at the proximal interphalangeal joint where it soon becomes irreversible. During surgery, care must be taken to avoid the neurovascular bundles. Z-plasties can provide extra skin but occasionally full-thickness skin grafts are needed. The palm wound can be left open — it will heal rapidly with dressings. Surgery is not curative and recurrence is very common.
Tendon disorders

Trigger finger

For reasons which are often obscure, the opening of the flexor tendon sheath (the A1 pulley) thickens and snares the tendon which may secondarily develop a small nodule. When the proximal interphalangeal joint is flexed it locks and then snaps into extension. This often starts only on awakening, and then gradually occurs more frequently during the day. If it does not resolve with a steroid injection into the sheath, then release of the pulley at the level of the metacarpophalangeal joint (distal palmar crease) is successful, watching for the neurovascular bundle. In infants, the thumb can trigger; this often resolves spontaneously by the age of 1 year, but if not surgery is needed, being aware that in the thumb the digital nerves run close to the midline (not the midlateral line as they run in the fingers). In rheumatoid arthritis, the triggering is caused either by synovitis or by a nodule in the tendon. Synovectomy, and if necessary excision of a slip of flexor digitorum superficialis, is safer than division of the pulley — the latter can worsen the tendency to ulnar drift of the metacarpophalangeal joints.

De Quervain’s disease

The extensor pollicis brevis tendon and abductor pollicis longus tendon run in a compartment beneath the extensor retinaculum. This compartment can constrict the tendons, causing pain at the base of the thumb. Usually occurring spontaneously in middle-aged women, it is also associated with late pregnancy and overuse. Finkelstein’s test is positive there is pain over the radial side of the wrist when the patient’s thumb is grasped and the hand is quickly abducted ulnarward. Splintage, nonsteroidal anti-inflammatory medication, steroid injection and ultrasound may help. Surgical decompression is often required, avoiding the superficial radial nerve (lest a very troublesome neuroma occurs) and remembering that there are often extra septae and slips of tendon — the condition will persist if these are overlooked.
Carpal tunnel syndrome

This is common. The typical patient awakens with painful tingling over the radial side of the hand; there is often loss of fine dexterity because of weakness of the abductor pollicis brevis muscle and altered sensation over the thumb, index and middle fingertips. On examination, Tinel’s percussion sign is positive over the carpal tunnel and Phalen’s test may be positive (tingling in the hand when the wrist is fully flexed). In advanced cases, the thenar eminence is wasted. The diagnosis, if not certain clinically, is confirmed with electrophysiology. Treatment includes splinting the wrist in extension at night, injecting steroid into the carpal canal and surgical release of the transverse carpal ligament.
Kienbock's disease

The aetiology is unclear, but probably involves both ischaemia and microtrauma in the lunate, causing sclerosis initially, then collapse and finally arthritis. Many patients have a relatively short ulna ('negative ulnar variance'). Patients complain of pain and weakness in the wrist. Very early, bone scan or MRI can detect disease before it shows on plain radiographs. Treatment is initially conservative, with splintage, avoidance of activity and simple analgesics. Surgical shortening of the radius reduces the compressive forces across the lunate and may help those with early disease. In advanced cases with painful osteoarthritis around the lunate, radiocarpal fusion is the most reliable treatment.
Ganglion cysts

These are the most common swellings in the hand. Patients present with concern about the lump and occasionally with pain. The swelling is smooth, well defined, fluctuant and transilluminable. A few resolve with aspiration or compression (‘hitting with the family bible’). Surgery should be meticulous otherwise recurrence is likely. Ganglia around the wrist should be traced down to their source, usually the scapholunate ligament and sometimes the scapho-trapezio-trapezoid joint. Histology shows a compressed collagen sheath filled with a mucoid substance.
Congenital differences

These affect about one in 500 babies (Fig. 30.18). Some have a clear genetic cause, while others may follow an intrauterine insult during the second month of pregnancy when the limb buds are forming. These need careful management of both child and parent; surgery is challenging and the patients are best referred to a specialist.
Further reading

**Congenital abnormalities**

Congenital abnormalities in the foot can be divided into minor and major abnormalities. Minor congenital abnormalities include many conditions which are inherited. These abnormalities rarely cause significant problems. They largely constitute toe abnormalities such as syndactyly or curly toes; these variations are not uncommon and rarely need any treatment. Congenital hallux varus is not common but can require surgery if severe or progressive. Hallux valgus is surprisingly rare considering its incidence in the adult population. Major abnormalities include genetic disorders, major chromosomal malformations, and failure of formation or differentiation. In addition, there are several conditions which, although present in the newborn child, do not fit into these headings. They can be described as either structural or postural deformities.

Of the major deformities clubfoot or talipes equinovarus is the commonest (Fig. 31.1). It has a familial incidence (one in 1000 live births reduces to one in 35 live births if one sibling is affected) and it has a varied incidence with different ethnic groups (Maoris having the highest incidence). Although this suggests a genetic propensity it seems likely there is a multifactorial mode of inheritance. The exact mechanism of the production of the deformity is unknown; it seems likely that a number of different conditions produces the same deformity. This should be taken into account when planning treatment.

**Treatment**

Treatment of talipes equinovarus needs to commence within 24 hours of birth. Various techniques for strapping or taping the foot or the use of plaster of Paris or special splints have been advocated. What is common to all of these techniques is the need for early treatment and the careful attention to detail. This form of treatment should go on for at least 3 months and, no matter what, should be followed by a period of stretching undertaken by the parents and a suitable therapist. At this stage care should be taken to avoid stretching the midfoot into a rocker bottom foot position in an attempt to correct tight posterior structures. If early treatment is instigated then between 30 and 40 per cent of feet will correct sufficiently not to require surgery.

The remainder of the feet will require surgical correction. Although there is a great deal of controversy about the exact timing of surgery, the extent of surgery and the expected functional result, most authors would advocate that it is undertaken during the first year of life. The aim of surgery is to achieve the best functional result. By ensuring that the foot can be placed in plantigrade (or flat to the floor) position this is likely to be associated with the most satisfactory result. This will require an adequate posterior release to allow the foot to dorsiflex actively at the ankle. The subtalar and midtarsal joints need to be released to allow the primary rotational deformity to be reduced. In many cases this will involve both medial and lateral releases. Continued therapy and splintage should then back up the surgery, having achieved adequate correction, during the first years of life. In particular, the weakness of the peroneal tendons seen in many cases will not improve until at least 18 months of age. Children with this condition should be monitored throughout the period of growth. The genetic propensity for the deformity is likely to continue to be expressed throughout the growing period.

Other major congenital deformities need treatment on their merits with the aim of achieving the best functional result for the child.
Developmental problems

During the period in which the foot is growing a variety of interrelated problems can arise. These fall into two groups of significant problems but represent a relatively small percent-age of the total population. The vast majority of children presenting to a surgeon will in fact be normal. The major cause for presentation will be parental concern about perceived problems about the shape of the foot or abnormal shoe wear. The two groups of disorder, foot shape and function, are the conditions leading to a progressive planovalgus (or flat) foot and those that lead to pes-cavus or a high arched foot. Some of the toe conditions start to become symptomatic in the childhood years but only in adolescence does the condition of hallux valgus appear as a significant developmental abnormality.

Planovalgus foot

The flat foot is normal providing that the longitudinal arch rises and falls dynamically. In activities such as standing on tiptoes the longitudinal arch rises. This is the basis of the clinical test of great toe dorsiflexion (Fig. 31.2). It is this that allows the body to store energy in the foot during walking. This in turn allows efficient, low-energy-cost locomotion.

The flat foot becomes pathological when one of three things happens. Anything which stops movement in one of the joints of the hindfoot will simply prevent the normal behaviour of this mechanism. The condition of tarsal coal-tion is the most obvious example of this. This is where there is an abnormal join (fibrous or bony) between two or more tarsal bones.

Second, conditions which affect the integrity of the primary restraints of the various joints involved will result in instability. This leads to the foot deforming into a valgus heel position and into an abducted (and supinated) forefoot position. Conditions such as Marfan’s syndrome are examples of this form of problem. Commoner is familial hypermobility, but only a few of these patients exhibit pathological foot function.

Third, imbalance between the secondary restraints can cause progressive deformity. The best example of this is in neurological conditions such as cerebral palsy. Here the spasm in the peroneal muscle groups overcomes the action of the inverters of the foot. The hindfoot is gradually pulled into valgus. This in turn leads to stretching of primary restraints. If the deforming force is un-resisted for long enough, the effect is to produce bony deformity; this fixes the deformity. Although this pattern of developing deformity can be applied to the adolescent foot, it also underlies the pattern of development of a progressive planovalgus foot in any age group. In the elderly rupture of the tibialis posterior tendon will cause imbalance of the secondary restraints.

Treatment

This will obviously be dependent on the underlying cause of the progressive deformity.

Primary treatment should always be conservative in nature. In the foot with increased mobility the use of orthoses will control the foot position while a shoe is worn. This diminishes the pressure on the foot created by the shoe; thus the symptoms due to pressure effects are reduced. The shoe itself is less likely to deform and produce abnormal wear contributing to the pressure on the foot. There is no evidence that such devices influence the long-term outcome for the foot. Corrective orthoses in conditions where the deformity is fixed, as in a coalition, do not work. In these circumstances orthoses should be used to increase the cushioning available in the foot. This can reduce symptoms by reducing the forces passing through the foot. Rest and modification of activity can have a profound effect on the symptoms that the patient experiences. This can mean that despite the rigidity of the foot the patient is pain free and has reasonable function. If the joints involved are irritable and painful an injection of a local anaesthetic agent with an intra-articular steroid injection can reduce symptoms until the child is older.

In the neurological conditions such as cerebral palsy, physiotherapy including stretching exercises has a role to play. This allows the imbalance to be corrected passively. The use of ankle foot orthoses to maintain the position of the foot is helpful (Fig. 31.3). If the increased tone in the peroneal and calf muscles is a particular problem then botulinum toxin injections into the muscle bellies can be useful. The effect wears off within days but during the period of reduced spasm the benefit of surgical treatment can be assessed in the knowl-edge that the paralysis will wear off in the fullness of time. During the period when the toxin is active physiotherapy may overcome the deformity further providing a longer-term benefit.

The principle of surgical treatment is first to balance the forces acting on the foot to remove the deforming forces; second, to correct any deformity that has already developed; third, to stabilise the foot in order to prevent deformity from recurring.

- Release of fixed deformity. This could be soft tissue (as in lengthening the peroneal tendons) or bony (as in the excision of a tarsal coalition).
- Correcting bony deformity. This can be achieved by lengthening the lateral border of the foot using a modified distraction osteotomy originally described by Dillwyn Evans (Fig. 31.4) or by an osteotomy of the os calcis designed to transfer the contact point of the calcaneum medially.
- Balancing the secondary restraints. This may involve tightening of the inverters of the foot. This may include formal reconstruction of the tibialis posterior tendon.
- Reconstructing the primary medial restraints such as the talonavicular joint capsule.

If these principles cannot be achieved then fusion of some or all of the joints of the hindfoot (as in a triple arthrodesis) will allow correction of foot position, reduce pain from damaged joints and prevent recurrence of the deformity.

Pes cavus

The mechanism of the generation of the deformity of the high arch foot is less easy to understand. This is partly because a number of conditions leads to similar although not identical deformity. The common feature of the condition is some element of neurological dysfunction. This leads to the problem of muscle imbalance. The intrinsic muscles are weak leading to a mismatch between the intrinsic and extrinsic muscle power. With equinus deformity the Achilles tendon is tight. This is not an invariable feature of pes cavus and in conditions where the calf muscles are weak there is a cal-caneus deformity. In addition there is a group of patients who have a relatively higher inverter power than everter power. This will lead to the foot rotating so that the lateral border is mainly in contact with the floor.

The clinical presentation of patients with pes cavus most commonly occurs in late childhood or early adolescence when the presence of the deformity becomes more obvious. The deformity is obviously influenced by growth but can progress after growth has ceased. Symptoms which are usually present are increased pressure on the forefoot due to clawing of the toes and equinus, pain on the lateral border of the foot due to a varus heel position and finally feelings of insecurity and weakness. Where there is an associated sensory neuropathy, patients can suffer with ulceration. Patients generally need to be monitored to analyse the rate and nature of progressive change.
Because of the variations in specific aetiology, and the progression and nature of the deformity, various management options need to be considered. The use of conservative treatment is important and largely revolves around the use of appropriate shoe ware. Shoes need to have extra depth to accommodate toe deformities. The sole needs to be cushioned to absorb the excess pressure. Adjustments can be made to the sole of the shoe with outside wedges to create a corrective force on the outer border of the foot. The same effect can be achieved with insoles.

If conservative treatment fails then surgical options need to be considered. With any part of the deformity the first thing to consider is whether it is mobile or fixed. In general terms mobile deformities can be corrected by soft tissue surgery. Fixed deformity requires bony or joint surgery. An algorithm for the management of pes cavus has to be based on the type of deformity and the nature of the clinical complaint (Table 31.1).

Although this guide gives a concept of the procedures that have to be considered when treating the cavus foot, there is a great variation in the pattern of deformity with different aetiologies. The deformity can progress throughout life. This again has to be taken into account in planning the management of each individual case (Fig 31.5).
Acquired foot problems

Injury

The foot is one of the commonest sites of injury in the body. Because of its relatively rigid structure a great deal of force is necessary to injure the hindfoot. The forefoot including the toes is relatively exposed and therefore susceptible to injury. Also, the high forces going through the foot mean that it is a common site for stress fractures. The principles of fracture management are discussed elsewhere. The foot does present particular difficulties in diagnosis because of the complexity of local bony and joint anatomy. This means that the importance of careful history taking, examination and investigation cannot be emphasised enough. The commonest missed injury is a tarsometatarsal dislocation.

In all foot injuries the full extent of the injury needs to be appreciated, with soft-tissue injuries often being associated with bony injuries. Post injury rehabilitation is important to treat these elements of the injury.

Infections

Infections in the foot can be considered to be minor and common, or major and fortunately rarer. With a significant proportion of the world’s population remaining barefoot, minor skin trauma is a frequent cause of local infection. In the shoe population poor shoe fitting has the same effect. The increased incidence of diabetes means that this is now a potent cause of major infections. With the combination of vascular insufficiency, neuropathy and poor cellular function, infection due to diabetes can be extremely difficult to treat. This has considerable implications for the patient. It is also part of why diabetes and its complications represent the greatest single cost drain on many health services in the world.

A careful history and examination must be aimed at elucidating predisposing factors, assessing the extent of the infection, including evidence of more generalised spread. Even with relatively minor bacterial infections lymphatic spread is not uncommon. This leads to lymphangitis and involvement of regional lymph nodes. Investigations must be aimed at establishing the extent of the infection, the nature of the organism involved and any increased risk factors such as poor peripheral blood supply or diabetes. Wound swabs, culture of discharged material and skin scrapings or nail clip-pings can be helpful in identifying the organism. A full blood count, plasma viscosity, blood sugar and blood cultures can be helpful in determining the exact diagnosis and monitoring the benefit of treatment. Plain X-rays remain the baseline investigation of deeper infection, but newer investigation modalities such as magnetic resonance imaging (MRI) can give extremely helpful information on the deeper spread of infection and particularly address the issue of soft-tissue spread.

Basic principles of management involve rest, elevation, antibiotics and, where necessary, surgical débridement. Regular dressings are needed. Desloughing agents and dressings which keep the recovering granulation tissue moist are important.

Minor infections

These include a variety of extremely common conditions including fungal infections, verrucas, infected blisters, infected bursitis and ingrowing toenails. Associated with ingrowing toenails are paronychia, which need formal surgical drainage. Infections created by chronic or repetitive trauma need the underlying cause treating in order to prevent their recurrence. A good example of this is the ingrowing toenail. This will usually need surgical treatment to get it to settle once infection has been established for any length of time. If the infection is severe simple nail removal maybe sufficient to settle the infection but recurrence is relatively common. Wedge resection of the border of the nail and the associated nail bed is the treatment of choice in most cases; this can be aided by phenolisation. It is important to neutralise the phenol on the nail after application. In some cases complete resection of the nail and nail bed (Zadik’s procedure) may be necessary.

Fungal infections are relatively common and can be important as they can cause generalised discomfort that can be mistaken for mechanical causes of pain. In addition they commonly affect the nails leading to nail thickening and distortion (onychogryphosis) which in itself can lead to mechanical symptoms.

Major infections

Diabetes accounts for a substantial number of the major foot infections seen. These may be superficial, often associated with ulceration. Deeper infection may involve soft tissues only with abscess formation or can involve bones (osteitis or osteomyelitis). This type of infection can also involve localjoints (pyogenic arthritis). The presence of poor vascularity and neuropathy further complicates both diagnosis and management. Neuropathy can lead to Charcot changes in the foot, disrupting joint stability and foot architecture (Fig. 31.6). This leads to increased pressure under the sole of the foot due to the loss of the normal capacity of the foot to absorb load. In addition the bone disruption produces a high incidence of prominence under the sole. This then leads to ulceration. There is a progression from this superficial form of infection through deep infection and abscess formation to osteomyelitis. If not brought under rapid control this will go on to gangrene.

Treatment

If ulceration is present without the presence of deeper infection the clear aim is to heal the skin. After desloughing the ulcer and removing hyperkeratotic skin the ulcer can be dressed locally. The application of a skin-tight plaster of Paris changed on a weekly basis will allow the vast majority of ulcers to heal. It also allows the patient to be mobile. Deep infection without abscess formation can be treated by strict rest, elevation, soft-tissue support and antibiotics. Any form of abscess needs to be drained urgently and the deeper tissues thoroughly débrided. Ulcers which are deeply penetrating in certain sites are more of a problem than elsewhere. The heel is a particular problem in that ulcers lead to a permanent loss of the heel pad. Once an ulcer is healed the use of appropriate insoles and shoes can prevent further ulceration this is much more difficult to achieve when the ulcer has been in the heel.

When fixed deformity occurs as a consequence of neuro-pathy or Charcot changes due consideration should be given to corrective surgery. The stage of development of the Charcot changes has to be considered. The changes progress through three stages. Stage 1 involves generalised inflammation and fragmentation of bone. In stage 2 the inflammation starts to settle and the bone starts to show signs of healing. In stage 3 the bone consolidates. Once the changes become stable, surgery to correct deformity, produce stability and reduce any high pressure points can be undertaken.

Ultimately if tissues are clearly not viable then an appropriate amputation should be planned. This should be undertaken at a level where there is a realistic chance of the wound healing.

Other serious infections

Probably the commonest serious ‘primary’ infection is seen in the madura foot. The causative organism of this is *Nocardia madurae*; this is a filamentous organism similar to actinomycoses. World-wide its incidence is still high, affecting particularly populations in the Asian subcontinent and in Africa who go barefoot. It is also has an increased incidence in other areas of the world including southern USA, the South American
states and the West Indies. The organism almost certainly gains access to the foot through minor penetrating injuries or splits in the skin. Subsequently the foot forms multiple painless nodules, which ultimately form vesicular eruptions. These ulcerate and form sinuses. These then become secondarily infected. Treatment involves rest, elevation, and antibiotics for the secondary infection and protracted treatment with dapsone or similar agents. Ultimately if the infection persists and leads to disability then amputation can be considered.

Other types of major infection include tuberculosis, bacterial osteomyelitis and/or arthritis, and finally infections such as guinea worm.
Arthritis

Arthritis affecting the foot is a common event in an ageing population. The vast majority will be osteoarthritis. The most common joint affected is the first metatarso-phalangeal joint.

Inflammatory arthropathies frequently produce foot problems. In rheumatoid arthritis the forefoot is the first part affected. Up to 40 per cent of patients suffering with rheumatoid arthritis regard their feet as being their most troublesome area. Other forms of inflammatory arthritis are also seen in the foot. Of particular note is psoriatic arthritis, which is commonly missed. It is a particular cause of symptoms following minor trauma. Gout is also a cause of a sudden acute arthritis.

Rheumatoid changes

Rheumatoid arthritis creates symptoms in three ways. In the early stages of the disease, pain may be caused by the presence of inflamed synovium, usually in the forefoot and the subtalar joint. It can also affect the tendon sheaths. If the synovitis persists the ligaments and tendons can be damaged and rupture. This means that the joints become unstable, and deform. The toes dislocate at the metatarsophalangeal joints. This produces fixed clawing, with the metatarsal heads being prominent in the sole of the foot. In the hindfoot a combination of instability of the subtalar joint and rupture of the tibialis posterior tendon will produce a progressive planovalgus foot. The synovitis also damages the joint surface.

Patients suffering from an inflammatory arthropathy will complain of pain and swelling in the affected joints. Subsequently, progressive deformity and arthritic change result in metatarsalgia. Pain over the medial side of the foot due to the progressive lateral tilt of the foot is common. Impingement between the calcaneum and the lateral malleolus produces pain on the lateral side. Stress fractures of the lateral malleolus can occur. The secondary osteoarthritis will cause pain in its own right.

Treatment

During the early stages the aim of treatment is to reduce the synovitis and to manage associated pain. Nonsteroidal anti-inflammatory agents are the first-line drugs. Additional pain relief can be obtained from well-cushioned shoes. If drugs do not bring swelling under control, synovectomy should be considered. Once deformity has occurred the treatment is aimed at controlling symptoms. Shoes with cushion insoles and extra depth to allow for toe deformities should be used. If forefoot symptoms persist, surgical correction of the toe deformities should be undertaken, aimed at reducing the symptoms of metatarsalgia. The exact technique used for correcting the forefoot remains controversial. The principles of surgery are to correct the alignment of the toes over the end of the metatarsals. This provides cover for the ends of the prominent metatarsals. The most common technique practised is to excise the metatarsal heads through either a plantar or dorsal approach. At the same time, the first metatarso-phalangeal joint is fused to restore the position of the great toe and allow it to take weight.

Progressive deformity of the hindfoot is probably best treated by surgery to correct the position and stabilise the foot; this usually involves fusion of one or the more hindfoot joints. Bone grafts are frequently necessary to help correct the deformity. Reduction of deformity has to be directed towards keeping the foot flat to the floor. Involvement of the ankle can further complicate matters, the ankle frequently tilting into valgus. If the ankle is symptomatically involved then consideration should be given to either arthrodesis or possible arthroplasty of that joint also. The choice between surgical treatments under these conditions will depend on the general and local state of the patient, the position of the patient’s hindfoot and their expectation.

Hallux rigidus

This is the most common arthritic condition affecting the foot.

The symptoms are those of limitation of movement and pain.

It can arise as early as the adolescent years. It is associated with various systemic causes of arthritis such as gout and psoriasis. Most commonly it arises ‘de novo’. Pathologically it is typified by the presence of dorsal osteophytes and by damage to the articular surface centrally and dorsally. The vast majority of patients present with severe joint involvement.

Treatment

The first line of treatment is conservative. Education about the nature of the condition is helpful. Advice about footwear and stiffening of the sole of the shoe under the first ray can be helpful.

Operative treatment falls into three groups depending on the severity of the condition. In mild or moderate disease dorsal wedge osteotomy of the proximal phalanx can help to reduce pressure over the dorsum of the great toe. If there are mild to moderate changes on the joint surface but a significant dorsal osteophyte a cheilectomy procedure, where the dorsal osteophyte and approximately the dorsal third of the metatarsal head is excised, can be undertaken. If there are severe changes two procedures can be considered. The first is to fuse the first metatarsal to the proximal phalanx. This produces the most reliable result but by definition there is a loss of the range of movement. Approximately 90 per cent of patients who undergo this procedure ultimately find it satisfactory. The second option is to undertake an arthroplasty. A variety of prostheses has been tried without consistent success.
Tumours

Like elsewhere in the body tumours may be benign or malignant, which may be primary or secondary. The foot shows three types of benign tumour: those that are latent or active, and finally those which are locally invasive but do not metastasise.

Primary malignancy is relatively rare but can arise in any of the tissues which go to make up the structure of the foot. They are usually graded on the basis of their differentiation, whether they cross anatomical barriers and obviously whether they have metastasised. More common are metastases from the common malignant tumours: lung, breast and prostate.

Plain X-rays can be helpful, but for thorough preoperative analysis of a tumour, investigations such as computerised tomography (CT) scans, technetium bone scans, MRI scans and high-resolution ultrasound for the vascular tumours may be necessary. Serological studies and investigations such as chest X-rays looking for evidence of distant spread may be required.

Treatment

This may involve simple local excision through to amputation, depending on the nature and extent of the tumour. In the foot it is particularly important to take into account the local anatomy when planning tumour excision.
Ageing in the forefoot

As the foot ages it undergoes a number of changes that relate to original shape of the foot and to changes which occur in the ligaments of the foot. There is a general tendency for the foot to become flatter and broader. The forefoot tends to abduct and the toes deform. The hallux gradually goes into increasing valgus and lesser toes become relatively crowded and longer. The consequence is increasing deformity of the lesser toes (Fig. 31.9). The hindfoot deformities that occur are largely covered by the sections on developmental and arthritic conditions.

Hallux valgus

This is probably the commonest condition seen affecting the forefoot. A wide variety of factors is involved in its aetiology.

*These include:*

- wearing shoes — hallux valgus is commoner in shod populations;
- hereditary predisposition;
- metatarsus primus varus;
- increased length of the first metatarsal; and
- hypermobility of the first ray.

Although all of these factors come into play the pathology of the progressing deformity is essentially the same, there are only two structures which prevent the toe going into valgus, the medial collateral ligament and the abductor muscle of the great toe. If the toe starts to deviate into valgus because of any of the above factors, then the medial capsule stretches and the abductor moves under the metatarsal head by virtue of its attachment to the medial sesamoid. The first metatarsal displaces medially in relation to the great toe and its associated sesamoids. Their position is maintained in relationship to the rest of the foot by both primary restraints (the plantar fascia and the transverse tarsal ligament) and the secondary restraints (the intrinsic and extrinsic muscles). The valgus displacement of the great toe exposes the metatarsal head creating a bony prominence, and an adventitious bursa can then form. In some patients the increasing deformity damages the joint producing a secondary osteoarthritis. As the great toe deviates further it impinges on the second toe producing hammering and ultimately dislocation of the second metatarsophalangeal joint. A cascade of increasing deformity then ensues. Associated with the increasing width of the foot a bunionette may form over the fifth metatarsal.

Treatment

Conservative treatment always has to be considered first. Advice about ill-fitting or tight shoes may relieve symptoms or prevent episodes of infection or minor ulceration. There is a perception that this advice will not be tolerated by women who wish to wear fashion shoes. This is incorrect. If properly advised about the potential risks and complications of surgery many patients will modify their expectations and their footwear. The relationship of the forefoot to the hindfoot has to be considered and can be improved while wearing suitable footwear by the use of suitable insoles.

Surgical treatment should be considered for persistent symptoms, recurrent ulceration or infection, or increasing deformity leading to increasing symptoms in the lateral part of the foot (Fig. 31.10).

No one operation is the answer to all cases of hallux valgus and a protocol of management should be assumed if results are going to be consistent (Table 31.2). Factors such as age, sex, hallux valgus angle, the angle between the first and second metatarsal, hypermobility of the first tarsometatarsal joint and degenerative changes in the first metatarsophalangeal joint have to be taken into account.

Lesser toe deformities

These include:

- hammer toe;
- mallet toe;
- claw toe;
- curly toe;
- metatarsalgia;
- Morton’s neuritis and neuroma.

Introduction

Neurological conditions are not common but they occupy a great deal of time and effort for orthopaedic surgeons. Polio and spina bifida are becoming increasingly rare in the developed world, as is cerebral palsy. Genetic counselling has reduced the incidence of the genetic disorders. In the developing world many of these conditions remain common but simple public health measures should reduce these dramatically in the future.

Classification of neurological disorders

<table>
<thead>
<tr>
<th>Static, e.g. polio</th>
<th>Progressive, e.g. Huntington’s</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sensory, e.g. leprosy</td>
<td>Mixed, e.g. motor, e.g. polio</td>
</tr>

<td>Flaccid, e.g. peripheral nerve section</td>
<td>Spastic, e.g. Abnormal movements, e.g. Huntington’s</td>
</tr>
<tr>
<td>disseminated sclerosis</td>
<td></td>
</tr>
</tbody>
</table>

Static versus progressive

From an orthopaedic point of view, neurological disorders are classified into those which are static and those which are progressive. Static disorders can in fact appear progressive. As an adult gets older and heavier, actions that were previously possible become impossible despite the fact that there has been no deterioration in neurological function. Nevertheless, some conditions such as cerebral palsy and polio tend to be static while other conditions, such as Duchenne muscular dystrophy, are progressive and require a different approach.

Sensory versus motor

Sensory loss such as that caused by traumatic nerve lesions, leprosy and multiple sclerosis may create a limb which cannot be protected from injury, but which is also functionless because the patient does not know where the limb is (loss of proprioception). Other conditions, particularly polio, are pure motor loss. Indeed if there is any associated sensory loss a diagnosis other than polio should be considered. In this case disability and deformity will be a result of loss of muscle power not loss of sensation.

Flaccid versus spastic versus abnormal movements

Flaccid paralysis occurs when a peripheral motor nerve is transected or in the early stages after an upper motor neuron lesion. The limb is flail, and ligaments are susceptible to damage, simply because there is no muscle power protecting them. Spastic paralysis is loss of cortical control of muscles despite the fact that they are contracted in spasm and hyper-reflexia. The conversion of an upper motor neuron lesion from flaccid paralysis to spastic paralysis some days after the original lesion may raise false hopes in the patient that recovery is imminent. Spastic paralysis will lead to contractures and gross deformity if great care is not taken to maintain limb mobility. Abnormal movements are a characteristic of other neurological conditions. In Parkinson’s disease there is a tremor and a repetitive pill-rolling manoeuvre of the thumb and index finger. In athetoid cerebral palsy, the limbs may writh and wave around in an uncontrollable manner.
Making a diagnosis

A careful history needs to be taken which includes family history, problems during pregnancy or at birth. If the problem is of recent onset, contact, ingestion or inhalation of heavy metals, pesticides and other toxins should be covered. On examination a careful check needs to be made of the spine for signs of spina bifida. All modalities of sensation need to be carefully checked. Muscle power should be graded according to the Medical Research Council (MRC) Scale and a careful check made for signs of wasting, fasciculation and hyper-reflexia.

Investigations

Electrolytes should be checked routinely as imbalances in both calcium and magnesium can cause neurological problems. Electromyelographs (EMGs) and even muscle biopsies may be needed to determine the diagnosis. Imaging of the spinal cord and of the brain may also be required.
Management

Sensory loss

If the sensory loss is likely to he temporary (such as caused by transected sensory nerve) then the limb should be carefully protected to avoid injuries such as burns. Splints and plaster should also be applied with great caution as the patient will be unaware when they are developing sores at pressure points.

Temporary flaccid paralysis

This can be managed with splints to prevent overloading of ligaments and to maintain function of joints. Physiotherapy will be needed to maintain joint mobility, and to build up muscle power as the nerve supply returns. Lively splints are fitted with springs so that the weak muscle does not have to function but nevertheless the limb can be kept moving by the opposing muscle whose function remains normal.

Spastic paralysis

This is much more difficult to manage and requires regular gentle physiotherapy to try and put joints through a full range of movement without creating spasm. Regular physiotherapy should prevent the development of contractures which may make the deformity very difficult to manage. As a general rule, splints do not work well in spastic paralysis as they can stimulate spasm. The result is then either stress or a broken splint. Deformity as a result of spasticity can only really be treated by weakening the spastic muscle. There are various ways in which this can be done:

(a) the muscle can be divided;
(b) the tendinous insertion of the muscle can be lengthened;
(c) the insertion of the muscle into bone can be released and allowed to slide along the bone reducing the mechanical lever arm;
(d) the muscle can be injected with either a temporary or permanent paralytic agent such as botulin toxin;
(e) the nerve supply to the muscle can be divided.

In children many of these actions causing defunction of the muscle are reversed by the natural healing powers of a child. Transected muscles heal. Divided nerves regenerate. The procedures may therefore need repeating.

In athetosis, paralysis of the muscle with botulin or by transection of the nerve is a possibility but there is usually considerable function available despite the irregular movements of the limb and this loss of function must be balanced against the improvement in abnormal movements.

Trick manoeuvres

Patients with paralysed muscles develop a set of trick manoeuvres aimed to overcome their disability. For example, paralysis of the quadriceps muscle makes it difficult to lock the knee when walking. Patients with this problem frequently walk with their hand in the trouser pocket pressing firmly on the front of the knee and heel strike. This serves to lock the knee for normal locomotion. Patients with paralysis of the shoulder girdle may develop trick manoeuvres with their trunk which enable them to throw their arm high above their head.
Cerebral palsy

Children with cerebral palsy are usually floppy babies at birth. It is some months before the spasticity starts to develop. Even if the cerebral palsy is severe, intelligence is usually normal. It is a grave mistake to underestimate the intelligence or comprehension of these children.

Nonoperative treatment

These children will need assessment of their special needs in terms of walking aids, wheelchairs, etc. They will also need intensive physiotherapy to avoid deformity during growth. The imbalance of muscles across joints and growth plates during the growing period can lead to abnormal growth of bone which can then be very difficult to correct later in life. This is especially true of the spine where a particularly vicious form of scoliosis may develop which is very resistant to treatment. Although every effort should be made to help the child walk, this goal should not become the only goal to the exclusion of everything else. If a child with severe cerebral palsy of the lower limbs does succeed in walking, this is likely to be a temporary triumph. As they get older they are likely to go off their feet again and return to a wheelchair. If all of the parents and the child’s efforts are devoted to walking to the exclusion of overall development the child’s interest will not be served in the long term.

Surgery for cerebral palsy in the lower limb

Toe walking

Children with cerebral palsy frequently walk on their toes and appear unable to bring the heel to the floor. There can be several reasons for this. If they have a fixed flexion deformity to the hip and a flexion deformity at the knee, the only way in which the foot can get to the ground is by toe walking. Under these circumstances attention should be directed to the hip and/or the knee. If however, correction of the flexion deformity of the hip will not get the foot plantigrade because the tendo achilles is tight, then there may be a place for releasing the tendo achilles at the same time. The old cerebral palsy philosophy was to release one joint at a time, and to review the situation. This was because the release of one muscle group appears to have profound effects on the others. The problem with this was that the child was subject to multiple admissions to hospital before any correction was obtained. A newer approach is to do a global approach to the whole limb releasing hip flexors and adductors as necessary, lengthening the hamstrings behind the knee and lengthening the tendo achilles at the heel. The problem with this one-stage global correction is that the muscles affected by cerebral palsy may already be weak. They will be further weakened by surgery and there may not be adequate strength to hold the leg straight when walking. Some deformities actually help other deformities. For example, if the child is walking with bent knees and weak quadriceps, a fixed plantar flexion of the foot may bring the centre of gravity forwards and provide sufficient power to help the quadriceps to extend the knee and allow the child to walk. Release of the tendo achilles may improve cosmesis but remove the support to the quadriceps so that the child can no longer walk.

Release of the tendo achilles

The tendo achilles can be released with a triple cut through three percutaneous stab incisions. Each incision enters the tendo-achilles vertically. This scalpel blade is then turned to the right angle and half of the tendon is cut through. The superior cut and inferior cut are medial, the middle cut is lateral. Stretch applied to the tendo achilles then results in a sliding release of the tendo achilles which will heal quickly in the lengthened position. The child is put in a plaster with the foot fully dorsiflexed and mobilisation started as soon as possible.

Release of the hamstrings

Hamstring release should allow the knee to come straight but in the older patient it may be necessary to release the posterior capsule of the knee as well. This is a very major undertaking and risks damage to the neurovascular bundle behind the knee. It is particularly difficult if the flexion deformity is very severe because access to the back of the knee becomes very difficult.

Adductor tenotomy of hip

The adductors of the hip can be released through a subcutaneous incision. If the femur is held firmly by the assistant applying steady pressure into abduction, the tendons can be felt tight as bow strings and divided as they insert into the ischial tuberosity. Adductor tenotomy dramatically improves the ability of a child to sit in a chair and makes perineal toilet much easier.

Scoliosis

This can be severe and aggressive in a child with cerebral palsy. Surgery will prevent any further growth of the spine but correction may have to be undertaken early because pulmonary function is being compromised by the deformity of the spine.
Polio and other flaccid paralysis

After the initial acute phase of polio, there should be a rapid improvement in motor function to a steady state. During this time it is important that joints are kept mobile and morale is kept up. In children, compensatory development of other unaffected muscles may allow the child to lead an almost normal life despite quite marked paralysis of some muscle groups. However, tendon transfers can prove very useful in any form of flaccid paralysis, especially if the following rules are adhered to.

- Muscles should only be transferred which are of normal power.
- It must be expected that muscles will drop at least one grade of power when transferred.
- Where possible, muscles should be transferred which operate in the same way or in the same phase of normal movement as the muscle that they are supposed to replace.
- Tendon transfers should not go round sharp corners where they will lose their efficiency.

In children it is important to try and balance muscle power around joints so that deformity does not arise.

Specific tendon transfers

Long thoracic nerve, weakness of thoracis anterior and wing-ing of the scapula can be treated by transferring the pectoralis minor into the inferiomedial aspect of the scapula musculocutaneous nerve. The brachioradialis is spared in an injury to the musculocutaneous nerve and remains as the only weak flexor of the elbow joint. If its insertion is advanced proximally up the humerus to obtain better leverage its power increases.

Radial nerve palsy

This is a common injury after a fracture of the humerus and if there is no prospect of return of function, then transfers of flexor tendons to the extensor side will stabilise the wrist and allow extension of the fingers. The classic transfer is the Robert Jones. Pronator teres is inserted into extensor radialis longus to restore wrist extension. Flexor carpi ulnaris is inserted into extensor digitorum to restore finger extension. Pal-mans longus when present is inserted into extensor polices longus to restore thumb extension.

Median nerve

There is a number of tendon transfers to improve function of the thumb depending on the level of the median nerve palsy. In distal median nerve palsy, flexor digitorum superfascialis of the ring finger can be passed across to the thumb to help with opposition.

Lateral popliteal nerve

This leads to a foot drop which can be treated by transfer of the tibialis posterior tendon to take the place of tibialis anterior by routing through the interosseous membrane.

Bone operations for flaccid weakness

Arthrodesis is especially useful where flaccid weakness is proximal with a normally functioning distal limb. Fusion at the wrist dramatically improves the function of the hand while fusion of the shoulder can make a flail limb functional again. The arthrodesis may also release active muscles for use elsewhere in tendon transfers. Arthrodesis does not work well in cerebral palsy where the spasticity tends to deform the arthrodesis. However, if spastic tendons have been released and there is a persistent fixed flexion deformity, an osteotomy may be simpler than a radical release of capsule. This is particularly true around the knee.

Splintage

Modern splints can be very lightweight and cosmetically not prominent. Splints can be built with springs and locks to improve function. Great care must be taken if there is any sensory loss in the limb to make certain that the splints fit well. Splintage may need to be combined with tendon release and with osteotomy, especially in the severe cavus foot of the child with cerebral palsy, where both a soft-tissue release and bony fusion will be needed to prevent recurrence of the deformity.

Leg length discrepancy

This can be corrected with a shoe raise and in some cases with stapling of epiphyses on the opposite side to reduce growth. Modern techniques of leg lengthening using external fixators offer the opportunity of restoring the patient to normal height, but take time and have severe complications.

Limbs with both sensory and motor loss

A flail limb without sensation may be more of a hazard than a help to the patient and may be better amputated. This is particularly true if the limb is scarred and deformed.
Inherited disorders

Friedreich’s ataxia

This is hereditary autosomal recessive. The child presents in early childhood with both a motor and a sensory loss pre-senting as clumsiness and difficulty walking. From an orthopaedic point of view the main problem is a cavovarus deformity of the foot, which in the young child can be corrected with soft-tissue release but in the older adolescent may require a wedge osteotomy.

Duchenne muscular dystrophy

This is cross-link recessive and again presents in early childhood with difficulty walking and classically with difficulty rising from a sitting position and climbing stairs. There are high levels of serum creatinine kinase and the muscle biopsy is diagnostic. In their early teens patients are wheelchair bound and they normally die in their early twenties. The main input from orthopaedics is correction of scoliosis to improve breathing.

Multiple sclerosis

This is a patchy demyelination of the central nervous system which develops later in life. The patient develops spasticity in the lower limbs with gross deformities. Splintage should avoid these causing too much trouble but tenomities are frequently required round the hip and knee to help the patient to sit.
Progression of static neurological disorders

As patients go into middle age, they put on weight and their muscles may weaken as does their motivation. Patients who were previously able to walk now find themselves confined to a wheelchair. It may be that this situation should be gracefully accepted, as static neurological disorders become an increasing disability to patients as they grow older.

Anatomy of the spine and spinal cord

Vertebral column

This provides a mobile yet protective midline dorsal scaffold housing the spinal cord and cauda equina. Comprising a series of interlocking vertebrae the spinal nerves emerge via intervertebral foramina, the cord joining the brain stem at the foramen magnum (Fig. 33.1a and b).

Developed from the union of adjacent mesenchymal blocks, the basic pattern of anterior body and posterior arch exists throughout. These surround the central canal through which passes the spinal cord, a derivation of the neural plate, and lower down the nerves of the cauda equina. Between each vertebra which are linked by anterior intervertebral disc and lateral facet joints — runs a series of connecting ligaments to provide significant stability to the spine. These include particularly the anterior and posterior longitudinal ligaments running the full length of the vertebral column from the foramen magnum, attached to the periosteum of each vertebral body by an annulus of each disc. The interspinous ligaments link each spinous process and the supraspinous ligaments skip between the tips of each spinous process along the full length of the spine (Fig. 33.2).

Cervical spine

This comprises seven vertebrae with areas of specialisation. The C1 and C2 vertebrae join to form the atlantoaxial complex, the body of C1 being incorporated into the body of C2 to form the odontoid peg or dens. The C1 or atlas vertebra, therefore, becomes a ring between the occipital condyles of the skull and the C2 or axis vertebra. The posterior arch of C1 has no spinous process and may be incomplete.

The axis or C2 vertebra forms an easily radiologically visible structure with the dens anteriorly and a large bifid spine posteriorly.

The remaining cervical vertebrae (C3 to C7) also have identifying features. Running in the lateral mass is the foramen transversarium through which passes the vertebral artery from its point of origin at the subclavian artery to where it loops over the lamina of C2 to gain access to the cranial cavity via the foramen magnum. The spinal process of these vertebrae (except C7) are usually bifid. The vertebral artery does not traverse the C7 vertebra and this also has a prominent spinous process which can be palpated, giving rise to its name, the vertebra prominens.

Thoracic spine

Uniform in shape, the heads of the ribs articulate with adjacent bodies of these 12 vertebrae. Gradually the size of the vertebral body and the articular processes increases down towards the more solid lumbar vertebrae.

Lumbar vertebrae

These represent a more mobile part of the spine and yet represent an area of great strength. Formed of five vertebrae the lateral mass, pedicles and laminae are thicker and the spinous processes shorter and more vertical. The last mobile joint between L5 and S1 (lumbosacral junction) joins the spine to the rigid pelvis via the sacrum.

Sacrum

Situated between the iliac bones and joined by the sacroiliac joint, the bones of the sacrum are fused into one triangular shape through which traverse the terminal sacral nerve roots— S2, S3 and S4.

The basic vertebral structure of each component of the sacrum is maintained, but the bones blend into one another to form a smooth anterior and posterior surface.

Coccyx

These very small vertebrae do not transmit any neural structure and are attached to the sacrum.

The spinal canal

This contains the spinal cord and cauda equina enclosed in layers of meninges.

The spinal cord extends from the foramen magnum at the cervicomedullary junction to the conus medullaris — an area of expansion of the cord at the L1/L2 junction.

From that point there is no spinal cord, the nerves continuing as the cauda equina. Surrounding the cord and the cauda equina is arachnoid mater, defining the cerebrospinal fluid (CSF) containing subarachnoid space, and the spinal dura or theca which is continuous with the cranial dura at the foramen magnum and forms a sleeve around each emerging nerve root. It is via this root sleeve that the sequential blood supply gains access to the spinal cord. The epidural space between the spinal theca and the bone of the spinal canal is filled with epidural fat and the epidural venous plexus.

The spinal cord

The cord itself is part of the central nervous system but arising from it are pairs of spinal nerves, each one composing a dorsal sensory root and a ventral motor root to form a numbered mixed spinal nerve (Fig. 33.3).

These emerge via the intervertebral foramenae and are numbered Cl to C8, T1 to T12, L1 to L5 and S1 to S4.

The spinal cord is uniform in appearance with two areas of expansion — in the cervical region corresponding to the origin of the nerve roots to the arm and in the lumbar region at the conus medullaris.

The blood supply to the spinal cord is formed from the descending anterior and spinal arteries, from the vertebral arteries and from the segmental spinal arteries which form an anastomosis up and down the spine. Some of these segmental arteries are significantly enlarged, for example the artery of Adamkewitz at D10.
Assessment of the spine

Trauma

Always assume that the patient has a spinal column injury until you have proved otherwise

It is of great importance to recognise the presence of a spinal injury as early as possible after the injury has occurred. This will prevent further injury to the spinal cord and nerve roots, and give the patient the best chance of a good long-term outcome. Throughout assessment and resuscitation the spine must be suitably immobilised. Initially this can be done with simple in-line immobilisation. Advanced trauma and life support (ATLS) protocols can then be used to resuscitate the patient in the normal way (see Chapter 4).

The patient should be suitably immobilised at the site of the injury on a spine board with a hard collar and with the whole of the spine immobilised. The head should be attached to the board with tape and steadied with sand bags or some similar device (see Fig. 33.4). The patient can then be safely transported to a suitable hospital for further treatment.

There are certain features in an injured patient which should alert the doctor that there may be a spinal injury of some sort:

- evidence of neurological injury;
- multiple injury;
- head injury;
- facial injury;
- high-energy injury (e.g. fall from a height);
- seat-belt abdominal marking (may suggest lumbar injury).

Assessment of the spine in the unconscious patient with multiple injuries is probably the most difficult. If there are associated life-threatening injuries, it is probably best to carry on and treat these first before the spine is fully assessed. For example, a patient with severe intra-abdominal bleeding may require urgent surgery. It is still mandatory that the spine is protected throughout management, for example moving the patient on to the operating table. Further spinal assessment can then be carried out later.

The spine must always be examined clinically as part of the secondary survey. This can be done easily when the back of the patient is examined. If this is not done, severe injuries such as an open spinal injury may be overlooked for some hours.

In the conscious patient without other severe injuries spinal injury can usually be excluded by the combination of absent pain and a normal clinical examination of the spinal column with a normal neurological examination.

In the conscious patient biplanar X-rays of the symptomatic part of the spine are adequate, and in the cervical spine open mouth view of the odontoid peg should be included. In the unconscious patient assessment of the spinal column is much more difficult because clinical signs are often absent. In the thoracic and lumbar spine full anteroposterior (AP) and lateral X-rays of the spine are required to exclude an injury to the spinal column. In the cervical spine unstable injuries of the neck are easily overlooked, and full AP lateral and odontoid peg views will still overlook about 5 per cent of injuries. One option is to carry out real-time flexion and extension X-rays of the cervical spine using an image intensifier. If there is any evidence of instability at any point the investigation is stopped. An alternative is to carry out magnetic resonance imaging (MRI) scans on all these patients but this is time consuming and difficult in the patient with multiple injuries.

The extent of an injury may not be apparent initially, and further imaging in the form of computerised tomography (CT) or MRI scanning may be required. For example, in the unconscious the upper and lower cervical spine may be very difficult to assess. Most of these patients will require a CT scan of the brain to exclude a space-occupying lesion, and it is convenient to carry out a few CT cuts at the occipitoatlantal junction and at the cervicothoracic junction to exclude a significant injury, particularly if the cervicothoracic junction has not been visualised on plain films. Similarly, the upper thoracic spine is a very difficult area to visualise on plain films and if there is suspicion of injury, CT scan should be used to assess the area. CT scan will show any disruption of the ring of the vertebra suggesting an unstable injury, and will allow assessment of canal compromise and of subluxation or dislocation of the vertebrae.

MRI scanning is very sensitive, but is better for assessment of soft-tissue injury and less sensitive for assessing bone injury. Where there is no fracture it can be useful for establishing the presence of a soft-tissue injury, it is useful for assessing spinal cord and nerve root compression as well as the extent of spinal cord injury, and it can be helpful in making a long-term prognosis about spinal cord recovery.

If an unstable injury is demonstrated, spinal immobilisation should continue until such time as the spine can be stabilised, or until healing has occurred.

Nontrauma

As in assessment of any part of the skeleton first principles should be followed, or clinical signs will be missed.

- Take a history — 90 per cent of diagnoses can be made at this point.
- Look at the spine standing and lying.
- Palpate the spine.
- Examine the neurological system.
- Examine the peripheral vascular system.
- Watch the spine moving.

The history should include past medical history of importance (e.g. injury or previous similar symptoms) and family history (e.g. for scoliosis).
Important parts of the history are:

• pain (site, nature, duration, pain scale, effects);
• disability (sitting, standing, walking, lifting, dressing, travel, social activities, sleep, sex life);
• physical impairment;
• work loss.

Many of these parameters are very difficult to assess in the spine. Pain is a very subjective sensation, and it is difficult to grade the amount of pain which a patient is experiencing. Methods of assessing the amount and quality of the pain include the anatomical pattern of the pain, the use of pain scales such as the visual analogue scale, and pain descriptions such as the short-form McGill pain questionnaire.

In assessing the pain and disability which a patient is experiencing it is important to include an assessment of how much distress and illness behaviour the patient is experiencing. This is because the type of treatment chosen may be very different for the patient with significant distress, and because the outcomes of treatment are very different. For example, the outcome of surgery for back pain in those with distress is very much worse than in those who are not distressed. Physical signs which suggest that the patient may be exhibiting abnormal illness behaviour include the following.

**Symptoms include:**

• whole leg pain;
• tailbone pain;
• whole leg numbness;
• whole leg giving way;
• never free of pain;
• intolerance of treatments;
• emergency admission to hospital.

**Signs include**

• superficial widespread non anatomical tenderness;
• lumbar pain on axial loading of the spine;
• lumbar pain on simulated rotation of the spine;
• straight leg raising which improves with distraction;
• regional sensory disturbance;
• regional motor weakness;
• jerky movements on motor assessment with giving way.

Litigation is an important confounding factor in the treatment of individuals with spinal pain. There is no doubt that the response to treatment is less good in those who are litigating, perhaps because there is little incentive for them to recover. However, there is also good evidence that few patients experience a significant improvement in their symptoms after settlement of the claim.

Physical impairment can be measured and lumbar spine measurements of impairment include those of the American Medical Association and the American Academy of Orthopaedic Surgeons. We have more experience with the use of the Oswestry Disability Index, a 10-question self-administered score of back pain and associated disability which is reliable and reproducible. This combined with a pain score is in regular use in our institutions and allows easy scoring of pain and disability and comparison of pretreatment and post-treatment pain and disability.

**Examination technique**

Make the patient feel relaxed. Watch how the patient moves and walks, and watch how the patient dresses and undresses. Look at the spine. Is there a deformity or muscle spasm, does the patient have a scoliosis? Are there any associated features such as birth marks or a leg length discrepancy which might suggest a congenital disorder? Examine the range of movement of the spine in the cervical, thoracic and lumbar spine with the patient standing up if possible. The range of spinal movement is difficult to assess accurately, but flexion and extension can be measured with a goniometer if necessary. Deformities should also be assessed for their mobility. It is usually easiest to have the patient lie prone to palpate the spine. This avoids putting the patient off balance, and also allows the muscles to relax. Look to see whether the deformity corrects, for example with a sciatic scoliosis, as opposed to a structural scoliosis which will not correct completely. Palpate the spine to see whether there is a step suggesting a spondylolisthesis. Remember to look for evidence of inappropriate signs (axial loading and simulated rotation).

With the patient prone the ankle reflexes can be assessed and posterior sensation examined. The femoral stretch test (hip extension with the knee flexed) can be carried out to see whether there is femoral nerve pain. The patient is then asked to lie supine. An assessment of muscle bulk can be made, and measurements made as required. A thorough neurological examination can be carried out including a sciatic stretch test (see Fig. 33.5 and Table 33.1).
Remember to examine the abdominal reflexes where there is any possibility of an upper motor neuron lesion. Hip and knee pathology frequently mimics back pain and these joints should be examined. Remember that spinal stenosis is often confused with intermittent claudication, and the peripheral pulses must be examined. Finally abdominal examination should exclude intra-abdominal pathology as a cause of back pain (e.g. aneurysm) (Table 33.2).

This sounds like a lengthy examination, but with plenty of practice it should be possible to carry out the examination reasonably rapidly (e.g. 5—10 minutes). Does the patient have back pain as the primary problem, does the patient have nerve root pain, or is there a combination? Are there inappropriate signs suggesting illness behaviour?

Investigations

Where malignancy or infection is a possibility haematological investigation is useful [full blood count (FBC), erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), bone biochemistry].

MRI scanning has revolutionised the diagnosis and treatment of patients with spinal problems. Plain X-rays still have their place, for example in the assessment of deformity or trauma, but for most other conditions MRI scanning is a very sensitive investigation. In some respects it is over-sensitise and has to be used carefully. MRI scanning does not replace clinical assessment and should be used either to confirm a diagnosis in order to plan treatment or to exclude a lesion, for example spinal dysraphism in a patient with scoliosis. The false-positive rate for abnormalities is very high, especially for conditions such as disc degeneration but even, for example, for disc prolapse. MRI scanning allows assessment of the discs and spinal column, the spinal cord and nerve roots as well as the structures immediately adjacent to the spine such as the psoas muscles. It allows assessment of neurological compression and of other abnormalities within the spinal canal.

In many parts of the world MRI scanning is not readily available. Plain X-rays will have more use in screening for conditions such as tumours or infection. Compressive lesions can be investigated with CT scanning and, if necessary, CT myelography can be carried out. Myelography alone may still have its place, for example in a compressive lesion in a patient with a metal implant in the spine. Bone scanning is a useful screening test where, for example, a bone tumour is suspected, but MRI scanning has largely replaced this as an investigation.

For assessment of back pain and nerve root pain provocative tests are widely used. Discography can help to assess whether spinal pain arises from a disc, and facet blocks can be used to assess pain in the facets, but also to treat facet pain. Nerve root blocks with local anaesthetic can help to assess whether a particular nerve root is responsible for pain, for example in a patient with multiple-level stenosis.

Nerve root blocks with local anaesthetic can help to assess whether a particular nerve root is responsible for pain, for example in a patient with multiple-level stenosis whether spinal pain arises from a disc, and facet blocks can be used to assess pain in the facets, but also to treat facet pain. Nerve root blocks with local anaesthetic can help to assess whether a particular nerve root is responsible for pain, for example in a patient with multiple-level stenosis.
Trauma management

Most spinal injuries are the result of high-energy trauma. Road accidents and falls are the commonest causes of injury, but in the USA gunshot injuries cause spinal injury relatively frequently. Associated injuries are common

- Spinal injury at another level 10—15%
- Head and face injury 26 
- Major chest injury 16 %
- Major abdominal injury 10%
- Long bone/pelvic fracture 8%

Ninety per cent of fractures are simple compression frac-tures and the majority of these will go on to heal with little consequence. They are best treated symptomatically, initially with rest and then with mobilisation and splinting as necessary.

Seventy-five per cent of patients with an unstable spinal injury will have some sort of neurological injury. The assess-ment of spinal stability is difficult, especially in the patient who is unconscious, and especially in the cervical spine. Look for general alignment of the spine and for soft-tissue shad-ows. Is there widening of the anterior cervical soft tissue shadow, for example? Is there subluxation or rotation of one vertebral on another? Flexion extension views can be useful (see above) but should only be done with care by suitably qualified staff.

A scoring system has been devised for assessing cervical stability.

- Anterior element disruption 2
- Posterior element disruption 2
- Sagittal translation >3.5 mm 2
- Sagittal plane rotation >110 2
- Positive stretch test 2
- Cervical cord injury 2
- Cervical root damage 1
- Abnormal disc narrowing 1
- Dangerous spinal loading in the future 1

If more than five points are scored, then the cervical spine should be considered unstable. In the thoracic and lumbar spine plain X-rays should alert the clinician to possible instability, but this may only be confirmed by CT scan in some cases. Remember that 10 per cent of all injuries are at multiple levels, so always search for the other injury.

Unstable cervical spine injuries

Adequate immobilisation of patients with unstable cervical injuries is mandatory. The patient should have a hard collar, with sandbags at either side of the head and the head should be taped to the bed until adequate treatment is started. Dislocations and fracture dislocations should be reduced as soon as possible. Delay in reduction makes it more likely that neurological injury will occur, and the longer the delay, the more difficult the reduction. However, beware of the possibility of disc prolapse in the presence of a dislocation. It is not uncommon for the intervertebral disc to prolapse posteriorly at the time of dislocation. When the dislocation is reduced, this can cause paraplegia as the spinal cord is compressed against the disc. This occurs in about 1 per cent of all these injuries. Therefore MRI scanning is mandatory before closed reduction of these fractures. If MRI scanning is not available, and not likely to be available over the following few hours, then it may be safer to carry out open anterior discectomy with fusion and instrumentation, in order to try to avoid this severe complication occurring.

Closed reduction can be best achieved either with halo traction or with Gardner Wells tongs. These are best applied under local anaesthetic which avoids any risk to the spinal cord with anaesthesia and intubation. Gardner Wells tongs are easier to apply, but do not allow correction of flexion or extension of the head once applied. The other advantage of halo traction is that the halo can then be used together with a jacket for immobilisation of the cervical spine if required (Fig 33.6 and Fig 33.7).

Neurological injury and its management

Some patients with unstable spinal column injuries will sustain damage to either the spinal cord or nerve roots. Further damage may be prevented by suitable immobilisation of the spinal column, although in a small number of patients remorseless deterioration in neurological dysfunction may occur. This is usually due to persistent compression on the spinal cord interfering with the blood supply to the neuro-logical tissues, but may be due to extension of haematoma or oedema in the area of the injury. Deterioration of neurological function following initial assessment is an indication for urgent treatment. Surgery should be considered to stabilise the spine and to decompress the spinal cord and nerve roots.

A randomised controlled study of a large group of patients has suggested that high-dose steroids may improve recovery after spinal cord injury.

The suggested regimen is:

- 30 mg per kilogram of body weight bolus of methylprednisolone;
- 5.4 per kilogram of body weight per hour of methylprednisolone for the first 23 hours.

There is some debate in the literature about the real efficacy of this regimen, but serious side effects are rare, and until there is evidence to the contrary it seems reasonable to offer patients high-dose steroids on presentation. If the steroids cannot be given within 8 hours, they are not effective and should be avoided.

It is important to establish as soon as possible whether the injury is incomplete or complete. Often the sacral nerve roots are the least affected in spinal injury probably because they are protected to some extent from the vascular effects of injury. Sacral sensation is best assessed at the same time as the patient is log rolled to examine the spine. If sacral sensation is intact, then the injury is incomplete. If spinal shock has developed, it will not be possible to assess function below the injury until the spinal shock has resolved. Reflex arcs can function below the level of the injury without higher func-tions. The anal wink and the bulbocavernosus reflexes are examples of these. If they are present, one can assume that the patient is not in spinal shock. During the period of spinal shock these reflexes will be absent and it is not possible to assess whether the spinal cord injury is complete or incomplete. Spinal shock will usually resolve within 24 hours.

Assessment of neurological injury is best carried out using various scoring techniques. For grading individual muscles the Medical Research
Cervical spine injuries

Upper cervical spine injuries

Severe neurological injury is rarely seen in practice because it is not usually compatible with life.

Occipital condyle injuries. These are unusual injuries which are difficult to diagnose on plain films. If this type of injury is suspected, CT scanning is the best method of investigation. Some of these injuries are unstable, and if so occipito-cervical fusion should be considered.

Jefferson fractures. This is a fracture of the ring of C1 and is usually caused by axial loading (Fig. 33.8). The ring can be split in two, three or four places. The amount of displacement can be assessed on the open mouth view, and if there is more than 6.9 mm of displacement, one can assume that the transverse ligament is ruptured, which suggests that the fracture is very unstable. Although the fracture can usually be seen on plain films, CT scan is useful to define the fracture pattern and to be sure that there is no associated injury at adjacent levels.

If the transverse ligament is divided a period of traction may be advisable. We usually treat these fractures in a halo jacket for 3 months; CT scan followed by supervised flexion extension radiographs is advisable at that point to be sure that healing has occurred and that there is no residual instability. Occasionally one part of the ring may fail to heal but the spine may still be stable. Persistent instability or failure to heal requires posterior occipitocervical fusion.

Odontoid fracture. This is the most commonly missed fracture in the cervical spine and comprises 10 per cent of cervical injuries. Failure to diagnose these fractures can result in spinal cord damage and death. Three types of fracture are described (see Fig. 33.9). Type 1 fractures are rare and are usually stable and can be treated symptomatically. Type II fractures (Fig. 33.10) cause the most problems because there is a high incidence of nonunion, especially in displaced fractures (up to 70 per cent). Undisplaced fractures can be treated with halo-jacket immobilisation, although it is also possible primarily to internally fix the fracture with one or two screws through an anterior approach. Displaced fractures can also be treated with anterior fixation which is quite a difficult technique, or with the more traditional technique of posterior C1—C2 fusion. In older individuals a period of immobilisation in a halo or even a sterno-occipitomandibular immobilizer (SOMI) collar may be considered, because they may heal in a stable position, even though the fracture itself does not unite. They are likely to put less demand on their neck, but stability should be assessed at the end of treatment with supervised flexion extension radiographs.

Type III fractures have a much better ability to heal and immobilisation in a halo jacket for 3 months will usually allow the fracture to heal. Again in the very old immobilisation in a SOMI brace or even in a Philadelphia collar may be adequate to allow healing. During treatment the position of the fracture should be monitored, and adjustments made to the position of the head as required to hold the fracture reasonably reduced.

Atlantoaxial instability. This is a common presentation in children and usually presents as inability to straighten the head, which tends to look right or left and slightly up, the so-called cock-robin position. The rotation may be fixed and often follows minor trauma, although it can present spontaneously, or occasionally as a result of local infection in the neck or oropharynx, so a careful examination of the head and neck is required. The diagnosis is made with radiographs and CT scans with the patient looking right and left. If the position of the axis is fixed in relation to the atlas on the two views, then fixed atlantoaxial rotation can be diagnosed. The subluxation can usually be corrected by a short period of halter traction, but occasionally surgery in the form of fusion is required.

Hangman’s fracture (Fig. 33.11). This is really a fracture of the pedicle of C2. It comprises 5—10 per cent of cervical injuries, and is caused by hyperextension of the spine. There are three types, type I being the most stable, and type III the most unstable. Type I fractures can be immobilised for 3 months in a halo jacket or in a suitable brace, and they will usually heal. The more unstable the fracture the more likely that spinal fusion will be required as primary treatment. If conservative treatment is chosen for unstable fractures, it is important that the fracture is reduced and held reduced until fracture healing has occurred. This can be established with supervised flexion extension radiographs to check for stability and with CT scans to look for bridging of the fracture.

Lower cervical spine injuries

Wedge fractures. These are the commonest fractures, and are caused by hyperflexion of the spine, but they must be differentiated from burst
fractures (see below). This can be done with CT scan. Symptomatic treatment is the rule, and surgery is rarely indicated.

**Burst fractures and teardrop fractures.** Burst fractures are caused by hyperflexion of the spine with or without axial compression. Fragments of bone are pushed circumferentially, whereas in wedge fractures the bone is simply compressed. Thus, the spinal cord or nerve roots may be compromised, and the majority of these fractures should be considered unstable. They should be treated either with immobilisation or with surgery in the form of fusion and instrumentation.

**Teardrop fractures** (Fig. 33.12) are really fracture dislocations where part of the injury goes through the lower part of the vertebra and part of the injury is ligamentous. These fractures often look quite benign on radiographs, but they are very unstable and should be treated with respect. Stabilisation is often necessary.

**Facet dislocation.** These injuries are caused by flexion or flexion and rotation. Either one or both facets may be dis-located (and this can usually be decided on plain films, where if there is less than 25 per cent displacement of one vertebra on the other it is probably one facet, whereas if there is more displacement it is probably both facets). About two-thirds of these patients have some sort of neurological injury, and a third have a complete cord injury. These dislocations should be reduced as soon as possible, provided an anterior disc prolapse has been excluded (see assessment above). If the patient has a complete cord injury, the dislocation can simply be reduced on traction (see Fig. 33.13).

Facet dislocations are unstable and once reduced, internal fixation and bone grafting is recommended.

**Thoracic and thoracolumbar fractures**

These fractures can be classified according to the mechanism of injury or according to the classification method developed by the AO. This classification corresponds with an increasing degree of injury and increasing incidence of neurological injury. It is helpful for communication and for classification in research.

**Thoracic fractures (T1 — T9)**

As in other areas of the spine the commonest fractures are wedge fractures, in the elderly often associated with osteoporosis. These stable fractures can be safely managed with pain relief and mobilisation. Occasionally bracing can be helpful for pain relief.

The spine is splinted by the ribs. Other patterns of fracture are often caused by high-energy injuries, and multiple injuries are not uncommon in these patients. Thoracic fractures and sternal fractures are often associated with aortic rupture, and a high index of suspicion is recommended in the patients. CT scanning will help to make the diagnosis.

Some thoracic fractures can be very difficult to diagnose, particularly in the upper part of the thoracic spine. Careful clinical examination should exclude these fractures in the conscious patient, but in the unconscious patients radiographs of the spine must be carefully examined, with a low threshold for carrying out CT scans.

Unstable thoracic fractures can easily displace in the first few hours after a fracture and great care must be taken when moving the patient. Early posterior stabilisation of these fractures is recommended.

**Thoracolumbar fractures (T10—L5)**

These fractures are more common than thoracic fractures because this part of the spine is not splinted by the ribs. The most common fractures are T12 and L1 because these are at the junction between the stiff thoracic spine and the mobile lumbar spine.

Stable wedge fractures are commonest and can be treated either with mobilisation alone or with bracing initially for pain.

Unstable fractures may cause spinal cord injury or nerve root injury depending on the level of the injury.

Burst fractures may be stable or unstable. If the posterior elements are intact, then the fracture can be considered stable. Unstable fractures can usually be diagnosed on the plain radiographs, with what may appear to be a fracture similar to a wedge fracture, but with widening of the distance between the pedicles (see Fig. 33.14). This implies a fracture of the anterior structures (the body) and the posterior structures (the pedicles). It may however be necessary to carry out a CT scan to see whether the posterior elements are frac-tured. Clinical examination in the conscious patient will allow some assessment of the posterior structures. If there is no pain and no palpable defect, then the injury is probably stable. In the unconscious patient this may be more difficult and occasionally MRI scans are necessary to assess the whether posterior elements adequately to see if there is ligamentous damage.

Distraction injuries are more commonly associated with neurological injury and are usually unstable injuries. Most of these injuries are a combination of bone and soft-tissue injury, but some pass through the bone alone, so-called chance fractures. Many of these fractures are associated with intra-abdominal injury and careful examination of the abdomen is important.

Rotational injuries are the most common and are usually caused by a combination of forces. They are associated with the highest incidence of neurological injury and are best treated with reduction and internal fixation.

Unstable fractures are best treated with posterior stabilisation of the spine but if there is associated neurological injury, particularly at the level of the conus (T12/L1), anterior vertebrectomy and stabilisation is probably best in order to decompress the spinal cord adequately. In the lumbar spine it is important that fixation is limited to the minimum number of levels in order to maintain lumbar mobility.
Degenerative diseases of the spine

Introduction

Pain due to degenerative disease of the cervical and lumbar spine is very common in the general population. A wide variety of terms is used describing this, including lumbago, wear and tear, spondylosis and a slipped disc. What is clear is that parts of the spine are subject to a series of changes in both the intervertebral disc and the adjacent vertebrae. They are associated with local pain and may be associated with the compression of the spinal cord or nerve root. It is also apparent that these changes occur with age. MRI scanning has provided excellent evidence of this disc degeneration, with loss of water content, these changing often without associated pain (see Fig. 33.15). Thinning of the annulus and the appearance of radial slits allow the nucleus to bulge — and may eventually rupture through causing disc prolapse. Progressive collapse of the disc space may allow additional movement, putting extra strain on the apophyseal joints, in which secondary degenerative changes occur with associated ligamentous hypertrophy. Osteophyte formation, due to calcification of the bulging peripheral fibres of the annulus, leads to further narrowing of the spinal, or root exit, canal.

Neurological involvement can therefore occur due to cord, cauda equina or root compression by soft disc, ligamentous hypertrophy or osteophyte formation.

Cervical degenerative disease

Two patterns emerge.

1. Cervical radiculopathy. Neck and radicular pain in the arm with, on examination, signs of a lower motor neuron lesion usually affecting C6 or C7. Functional changes and signs of weakness may be apparent, the arm pain being the predominant symptom (see Fig. 33.16).

2. Cervical myelopathy. Pain and stiffness in the neck with a gritty feeling in the tips of the fingers. Patients will complain of stiffness and a loss of dexterity, with unsteadiness of gait.

The symptoms are usually slowly progressive with, on examination, signs of an upper motor neuron lesion with a glove and stocking distribution sensory loss. The neck pain may not be a major feature. Examination will usually reveal a restricted range of cervical spine movement (see Fig. 33.17).

Commonly seen in the midcervical region, signs of radiculopathy at the affected level may be superimposed. Presence of the deltoid jerk suggests compression above the C4/5 level.

Investigation

Following a careful history and examination to define the pattern of neurological compromise and the clinically affected level, plain X-rays in flexion and extension with an MRI represent the investigations of choice. Cervical myelo-graphy may be helpful if MRI is not available.

Plain X-rays provide details of the bony architecture and evidence of osteophyte formation. Instability can be seen and measured (see Fig. 33.18). MRI in sagittal and axial views allows detailed study of the spinal cord — including changes within the cord itself — together with views of the exiting nerve roots and root canals. MRI does not provide ‘dynamic’ information about the cervical spine and should be used in conjunction with plain X-rays in flexion and extension (see Fig. 33.19).

Differential diagnosis

For cervical radiculopathy the diagnosis is usually apparent. The differential includes cervical rib, producing a T1 syndrome, ulnar or median nerve entrapped syndromes, meta-static disease in the cervical spine, or even direct brachial plexus involvement via an apical lung tumour (Pancoast syndrome).

For patients with a myelopathy, clearly other causes of spinal cord compromise rarely occur, but should be considered. These include an intraspinal tumour, infection or instability associated with conditions such as rheumatoid arthritis. Beware the tumour at the level of the foramen magnum leading to wasting of the small hand muscles.

Management

Radiculopathy. In over 75 per cent of patients the symptoms will resolve with conservative measures, including rest, analgesia, the use of a cervical collar and physiotherapy by an experienced therapist. Physical therapies are becoming increasingly specialised and appropriately timed treatments will usually produce good results.

Care should be taken with cervical collars. A short-term support can become a long-term crutch. Their length of use should be avoided.

Surgery is indicated according to the duration and severity of the pain, physical signs, the radiological appearances and most importantly the patient’s wishes. A good history with physical signs and corresponding radiological changes, and providing a good decompression is achieved, will produce good results.

To effect decompression of the nerve root, either an ante-rior cervical discectomy approach can be used, or posterior foraminotomy. For soft disc prolapse causing nerve root compression, an anterior approach is most frequently used.

Myelopathy. There is much debate about how and when to proceed to surgery. The aim of the operation is to prevent further deterioration. If there is improvement, then this is to some extent a bonus and it is important that the patient and their family are advised of this. Despite decompression, in 30 per cent of patients there will be further deterioration, probably due to vascular changes within the cord itself.

Surgical decompression is, therefore, appropriate for those who are deteriorating, whose symptoms interfere with normal activity; and are accepting of the risks of the procedure.

The aim is to decompress the spinal cord and maintain or establish stability. This can be done by an anterior or a posterior approach to the spine. Anterior approach requires removal of soft disc, osteophytes and hypertrophied ligamentous, often over multiple levels. Fusion, intervertebral grafts or onlay plates can then be achieved.

A posterior cervical laminectomy provides easy access to decompress the spine over multiple levels and great care must be taken to avoid
spinal cord injury. The decision between anterior and posterior approaches depends again on the pathology, the presence of instability and the experience of the surgeon.

The advantages and disadvantages of the two approaches are considered in Table 33.3.

Inflammatory disorders involving the cervical spine

Rheumatoid arthritis

This commonly affects the spine and particularly the cervical spine. Patients often present with stiffness and pain in the neck, and some patients present with neurological symptoms due to compressive myelopathy in the neck. Diseases in the joints in turn lead to soft-tissue destruction and then instability.

The three common abnormalities are:

• atlantoaxial subluxation;
• proximal migration of the odontoid with basilar impression;
• lower cervical spine subluxations.

Investigation with flexion and extension radiographs of the neck and MRI scan allow assessment of stability and cord compression. A certain number of patients may require decompression of the spinal cord and appropriate stabilisation. Anterior decompression (transoral), fusion and instrumentation may be appropriate with localised disease. This may be necessary in either the lower or the upper cervical spine (see Fig. 33.20a—c).

Ankylosing spondylitis

This is relatively uncommon, but can present with painful stiffness of the spine. It is more common in males, most of whom will be human leucocyte antigen (HLA) B27 positive. Other inflammatory markers will be raised. In general physiotherapy combined with anti-inflammatory drugs will control symptoms adequately. However, severe deformities will occasionally be seen and these may require major surgery to the spine to effect correction. Occasionally patients with ankylosing spondylitis will present after minor trauma with unstable fractures. These patients should be assumed to have an unstable injury until this has been excluded. Surgical stabilisation leads to satisfactory results in most cases.

Thoracic spinal degenerative disease

This is rare. Thoracic disc is the commonest form of degenerative thoracic disease that requires surgery.

Presentation

More common in males (5:3 ratio) and usually in the lower thoracic spine, the patients may present with a history of injury but this usually occurs spontaneously.

Pain may not be a major feature. The symptoms will progress very rapidly over a few days, or may occur insidiously over years. The presenting features are those of progressive spinal cord compression with, initially, often dissociating signs, but if undiagnosed will finally progress to a paraplegia with a sensory level, to loss of sphincter function.

Investigation

Plain X-ray may reveal calcification in the disc at the affected level, with calcification of the protruding disc visible.

CT scan. As part of a CT myelogram, this will confirm the epidural compression at the level of the disc prolapse.

MRI scan remains the investigation of choice. Be aware of the level of the disease and whether it is lateral or central (see Fig. 33.21a and b).

Management

Removal of a thoracic disc represents a very different operation to that of cervical or lumbar disc. The prolapse can be hard and calcified or occasionally soft and liquid, appearing like pus. The dura may even be eroded.

A standard laminectomy is dangerous and a lateral or anterior transthoracic approach is required to excise these lesions.

If truly central, a transthoracic route, with drilling out of the vertebral body above and below the level of the disc prolapse, will allow piecemeal removal of the disc and decompression of the spine.

For the laterally placed discs a costotransversectomy with division of the paravertebral muscles and excision of the rib head provides good access, again drilling away the vertebral bodies above and below the disc to allow its removal. Check the levels very carefully by preoperative and/or peroperative imaging and warn the patient, especially about the risks of paralysis due to surgery.

Lumbar spine

Degenerative disease of the lumbar spine is almost universal with increasing age. The disc ages owing to deterioration of the proteoglycan within the disc, which becomes dehydrated as a result. Therefore the disc becomes narrower and this in turn narrows the nerve root canals where the lumbar nerve roots exit from the spinal canal. Secondary changes also occur in the facet joints with loss of joint space, sclerosis and osteophyte formation.

Between 70 and 90 per cent of individuals will experience back pain at some point in their lives. The commonest site of pain in the spine is the intervertebral disc. Although the central part of the disc has no nerve supply, the annulus is very sensitive and is often a source of pain. Degeneration tears often occur in the annulus and these can be a source of pain.

Neurological symptoms can also occur as a result of degenerative disease in the spine. Tears of the annulus can allow part of the nucleus
Disc prolapse occurs most commonly in middle age although it can occur in adolescence and in the elderly. The typical history is of an episode of back pain either related to lifting and/or twisting or which occurs spontaneously. Eighty per cent of disc prolapses occur in the lumbar spine, the majority at L5/S1 (see Fig. 33.22) and at L4/L5. The back pain commonly lasts for 2—6 weeks and may continue for longer. The back pain will often improve then but is followed almost immediately by sciatica or nerve root pain. The pain will usually follow one or more dermatomes, and is often associated with neurological symptoms, altered sensation and weakness in the muscles innervated by the compressed nerve roots. Serious neurological symptoms may be an indication for urgent surgery to decompress the nerve roots, but in general a period of waiting is best because 90 per cent of patients will have relief of their pain within 6 weeks. Minor degrees of weakness and numbness will usually improve with time and may resolve completely. Motor weakness is more likely to recover than sensory change.

**Spinal stenosis**

Spinal stenosis presents typically in the elderly patient and tends to develop gradually (Fig. 33.23). The patient may develop back pain, especially standing and walking, which is associated with neurological symptoms in the legs. Patients report pain, weakness and numbness in the legs on standing or walking, and their walking distance is usually limited. They may complain that their legs go rubbery or tend to give way. Their symptoms usually resolve with rest, especially sitting down for 5—10 minutes, and then they can continue. They often report fewer symptoms going up hill or walking using a rollator or a shopping trolley. The reason for this is that the spinal canal is made wider with spinal flexion. This helps to differentiate these patients from those with vascular claudication who find it worse uphill. Usually the symptoms of vascular claudication will be relieved more rapidly.

**Treatment**

The majority of patients with back pain can be treated with physical treatments such as physiotherapy, chiropractic, or the various other treatments available. Explaining to the patient that they have a nonprogressive condition which is very common will help them to cope with the symptoms. Medications such as analgesics and anti-inflammatory drugs can also be used. Adjustments to work situations (e.g. seating) and to day-to-day life (e.g. less driving, more physical activity, weight loss) are often much more effective that other measures. A small proportion of patients will develop more severe symptoms which require more intensive physical treatments such as rehabilitation. Surgery to fuse or stabilise the spine is a last resort, and should only be used in selected patients where less invasive methods have been used. Combined anterior—posterior surgery probably has the best results in these patients.

**Disc prolapse**

Disc prolapse usually resolves within 6 weeks, and simple pain relief may be all that is required in these patients. Longitudinal studies have demonstrated that most of these disc prolapses will resolve with time. Patients with evidence of cauda equina compression must be managed as an emergency.

**Symptoms suggestive of this are:**

- very restricted straight leg raising bilaterally;
- numbness in the perineum;
- inability to void or difficulty voiding urine;
- inability to have or difficulty in having bowels open;
- lax anal sphincter;
- severe pain.

Not all of these signs are necessarily present in each patient. Emergency MRI scanning or, if not available, CT scan or myelogram will confirm the diagnosis, and treatment is surgical decompression and partial discectomy.

**In the patient with simple sciatica various options are available.**

- Epidural steroid injection — about 30 per cent success rate, low complication rate, day-case procedure.
- Chemonucleolysis (injection of chymopapain into the disc itself) — about 70 per cent success rate, day case or overnight stay. Often causes back pain in the early stages. May take some weeks to be effective. Low complication rate, occasional anaphylactic reaction to the chymopapain.

An important point to note is that conservative treatments are usually very effective in the early stages of disc prolapse and sciatica.
• Laser discectomy (laser coagulation of the disc) — success rate 50—70 per cent, less back pain than chemonucleolysis, day-case procedure, low complication rate.

• Microdiscectomy — success rate 80—90 per cent. Three per cent long-term complication rate (e.g. nerve damage, infection, long-term back pain). Requires hospital admission for a few days. Longer convalescence.

• Standard discectomy — as for microdiscectomy, but longer scar, longer in hospital, longer recovery.

   There is no reason in most cases why closed techniques cannot be used initially and then open surgery used if other methods fail. In older individuals associated spinal stenosis is common and open techniques are more likely to be effective.

Many patients with spinal stenosis are elderly, and nonsurgical methods of treatment may be better for some. Various treatments have been used with fairly low success rates such as lumbar corset, epidural injection of steroids and traction. Physiotherapy with flexion exercises can be helpful in a minority of patients. Calcitonin has been used with some success for treating spinal stenosis, particularly in the elderly who may not be fit for surgery. One-hundred international units of calcitonin are given by intramuscular (i.m.) injection 4 days a week for 4 weeks. Success rates of 20—30 per cent have been reported, but to date there has not been a randomised trial to assess the treatment.

Surgery is effective in about 70 per cent of patients with spinal stenosis. Decompression of symptomatic nerve roots and central stenosis can give very effective relief.

Spondylolisthesis

Spondylolisthesis is a common condition and is usually caused either by spondylolysis or by degenerative change (Fig. 33.24). Spondylolysis is a defect in the bone in the pars interarticularis, and causes a slip between one vertebra and another in some cases. It is present in about 6 per cent of the normal population, is usually asymptomatic and is a common incidental finding. In young individuals presenting with back pain nonoperative measures such as physiotherapy are usually successful in resolving pain, and occasionally a plaster jacket can resolve symptoms. Indications for surgery include non-resolving and serious pain or progressive slip between the two vertebrae. If the spondylolysis is undisplaced and the intervertebral disc at that level is normal, direct repair by bone grafting and internal fixation can be carried out. Otherwise fusion of the motion segment is required. In children internal fixation is seldom required but in adults most surgeons use fixation with inter-pedicular screws.

Degenerative spondylolisthesis is common in the elderly and occurs owing to degeneration of the disc and the associated facet joints. It can be associated with spinal stenosis, and if decompressive surgery is contemplated, it is usually best to carry out an un-instrumented fusion to prevent progression of the slip.
Developmental anomalies

The commonest problem to affect the spinal column is failure of the neural tube to close fully, producing one of many patterns of neurospinal dysraphism or spina bifida.

- Spina bifida aperta. The neural tube is open with no skin coverage, through a defect in the posterior vertebral arch. CSF leakage usually occurs with an associated risk of infection (see Fig. 33.25).

- Spina bifida cystica. In this situation there is skin covering the defect which may contain just CSF, so forming ameningocele, or may have neural tissue within the sac, a myelomingingocele.

- Spina bifida occulta. The posterior vertebral arch has a defect within it, but there is no herniation of the neural tube. This defect may be found within 10 per cent of the population. On the skin over the defect various skin changes may be seen, for example a hairy patch (see Fig. 33.26), an area of pigmentation, a fatty lump or dermal sinus. There may also be associated intradural lesions, including lipomas, dermoids, epidermoid tumours and tethering of the cord with thickening of the filum terminale.

Management

Any discussion regarding the treatment of children with this condition should include inheritance. Whilst the majority (90 per cent) of cases occurs sporadically, with an incidence ranging from one to eight per 1000 of the population, children of parents with spina bifida have a 5 per cent risk of having the condition as well.

Prenatal screening to detect alpha-fetoprotein in blood or amniotic fluid, obtained by amniocentesis, together with the use of ultrasound allows the detection of such defects in over 80 per cent with an open neural tube.

Problems of development tend to occur in the lumbo-sacral area and are especially associated with changes in bladder and bowel function. These changes may not become apparent for the first few years of life and can be associated with a totally normal neurological examination.

The higher the lesion the more severe the defect and the worse the neurological condition. In severe cases it can be associated with a complete failure of development of the legs with a complete paraplegia and loss of bladder and bowel function.

If the lesion is open then there are attendant risks of meningitis as well.

Other associated disorders include Arnold—Chiari malformations and, in up to 80 per cent, hydrocephalus.

Investigations

The investigations include:

- complete neurological examination;
- head circumference measurements;
- plain X-rays of the spine (see Fig. 33.27);
- MRI scan of brain and whole spine.

Treatment

For the majority of cases of open dysraphism, closure should be carried out as soon as possible with treatment of the hydrocephalus. Often this is the first of many procedures best provided by a team of surgeons, paediatricians, therapists and nurses.

As regards the patients with closed lesions at birth, they may require surgery at a later stage should progressive neurological signs develop. It should be noted, however, that any procedure may be associated with neurological deterioration.
Spinal tumours

These have been divided into:

- tumour of the vertebral column;
- intraspinal tumours.

Tumours of the vertebral column

Between 90 and 95 per cent of spinal tumours are secondary tumours, and occur mostly in older individuals. Although almost any tumour can metastasise to bone, the six most common are:

- thyroid;
- breast;
- lung;
- GI tract;
- renal;
- prostate.

The most common among these are breast, lung and prostate. Pain is the commonest cause of presentation and only 10 per cent of individuals present with neurological symptoms alone. Pain in the spine itself due to collapse or instability of the spine, or with radicular pain in the distribution of a nerve root. Features of pain which should alert the clinician are night pain and uncontrollable pain which is not relieved by rest. Patients will usually have a history of weight loss and may have a history of previous tumour.

Careful examination of patients presenting with spinal pain may pick up the primary site of the tumour, although in many cases the primary site is not evident.

Plain radiographs of the site of the pain may show vertebral collapse, loss of a pedicle on the AP radiograph, loss of bone substance or occasionally sclerosis of bone (prostate). Bone scans may show turnouts, although they are unreliable in myeloma and plasmacytoma. An MRI scan is the most sensitive and reliable way of diagnosing spinal tumours, and allows assessment of the size and invasiveness of the tumour. CT scans can also be used for better definition of bone and bone destruction. Myelography is seldom required now unless MRI scans are impossible (e.g. pacemaker) or difficult technically (e.g. previous metallic implant).

Primary bone tumours do occur in the spine. The most common are:

- benign:
  - haemangioma (10 per cent of autopsies),
  - osteoid osteoma,
  - osteoblastoma,
  - aneurysmal bone cyst,
  - giant cell tumour;
- malignant:
  - myeloma,
  - lymphoma.

Biopsy is indicated in most cases either to confirm the diagnosis or to make the diagnosis. In the terminal patient with a known primary diagnosis biopsy is sometimes not necessary. Diagnosis of the tumour allows planning of appropriate treatment. For example, some tumours are radiosensitive (e.g. lymphoma), whereas others are relatively radioresistant (e.g. lung secondaries).

Three types of biopsy are possible: excisional, incisional and needle biopsy. Occasionally a posteriorly sited tumour will be suitable for excisional biopsy but this is unusual. In most cases a needle biopsy will provide enough material for a diagnosis to be made histologically, but in more complex lesions where there is a subtle differential diagnosis incisional biopsy is probably best. Frozen section can be used so that the whole procedure can be done under one anaesthetic, as long as appropriate staging of the tumour has been carried out beforehand. The needle biopsy should be sited so that the entry point can be excised at the time of definitive surgery.

Excision of the tumour is most commonly carried out for benign tumours in younger individuals where there is a real possibility of cure and where recurrence is possible, for example giant cell tumour. This may require simultaneous anterior and posterior en bloc excision of the affected vertebra with a cuff of normal tissue, and then reconstruction of the spine. Osteoid osteoma, in contrast, on the other hand usually requires simple excision of the affected part of the vertebra.

Total excision of malignant tumours may be carried out where the tumour is an isolated tumour and cure of the patient is possible (e.g. some plasmacytomas), but in many cases the tumour cannot be cured either because there is widespread infiltration of the tumour, the tumour has metastasised, or most commonly because the tumour is a distant metastasis of a primary tumour and cure is not possible. In these cases decompression of the neurological structures and stabilisation of the spine are most appropriate.

Intraspinal tumours

‘Lumps’ within the spinal canal can be classified anatomically or pathologically. Anatomically they may be intradural or extradural. Pathologically they may be benign or malignant (primary or secondary). Thus a combined classification can be devised (see Table 33.4).

Occurring in one per 100 000 of the population, meningiomas are the commonest intradural lesion accounting for 23 per cent of those visualised, whilst metastatic tumour forms the commonest extradural lesion.

Presenting features

Pain. Usually localised to the anatomical location of the tumour, the pain is progressive over weeks or months, although it may fluctuate in intensity. Characteristically the pain is nocturnal and will often wake the patient at 3 a.m. to 4 a.m. causing them to get up, walk around and maybe try to sleep in a chair. Local tenderness may be present but this is more common with extraspinal tumours.

Radicular signs. Owing to the root irritation this may result in pain in a radicular distribution with associated pins and needles in the
corresponding dermatomal area.

Clearly if the root involved is cervical or lumbar in origin the symptoms may mimic cervical brachalgia or sciatica. If the tumour is in the thoracic region the pain will radiate around the chest wall in a dermatomal distribution. Clinical examination may reveal signs of a radiculopathy — indicated by a lower motor neuron lesion of the affected nerves.

**Spinal cord/cauda equina signs.** Here the signs and symptoms are dependent upon the level of the tumour. If it is above the L1/L2 junction leading to compression of the spinal cord, the patient will develop a progressive spastic paraparesis/quadricepsparesis with an ascending sensory level, although there may be suspended. Pain due to pressure on the spinal cord is rare. The patient will usually present with a progressive loss of function with pins and needles in the feet (and hands) with, on examination, signs of an upper motor neuron lesion with increased tone, pyramidal distribution weakness, brisk reflexes and extensor plantar responses. Although there is an ascending sensory level, perianal and perineal sensation may be spared.

Cauda equina compression (below L1/L2 junction) results in symptoms and signs of a lower motor neuron lesion with radicular pain, dermatomal sensory loss and myotomal loss of power. The reflexes will be reduced with normal or absent plantar responses. Perineal sensation loss should specifically be examined for, having also made enquiry for changes in bladder, bowel and sexual function. A lack of awareness of the bladder filling, an inability to distinguish the passage of flatus or faeces, and in men erectile dysfunction, all indicate neurological compromise. It should be noted that the neurological picture may be incomplete in the early stages of compression. For example a Brown-Séquard syndrome or contralateral pain and temperature loss with equilaterial loss of light touch is occasionally found.

**Investigations**

Magnetic resonance imaging. With and without gadolinium enhancement, this now forms an investigation of choice. Careful clinical examination with a knowledge of spinal cord anatomy will direct where the imaging is done. A differential diagnosis, according to the classification seen in Table 33.4, can then be made. It should be noted that some tumours can spread throughout the CSF pathways including into the brain, and thus whole neuraxis imaging will be required (Fig. 33.2a and b).

Plain X-rays/CT scan. When dealing with extradural malign-ant disease the anatomy of the surrounding bone is vital when considering the stability of the spine. This clearly influences the management options. Plain films may show enlargement of the intervertebral canal with a dumb-bell neurofibroma, or scalloping of the vertebral body. In the absence of MRI a CT myelography will provide details of the level of disease, but not the extent, and some information about the relationship to the cord, but not the internal features. CT scan is particularly helpful, however, in performing CT-guided biopsies for extradural tumours (Fig. 33.3a and b).

Other investigations. It should be noted that intraspinal tumours may form part of a systemic disease, for example metastatic tumour, and thus general examination with chest X-ray and routine laboratory tests should always be done.

Only after a careful history and examination have been performed with review of the radiology and other tests can the course of management be decided. In principle, symptomatic intraspinal tumours should be excised as completely as possible using micro-neurosurgical techniques and, furthermore, this may have to be done urgently if there is progressive neurological dysfunction.

**The aims of treatment are:**

1. relief of pain;
2. to achieve a histological diagnosis;
3. excision of benign tumours;
4. prevention of further neurological deterioration.

**Pain relief.** Decompression of the spine with removal of the tumour will usually provide immediate pain relief, even if this is incomplete. Radiotherapy of malignant tumours will provide some pain relief but not immediately. Clearly, the patient will suffer postoperative pain, but the severe noc-turnal pain, often interscapular pain will immediately be relieved once the dura is decompressed and the tumour removed.

**Achieve histological diagnosis.** Clearly this is important when deciding whether further adjunctive therapy will be required. For extradural tumours when surgery is not feasible, a CT-guided needle biopsy can be carried out with a good chance of achieving a histological diagnosis and minimal risk of morbidity.

**Excision of benign tumours.** Irrespective of whether the tumour is inside or outside the spinal cord, surgery represents the mainstay of treatment using micro-neurosurgical techniques. Careful definition of the anatomy, debulking of tumour, teasing it away from the surrounding tissues will allow removal with minimal risk of morbidity.

**Prevention of further deterioration.** Decompression of the spinal cord or cauda equina with either malignant or benign disease will prevent further deterioration and may allow some neurological improvement.

**Surgical technique**

Patients and their families should be carefully consented prior to operation. A back marker will help with localisation, although advances in technology using the optical tracking systems will now allow help with localisation but also help to define the extent of the dissection, especially with intramedullary disease.

A posterior or dorsal approach is usual via a midline inci-sion through a laminectomy. The full cephal-ocaudal extent of the tumour should be exposed and, ii extradural, the dural tissue above and below should be identified to allow gentle excision of the tumour.

Care should be taken to keep the dura intact if at all possible and to avoid injury to the emerging spinal nerves. Surrounding the extradural tumour is often a plexus of veins that will bleed quite profusely as the tumour is decompressed. These should be controlled using bipolar coagulation. The lateral extension of a neurofibroma will often require a second approach at a later stage.

It an intradural tumour is the dura should be opened above and below the tumour and, if required, the dural opening should be done using the microscope. Retaining sutures will retract the dura and all dissection thereafter should be carried out using micro-instruments with the help of a microscope. Excision of a neurofibroma will require isolation of the root of origin and its subsequent division. Meningiomas require careful debulking and excision of their origin, whilst keeping the arachnoid planes intact to preserve and protect the spinal cord itself. Care should be taken to avoid any additional compression or distortion of the spinal cord.

If an intramedullary tumour is visible on the surface of the cord then this can be used as a portal of entry to the tumour. If not, a midline
myelotomy can be used with tiny pial retraction sutures. This will then allow access to the tumour itself.

For ependymoma or haemangioblastoma a plane intersection can usually be identified, which will allow the tumour to be gently teased away using any cystic component of the tumour to assist with that dissection. Astrocytomas, however, may not have such a well-defined plane and their removal, therefore, is more difficult.

For tumours within the cauda equina, again careful definition of the anatomy — especially the arachnoid planes — is vital. To fully excise a cauda equina ependymoma requires division of the filum terminale. Beware of the sacral roots, which are often closely attached.

Dural closure follows careful haemostasis. This should be watertight to prevent postoperative CSF leakage. Spinal cord monitoring should be carried out where possible.

**Spinal arteriovenous malformations**

First successfully operated on in 1914 by Ellsburg, the classification of these rare lesions has changed as understanding of the aetiology and anatomy has developed.

The revised classification of spinal vascular malformations is as follows.

**Dural AV fistulas.** This represents a low-flow shunt in the dural sleeve supplied by a dural branch of intervertebral artery. Drainage to superficial intradural veins produces local venous hypertension with venous congestion and an associated myelopathy.

**Intradural AVM’s.** (a) Juvenile — fed by multiple feeders, these high flow lesions may involve the vertebral column. (b) The glomus type — this has a rightly packed nidus usually supplied by one vessel. It may be associated with the arterial aneurysm.

**Intradural.** This is a direct fistula between the intradural spinal artery and vein. It is defined by an absence of the nidus and associated with haemorrhage from aneurysm or venous varix.

**Cavernous angiomas.** These are angiographically occult, with normal vascular anatomy. They appear as small black-berry-like lesions, with low flow and are demarcated on MRI scan.

**Management**

This is usually with progressive symptoms with an ascending myelopathy; it may occasionally present with subarachnoid haemorrhage.

**Diagnosis**

Depends upon a high index of suspicion, often with the identification of a draining vein on MRI scan. Confirmation should be via the spinal angiography (Fig. 33.31).

**Treatment**

The aim is to eradicate the fistula and the nidus without compromising the blood supply to the spinal cord. Depending on the vascular anatomy and the type of lesion, this can be achieved either by intravascular therapy, using particle embolisation, or by surgical exposure of the lesion with identification and closure of the fistula (Fig. 33.32).
Spinal infection

Spinal column infection

Spinal column infection is not common and 30 per cent of cases have a significant delay in diagnosis, the average being 3 months. The common presenting symptoms are fever and unremitting pain especially at night. The distribution is bimodal, occurring in the very young and the very old. In children the infection is frequently sterile and may simply be a discitis. Very young children may present simply with malaise and inability to walk. There may be a scoliosis. The infection is usually centred on the disc, and in the early stages there may be no X-ray changes although MRI will show the typical changes of oedema in the end plates and disc, with changes in the surrounding soft tissues. After 2 weeks narrowing of the disc space usually occurs. Needle biopsy of the disc only grows bacteria in about 40 per cent of cases. Unless the child is septicaemic, expectant treatment can be tried. Established infection or failure to improve requires treatment with broad-spectrum antibiotics. A plaster jacket may be helpful in controlling pain and accelerating resolution of symptoms. In the long term the disc may reconstitute, or occasionally spontaneous fusion of the disc may occur.

Infection of the spinal column is usually more serious in adults. As in children it is usually centred on the disc, and by the time of presentation X-ray changes are usually present in the form of disc space narrowing with destruction of the end plates. The patient may be generally unwell and septicaemic. Many patients have reduced immunity to infection due to conditions such as diabetes or carcinoma, and recent urinary catheterisation or surgery is not uncommon. It is important to establish the bacterium causing the infection if possible before starting treatment. The most common bacterium is *Staphylococcus aureus*, but almost any bacterium can cause the infection and tuberculosis must always be considered as a possibility (see below). Blood cultures should always be carried out and in many cases this will establish the type of bacteria. Needle biopsy of the disc space is an alternative method of diagnosis. This is done under local anaesthetic with X-ray control, and will confirm the diagnosis in about 60 per cent of cases. Surgery tends to be used for patients where there is considerable bone destruction or deformity, neurological compromise due to compression on the spinal cord or failure to eradicate the infection with antibiotics. Simple stabilisation of the infected area combined with antibiotics may be adequate in older individuals, but otherwise débridement of the disc space, bone grafting and stabilisation are most likely to result in cure. Surprisingly internal fixation in these patients rarely seems to cause problems of persistent infection, although it may be advisable to remove the fixation once the bone has healed. Antibiotic treatment is usually continued for some months.

Some cases of disc space infection will progress to epidural abscess. This will present with neurological symptoms and signs and should be drained as a surgical emergency (see below).

Tuberculosis

Tuberculosis is more frequently seen in the Third World than in the developed world but it is becoming more common, and should always be considered as a possible diagnosis in those with spinal infection.

Treatment with multiple antibiotics over long periods has proven very effective in treating spinal tuberculosis, and has been shown to be effective in managing some patients with paraplegia. Eventual fusion of the infected area can be expected in around 80 per cent of patients without surgery. Surgery combined with antibiotics is used where there is a large abscess which requires draining or considerable deformity of the spine. Failure of antibiotic treatment may also be a surgical indication. In general the best surgical results are with anterior débridement and bone grafting of the infected area.

Spinal epidural abscess

Infection within the epidural space is a rare but potentially disastrous condition. Usually due to haematogenous spread from remote sites or associated with intravenous drug usage, pus can collect and spread within the epidural space and cause compression of the spinal cord or cauda equina. Infection may spread from local sites (discitis/vertebral osteomyelitis or paravertebral infection) (see Fig. 33.33) and may present as a postoperative complication.

*Staphylococcus aureus* represents the commonest causative organism. A variety of other organisms including bacteroides, aerobic and anaerobic streptococci may be found. Consider unusual organisms in association with immune compromise, including fungal infections.

Presentation

**Presentation includes:**

- severe local pain;
- systemic signs of infection;
- radicular signs;
- onset of symptoms and signs of cord and cauda equina compression.

Progression of symptoms can be very rapid and therefore early recognition is vital to allow a good outcome. A high index of suspicion to achieve diagnosis before the onset of complete paralysis is very important. If the diagnosis is delayed to this point, vascular thrombosis may result in irreversible paralysis.

Diagnosis

**Diagnosis includes:**

- clinical awareness of the condition;
- general tests: haemoglobin, white cell count, ESR, CRP, blood cultures, midstream urine;
- plain spinal X-rays, chest X-ray;
- MRI scan.
Plain X-rays may show evidence of osteomyelitis and should be performed, but MRI is the investigation of choice (see Fig. 33.34). The precise location of the abscess and its extent and position in relation to the cord can all be identified. If suspected the investigation must he carried out as an emergency.

In the absence of MRI, myelography and CT myelography would enable the diagnosis of an epidural mass, but it is harder to define the full extent of the lesion. Care must be taken to avoid carrying infection into the intradural compartment at the time of lumbar puncture. If a cervical abscess is suspected, a lumbar spinal puncture can be used, the contrast being run up to the cervical region. However, if the abscess is thought to be in the thoracolumbar region, a cervical puncture must be made. CT myelography will help to define the extent of the lesion and will also provide important anatomical information about adjacent vertebral bodies. CSF examination shows a mild leucocytosis with elevation of the neutrophil or lymphocyte counts. Protein levels will be increased.

Management

Management of this condition includes:

- surgical drainage of the abscess;
- antibiotic therapy;
- treatment of source of infection/paravertebral infection;
- management of neurological disability.

Patients with an epidural abscess showing signs of severe systemic infection require full supportive therapy. Drainage of the pus via a posterior or anterior approach should be carried out as an emergency once a diagnosis is suspected. For anteriorly placed lesions, usually in the cervical region, an anterior cervical discectomy with opening of the posterior longitudinal ligament reveals the pus. Samples should be sent for microscopy and Gram stain, set up for culture and antibiotics started. Avoid instrumentation or insertion of bone grafts.

Dorsally placed collections can be drained via a laminectomy.

If available, the advice of a bone infection unit should be taken. Certainly, advice from a medical microbiologist will help in the choice of antibiotic and the duration of treatment. In principle, intravenous therapy via a long intravenous line, and modified according to culture results, should be continued for at least 2 weeks. Be prepared to repeat the MRI scans to ensure that the abscess has been fully drained.

Any residual neurological deficit will require input from physiotherapists and occupational therapists, directed by a rehabilitation facility. Recovery, however, may be slow and protracted over many months. Finally, any other site of infection should be dealt with as indicated.

Introduction

The nervous system is divided into the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of the brain, spinal cord and the first two cranial nerves, while the remaining cranial nerves and the spinal nerves constitute the PNS. The CNS and PNS have fundamentally different responses to injury, the CNS having little ability to regenerate, while the PNS has considerable potential for recovery if conditions are favourable. This chapter deals mainly with surgical disorders of the PNS. Injuries to peripheral nerves have a major effect on the functional outcome after trauma, and therefore careful management from an early stage is important to obtain the best results possible.
Principles of peripheral nerve surgery

Structure of the peripheral nerve trunk

The anatomy of a peripheral nerve trunk is shown in Fig. 34.1. Nerve impulses are conducted by axons. The nerve contains many axons which are supported by connective tissue structures. Neurons consist of a cell body, associated dendrites and usually one axon. In order to remain viable an axon must be connected to its cell body. All axons are sur-rounded by Schwann cells. In myelinated fibres the Schwann cells form an insulating sheath, each Schwann cell being asso-ciated with only one axon. Integrity of the myelin sheath is necessary for conduction of nerve impulses in myelinated fibres. Unmyelinated fibres are composed of several axons wrapped by a single Schwann cell. The Schwann cell base-membrane, together with endoneurial collagen fibres, forms the endoneurial tube. Large numbers of nerve fibres are gathered in fascicles surrounded by a connective tissue sheath called the epineurium. The fascicles are bound together and the whole trunk ensheathed by a further connective tissue layer called the epi-neurium.

Response of a nerve to injury

If trauma to a nerve is sufficient to disrupt axons then the distal part of the nerve undergoes Wallerian degeneration. In this process there is lysis of the axoplasm and fragmentation of myelin sheaths leaving an endoneurial tube containing Schwann cells. The axons in the proximal part of the nerve have the potential to regenerate into the endoneurial tubes of the distal segment and subsequently make connections with target organs. The regeneration proceeds slowly with axons growing at only 1—2 mm/day in humans. The extent of dam-age to the supporting connective tissue layers influences the quality of recovery and is, hence, the basis of the classifica-tion of nerve injuries.

Classification of nerve injuries

The most widely used classification of nerve injuries in the UK was described by Seddon (1942) after study of a large number of battle casualties during World War II. There are three types of injury of increasing severity:

- Neuropraxia;
- Axonotmesis;
- Neurotmesis.

Neuropraxia (nerve not working)

This is a local block to conduction of nerve impulses at a dis-crete area along the course of a nerve. The axons are in con-tinuity and therefore Wallerian degeneration does not occur. Nerve conduction distal to the site of injury remains normal. Experimental work suggests that the conduction block results from localised demyelination of fibres in the damaged segment of nerve. Neuropraxia is a relatively mild injury typi-cally caused by moderate compression such as that caused by a tourniquet, slight stretching or the passage of a missile close to a nerve. Recovery is complete providing the cause is removed, but the time varies from days to several weeks.

Axonotmesis (axons divided)

This represents an anatomical disruption of the axons and their myelin sheaths. However, the supporting connective tissue structures including the endoneurial tubes, epineurium and perineurium are still intact. Wallerian degeneration occurs distal to the site of injury and, hence, distal conduc-tion is lost. Axonotmesis results from a more severe blow or stretch injury to a nerve. For example, radial nerve palsy associated with fracture of the humerus is usually an axonotmesis. Recovery occurs by axon regeneration proceed-ing at a rate of 1—2 mm/day. Axons regenerate along the same endoneurial tube and therefore connect with the same end organ as before injury. The prognosis is good, restoring near-normal sensory and motor function.

Neurotmesis (whole nerve divided)

This is the state where the nerve has been completely severed or is so seriously disorganised that spontaneous recovery is not possible. The axons and the supporting connective tissue structures are disrupted, and Wallerian degeneration occurs distal to the site of injury. Typically neurotmesis occurs as a result of an open injury such as a stab wound but high-energy traction, injection of noxious drugs and ischaemia can also destroy a nerve in this way.

If appropriate surgical repair is carried out then recovery may occur by axonal regeneration at a rate of 1—2 mm/day. In contrast to axonotmesis, the quality of recovery is never per-fect after neurotmesis. This is probably the result of the failure of correct ‘rewiring’. Because the endoneurial tubes and other connective tissue structures have been disrupted, even with the best repair, regenerated nerve fibres connect with muscles or sensory organs which they did not previously innervate.

Sunderland’s classification

In 1951 Sunderland defined five degrees of nerve injury on the basis of increasing anatomical disruption of the nerve trunk (see Table 34.1). Although Seddon’s classification is simpler and more widely used in the UK, Sunderland’s classification is useful in its distinction between third- and fourth-degree injuries when exploring a damaged nerve. If the fascicles are in continuity (not worse than third-degree injury) then sponta-neous recovery is possible, whereas if the fascicles are disrupted (fourth-degree injury) then spontaneous recovery will not occur and immediate nerve grafting may be considered.

Injection injuries

Injection of toxic substances directly into a nerve leads to a very intense fibrotic reaction in the nerve. Immediate exploration, incision of the epineurium and irrigation of the nerve trunk is recommended, but the outcome is poor.

Clinical features of nerve disorders

As with other medical and surgical problems, diagnosis of conditions affecting nerves is based upon history, examination and special investigations. In the case of trauma it is partic-ularly important to establish the mechanism. High-velocity and open injuries produce more severe nerve injuries.

The clinical findings on examination of patients with nerve injury include motor and sensory dysfunction but depend, in part, upon the grade of injury. With neurapraxia there is usually complete paralysis of the appropriate muscle groups but some sensation and autonomic function is...
preserved. In the case of axonotmesis and neurotmesis there is complete loss of muscle power, sensation and autonomic function. The latter is most easily shown by lack of sweating in the distribution of the nerve. This is a useful objective sign as it does not require a co-operative patient. The nerve injured and the level at which the injury has occurred can be worked out from a careful physical examination and knowledge of the anatomical distribution of the nerves. Nonetheless, there is significant crossover in sensory function and also in some motor function, particularly when considering nerve roots (Table 34.2 and Fig. 34.2).

It is useful to grade the level of dysfunction of nerves, particularly in the assessment of recovery and the results of treatment. The system widely used is the 1975 update of the 1954 Medical Research Council (MRC) classification (Tables 34.3 and 34.4). This grading system is good, and widely used, but is still a rather coarse measure of muscle function and sensation.

Clinical examination needs to be conducted with care, particularly with those patients who may have difficulty co-operating. The findings should be accurately documented. Two-point discrimination is particularly useful for assessing sensation in the hand as it is an objective measurement and normality (approximately 4 mm on the finger pulps) excludes significant nerve injury. If there is any doubt initial first aid should be carried out and the patient re-examined within 48 hours. Diagnosis can be difficult and severe nerve injuries are regularly missed.

Investigation

While the most important assessment of nerve pathology is undoubtedly clinical, useful additional information can sometimes be obtained from neurophysiological studies or imaging.

Neurophysiological investigations require complex stimulation and recording apparatus. Interpretation of the results requires experience and is reliant upon the skill of the neurophysiologist. There are two types of test available.

• Nerve conduction studies —these involve recording sensory or motor nerve action potentials and calculating the conduction velocity for given anatomical segments. Compression neuropathy can be identified by slowing of conduction.

• Electromyography (EMG) —in this test muscle action potentials are recorded in response to voluntary activity. Denervation can be diagnosed and distinguished from reinnervation.

Using these tests it is possible to distinguish between a nerve injury where axons have not degenerated distal to the lesion (neurapraxia) and one were Wallerian degeneration has occurred (axonotmesis or neurotmesis). Axonotmesis and neurotmesis cannot be distinguished.

Magnetic resonance imaging (MRI) is showing some promise in displaying peripheral nerve pathology and is likely to be used routinely in the future. Currently, its main application is in imaging cervical nerve roots after brachial plexus injuries.

Treatment

Open injuries

If there is clinical evidence of a nerve injury associated with a wound, then it should be assumed that the nerve is divided until proven otherwise.

Surgical exploration of the nerves is advisable, once life-threatening haemorrhage has been controlled and providing the general condition of the patient allows operation. In addition, wounds in areas where important nerves are vulnerable to damage should be routinely explored even in the absence of obvious neurological deficit, for example the flexor compartment of the forearm. Early repair of any divided nerves should be performed if possible. Exploration should therefore be undertaken by a surgeon with appropriate experience to carry out repair of nerves if necessary. If a vascular repair is required then nerve repair should normally be carried out at the same time. If the injury is in a site which is difficult to expose surgically, for example the brachial plexus, then transfer to a specialist unit should be arranged as soon as possible.

Closed injuries

Management of closed injuries where nerves have been subjected to stretch or compression is more difficult because the severity of nerve injury may not be clear. Neurapraxia and axonotmesis will recover spontaneously providing the cause, for example compression, is removed. However, surgical repair of the nerve is necessary for there to be any chance of recovery after neurotmesis. Results are markedly better if this repair is carried out early after injury.

Exploration and repair of nerves may be combined with fixation of any associated skeletal injury. In cases of low-energy injury it is reasonable to observe the nerve injury initially, unless operation is being carried for fracture fixation in which case the opportunity should not be missed to carry out nerve repair. Cases managed nonoperatively should be followed up carefully. If there is clear evidence of recovery after 2—3 months then nonoperative management can continue. If not, then surgical exploration should be considered without further delay.

Neurophysiology may be helpful in making the decision in some cases as the tests may detect early recovery which is not evident clinically.

Surgical repair

The essence of a good surgical repair of a nerve is accurate coaptation of the nerve ends without tension in a healthy bed of tissue. At operation the nerve ends are exposed, carefully avoiding further injury. If there has been a clean division of a nerve, then little dissection is usually required and direct suture can be carried out. However, if the nerve ends are ragged or the disruption has been caused by blunt trauma, it is necessary to trim the nerve back to healthy tissue with bulging nerve bundles. In delayed repairs significant scarring and retraction of the nerve ends may have occurred and it is, again, important to trim the nerve back to normal tissue. In these circumstances there will be a gap between the nerve ends. In the past extensive mobilisation of some nerves was recommended to allow direct suture. However, it is seldom possible to get much length by this manoeuvre and the repair is invariably under tension. Therefore, if there is a significant gap then it is usually better to perform nerve grafting. Occasionally, when a nerve injury is combined with a fracture, bone shortening may be justified to allow direct nerve suture.

Timing of nerve repair

Early nerve repair provides the best chance of satisfactory recovery and should be carried out provided that a well-trained surgeon and suitable equipment are available. Occa-sionally, if a wound is very contaminated then primary nerve repair may not be appropriate. In most circumstances it is possible to carry out early repair if sufficient wound debridement is carried out and plastic surgical expertise is available to provide flap cover of soft-tissue defects. If primary repair is not carried out then it is useful to apply one or two nonabsorbable sutures, either to hold nerve ends together or to suture a nerve end to local soft tissue, thereby minimising retraction and aiding identification at later surgery.
Direct nerve suture

When repairing a nerve, a microscope should be used to aid accurate alignment of the nerve and placement of sutures, which range in the order of 6/0 for large nerves (such as the sciatic nerve), 8/0 for the median nerve in the forearm, and 9/0 or 10/0 for digital nerves. It is important to orientate the nerve ends with the correct rotation in order to minimise crossover during recovery. The pattern of nerve fascicles and surface blood vessels can be used as guides for alignment. Sutures are usually placed in the epineurium (epineurial repair). There is probably no advantage in performing interfascicular repair except at distal sites where the nerve is dividing into terminal branches. Sufficient sutures are inserted to provide epineural cover for all nerve bundles (Fig. 34.3).

Nerve grafting

When direct nerve suture is not possible an interpositional nerve graft is necessary. This involves harvesting a length of an ‘expendable’ nerve trunk, such as the sural nerve or the medial cutaneous nerve of the forearm. These are long slender nerves which supply only small areas of sensation. The nerve graft is usually cut up so that a number of strands can be used to build up a similar thickness to that of the nerve trunk being repaired (cable grafting; Fig. 34.4).

Postoperative management

After wound closure, the limb is immobilised to minimise any tension on the suture line with appropriate flexion of proximal and distal joints. These are held in a cast for a minimum of 3 weeks. It may then be appropriate progressively to extend the proximal and distal joints, thus gradually restor-ing normal tension to the nerves. After 6 weeks, free mobil-i-sation is permitted, assisted by appropriate physiotherapy.

Follow-up management

After nerve repair patients should have regular physiotherapy to maintain the passive range of movement in all joints prior to muscle recovery. In addition, patients should be monitored clinically to check that nerve recovery is occurring at the expected rate. Tinel’s sign is useful in monitoring axon regen-eration and should advance at about 1 mm/day. (Elicited by percussing over the course of the nerve, the patient feels tingling in the distribution of the nerve.) In the event of nerve recovery not progressing, then re-exploration of the nerve may be justified.

General factors affecting prognosis

The factors governing the prognosis of nerve repair are both general to all nerves and specific to certain nerves.

Age

Children recover much better than adults and this is probably the most important prognostic factor. Nonetheless, the secondary consequences of paralysis in children may be worse because of the associated growth abnormalities. Age over 50 years is a particularly poor prognostic factor for proximal nerve injuries.

The severity of injury to the nerve

Seddon’s classification of nerve injuries relates the severity of injury to the prognosis. However, there are varying grades of neurotmesis which affect the chance of recovery after repair. A clean-cut nerve injury has the best prognosis, whereas high-energy injuries, such as high-velocity gunshot wounds or severe traction injuries, damage a greater length of nerve and have a much worse prognosis.

The level of injury

In general, proximal lesions do worse than distal lesions although there do appear to be some exceptions to this rule.

The type of nerve

The classic teaching is that nerves with both sensory and motor fibres fare worse than pure sensory or motor nerves. The latter do not truly exist, as all motor nerves have some afferents from muscle spindles. However, it is certainly true that motor nerves to large muscle groups not requiring fine control have a better prognosis than motor nerves supplying the small muscles of the hand.

Associated injuries

Nerve repairs with associated vascular injuries, soft-tissue damage and fractures are less likely to heal with a satisfactory result. It is important that associated vessels and other structures are repaired as far as possible.

Delay

Early repair of nerves, that is within a few days of injury, gives the best results and is one of the main factors which the surgeon can influence.

Special types of nerve injury

Compression neuropathy

This is the term used to describe chronic dysfunction of a nerve as a result of local compression at some point along its course. Compression neuropathy is one of the most frequent single conditions presenting to orthopaedic and hand clinics. The most common sites of compression are the median nerve at the carpal tunnel and the ulnar nerve at the cubital tunnel or Guyon’s canal. These are anatomical sites where the nerve is surrounded by unyielding bone and ligaments. Sometimes there is an identifiable cause such as tenosynovitis within the carpal tunnel, but in many cases there is no obvious cause. Compression of a nerve has a direct effect on the myelin sheaths, as well as causing ischaemia of the nerve with con-sequent fibrosis. It also appears that damage results from loss of mobility of the nerve at the point of entrapment. The patient initially complains of pain and altered sensation in the distribution of the affected nerve. In more advanced cases there is loss of sensory and motor function. Most compr-e-sion neuropathies respond to surgical decompression of the affected nerve.

Irradiation

Radiation neuritis can occur up to 20 years after the radiation, the classic site being the infraclavicular brachial plexus following radiation for breast cancer. Fortunately, this is rare. Characteristically, there is severe pain with some motor and sensory changes. The pain is cry difficult to
treat. Surgical exploration and release of nerves has been beneficial in some patients.

**Pain**

The pain following nerve injuries or other nerve pathology can be of the most severe intractable type, leading to requests for amputation and even depression and suicide. The cause of this pain is poorly understood. Local nonoperative treatment includes encouraging use and movement of the limb, and transcutaneous electrical nerve stimulation (TFNS). This works as a counter-stimulus to the pain. In addition to simple systemic analgesics, medication to suppress nerve excitability, such as carbamazepine, and antidepressants, such as amitryptilline, can be useful. There are certain occasions where pain of nerve origin may be influenced by surgical intervention.

**Cusalgia**—pain as a result of an injury (often partial) to a major nerve. The pain typically has an intense burning character. This pain tends to improve with nerve recovery and therefore any surgical measures should be aimed at facilitating this. Sympathectomy may be helpful in resistant cases.

**Nerve compression** may cause severe pain (neurostenalgia). *Avulsion* of spinal nerve roots from the spinal cord, for example with traction injuries to the brachial plexus. This is a complex pain syndrome involving damage to the spinal cord and loss of the normal afferent signals from the limb. Re-establishment of some neurological input is by nerve transfer. In the case of the brachial plexus intercostal nerve transfer may prove useful. Neuroma—if a nerve is wholly or partially divided and not repaired, for example at amputation, then axons attempting to regenerate form a neuroma on the nerve end. The neuroma may be exquisitely sensitive to any pressure, particularly if it is tethered in scar tissue or situated at a prominent point. Surgery may be helpful to restore continuity of the nerve by repair or grafting, if possible, or to move a neuroma to a less prominent position.

**Reflex sympathetic dystrophy** (algodystrophy)—this is a specific syndrome which can occur after trauma or surgery where a cycle of pain and dysfunction is set up and leads to a chronic state associated with sympathetic over-activity. The limb involved becomes painful and tender to normal stimuli. This leads to disuse, stiffness and trophic changes. It is important to recognise the condition as early as possible and to break the vicious cycle. In addition to standard analgesics, guanathedine blockade to suppress sympathetic activity is useful to facilitate vigorous physiotherapy.
Specific nerve injuries

Brachial plexus lesions

Damage to the brachial plexus is caused by:

• traction as a result of violent displacement of the shoulder girdle and cervical spine;
• open, penetrating injuries by knife or missile;
• operation in the area (for example, for removal of lymph nodes);
• malignant infiltration at the base of the neck, for example Pancoast syndrome.

Traction injury is particularly associated with road traffic accidents to motorcyclists. Any component of the plexus (Fig. 34.5) can sustain any grade of injury (neurapraxia, axonotmesis, neurotmesis). In addition, nerve roots may be avulsed from the spinal cord (preganglionic injury). According to the degree of injury the paralysis varies from a completely flail and useless arm and hand to paralysis of groups of muscles and anaesthesia according to the roots affected. Injuries are usually divided into:

• supraclavicular;
• infraclavicular;

although it is possible for there to be damage both above and below the clavicle.

The most common pattern of injury to the supraclavicular plexus is a lesion of the CS and C6 roots and upper trunk (Erb—Duchenne palsy). There is loss of shoulder abduction and external rotation, elbow flexion and forearm supination. Sensation is absent on the outer aspect of the arm and hand. Klumpke described a lesion of the lower roots, but this is rare on its own. Injuries to all of the roots are more common.

Management of traction injuries

It is important to establish the mechanism of injury as nerve ruptures are more likely after high-energy trauma. The nerves affected can largely be deduced from careful clinical examination. Signs of preganglionic injury include:

• Hornet’s syndrome;
• paralysis of the thoracoscapular muscles (innervated by branches near the roots);
• swelling in the posterior triangle of the neck;
• severe pain in the anaesthetic arm.

Investigation

Includes radiographs of the chest and cervical spine to look for vertebral or rib fractures and to assess phrenic nerve function. In cases of supraclavicular injury myelography, preferably combined with computerised topographic (CT) scanning, or MRI gives useful additional information on the integrity of the roots before surgery (Fig. 34.6). Neurophysiological assessment is not usually helpful until 2—3 weeks after injury.

Severe traction injuries to the brachial plexus have a devastating effect on the limb and the outlook is often poor. Careful management is therefore important to maximise recovery. If clinical examination reveals complete absence of function of any part of the plexus and the injury was caused by high-energy trauma, then exploration of the brachial plexus is indicated as soon as the general condition of the patient allows. Therefore, transfer to a specialist unit should be arranged as soon as possible. If early surgery is not possible then every effort should be made to operate by 3 months from injury, as the results of repair are undoubtedly worse with increasing delay. At operation the damage to the plexus is carefully documented and nerve grafting is carried out for nerve ruptures. Until recently, repair of avulsed roots was not thought to be possible, but some recovery has now been obtained after repair of ventral (motor) roots within the spinal canal. Alternatively, nerve transfers are performed to restore the most important functions of avulsed roots as far as possible.

Stab wounds

Any sharp injury to the brachial plexus should be explored as soon as possible and repaired using nerve grafts.

Obstetric brachial plexus palsy

Injury to the brachial plexus can result from traction on the shoulder girdle during birth. The upper roots are most commonly affected (Erb—Duchenne palsy). The prognosis is good with conservative management in most cases. Physiotherapy is necessary to prevent joint contractures, particularly of the shoulder. The prognosis is improved by surgery to the brachial plexus in approximately 10 per cent of cases. Indications for operation are:

• failure to regain elbow flexion by 3—6 months;
• complete paralysis of the limb.

Branches of the brachial plexus

Axillary or circumflex nerve

This is most commonly injured in association with dislocation of the shoulder joint. The deltoid muscle is paralysed and there is a patch of anaesthesia over the outer side of the arm. The majority of cases recovers spontaneously, but rupture of the nerve does sometimes occur and then recovery is only possible if nerve grafting is carried out.
The long thoracic nerve

The long thoracic nerve to serratus anterior (nerve of Bell) may be injured by operations on the breast or chest wall, or is occasionally involved in neuropathies. Paralysis of serratus anterior results in 'winging' of the scapula and difficulty in elevating the arm above a right angle (Fig. 34.7).

Radial nerve

This nerve is most commonly injured in the radial groove in association with fracture of the shaft of the humerus or as a result of pressure, as in 'Saturday night' palsy due to falling into a heavy sleep with the arm over the sharp back of a chair. Clinical features include:

• motor — paralysis of brachioradialis, the wrist extensors and extensor digitorum. It should be remembered that extension of the interphalangeal joints will still be present if the hand is supported because of the action of the lumbricals and interossei, which are inserted into the extensor expansions. In higher lesions the triceps will also be affected;

• sensory — loss of sensation over the dorsum of the thumb and the first web space. In higher lesions sensation is also lost on the dorsum of the forearm (Fig. 34.8).

Recovery of the radial nerve is usually good either after conservative management or repair, if appropriate. If not, then good results can be obtained by tendon transfer.

Median nerve

The median nerve is classically injured at the elbow or wrist. Injuries at the elbow are due to fractures of the distal humerus or dislocation of the elbow joint. Clinical features include:

• motor — paralysis of the pronators of the forearm and flexors of the wrist and fingers, with the exception of the flexor carpi ulnaris and the medial part of the flexor digitorum profundus. The index finger and thumb cannot be flexed at the interphalangeal joints, but flexion of the other fingers is performed by the portion of the flexor digitorum profundus which is supplied by the ulnar nerve. The thenar muscles are paralysed with resulting loss of abduction and opposition of the thumb;

• sensory — sensation is lost over the palmar aspect of the thumb, index, middle and the radial half of the ring fingers, as well as part of the palm.

Damage to the median nerve at the wrist is comparatively common as a result of lacerations, fractures of the distal radius or compression in the carpal canal. Clinical features include paralysis of the thenar muscles and loss of sensation on the palmar aspect of the radial three and a half fingers (Fig. 34.9).

Ulnar nerve

The ulnar nerve is most commonly damaged by lacerations in the forearm or entrapment as it passes behind the medial epicondyle of the humerus, in which case decompression or anterior transposition may be indicated.

Clinical features include:

• motor — paralysis of the small muscles of the hand, with the exception of the thenar muscles and lateral two lumbricals. The patient is unable to abduct and adduct the fingers, or indeed grip a piece of paper between them (Fig. 34.10). Weakness of flexion of the metacarpophalangeal joints and extension of the interphalangeal joints result in a claw-type deformity. If the patient pinches a piece of paper between the thumb and the index finger the distal phalanx of the thumb assumes a flexed position, as weakness of the adductor pollicis permits over-action of flexor pollicis longus (Froment's sign, Fig. 34.11). In longer standing cases, muscle wasting will be evident in the interosseous spaces and along the medial border of the hand. Lesions proximal to the elbow also cause paralysis of the flexor carpi ulnaris and medial half of the flexor digitorum profundus;

• sensory — sensation is lost on the medial one and a half fingers (Fig. 34.12).

Lower limb nerves

Sciatic nerve

The sciatic nerve is occasionally injured by wounds, fractures of the pelvis, posterior dislocation of the hip, operation for hip replacement or tumours. The prognosis for recovery is poor, particularly in proximal injuries. If the lesion is above the origin of branches to the hamstrings, the following features will be present:

• motor — the flexors of the knee are paralysed, but some degree of flexion is possible owing to the action of the sartorius and gracilis muscles. Complete paralysis exists below the knee, and the pull of gravity therefore causes foot drop;

• sensory — complete loss below the knee, with the exception of the skin supplied by the saphenous nerve, i.e. the medial border of the foot;

• causalgia may complicate partial lesions.

Common peroneal (lateral popliteal) nerve

Partial lesions of the sciatic nerve affect the peroneal division much more frequently than the tibial division. The common peroneal nerve itself is quite sensitive to injury by fractures or dislocations around the knee, pressure from plasters o splints and operations around the knee. Complete lesions will cause:

• motor — complete paralysis of the extensor muscles of the ankle and toes and the peroneal muscles, with resulting foot drop and tendency to inversion of the ankle;

• sensory — anaesthesia of the dorsum of the foot and toes.
The prognosis depends on the severity of injury, but is poor even after repair for neurotmesis. Function may be improved by tendon transfer at the ankle.

**Femoral nerve**

The femoral nerve is occasionally injured by stab wounds or operations on the groin. Paralysis of the quadriceps results. The prognosis is good if a laceration of the nerve is repaired early.
Cranial nerves

I. Olfactory nerve

The fine olfactory filaments pass through the cribiform plate to join the olfactory bulb that runs on the undersurface of the frontal lobe. Damage can result from acceleration/deceleration injuries causing shifts in the position of the brain, fractures of the ethmoid bone and meningioma arising from the floor of the anterior cranial fossa. The sense of smell is impaired, and because of the strong relationship between smell and taste this can considerably affect the enjoyment of food and drink.

II. Optic nerve

The optic nerve is an outgrowth from the cerebrum and has an investing nerve sheath, enclosing cerebrospinal fluid, which allows intracranial hydrostatic pressure to be transmitted to the optic fundus. A rise in intracranial pressure may be manifest by swelling of the optic disc (papilloedema). The optic nerve may be damaged as it leaves the skull and glial tumours may arise within the substance of the optic nerve, particularly in children. By testing the visual field, it may be possible to infer the site of intrinsic or extrinsic lesions affecting the optic pathways.

III. Oculomotor nerve

A complete lesion of this cranial nerve causes total paralysis of the levator palpebrae superioris, resulting in ptosis. A proptosis will occur because of loss of tone of the extraocular muscles which normally exert traction on the globe. Owing to the unopposed action of the sixth and seventh cranial nerves, the eye is deviated downwards and outward and, when the lid is lifted, diplopia will occur. Because of the unopposed action of sympathetic fibres there is dilatation of the pupil, which is unresponsive to both light and accommodation. The length of the intracranial course of the third cranial nerve exposes the nerve to damage either intracranially, as it leaves the skull, or within the orbit. In circumstances of raised intracranial pressure, herniation of the uncus of the temporal lobe through the tentorial notch leads to pressure on the third cranial nerve and a dilated pupil. This is a late and serious sign of raised intracranial pressure.

IV. Trochlear nerve

The fourth cranial nerve supplies the superior oblique muscle and is rarely involved by itself. It is associated with mild diplopia.

V. Trigeminal nerve

This nerve has a sensory portion, conveying sensation from the face and a motor root, supplying the muscles of mastication. There are three divisions of the sensory part of the nerve: the ophthalmic, the maxillary and the mandibular (Fig. 34.13). Large tumors in the cerebellar pontine angle may affect the trigeminal nerve. However, the commonest clinical manifestation of trigeminal nerve dysfunction is trigeminal neuralgia. This condition occurs predominantly in the middle aged and elderly, with a female predominance. It is characterised by severe, dagger-like pain within one or more divisions of the trigeminal nerve. Frequently the pain is triggered by any movement or stimulus to the face. It is becoming increasingly recognised that ectatic vascular loops may cause compression of the fifth nerve, producing these symptoms. Management of trigeminal neuralgia is, in the first instance, with carbamazepine. However, if this fails surgery may be considered to relieve vascular compression in the posterior fossa or to disrupt the trigeminal ganglion using percutaneous thermocoagulation.

VI. Abducent nerve

This nerve supplies the lateral rectus muscle and, when it occurs in isolation, results in diplopia due to the unopposed action of the medial rectus muscle. Because of its long intra-cranial course, the sixth nerve may be affected by fractures of the skull base or, alternatively, a supratentorial mass lesion may result in traction of the nerve as it passes over the petrous tip.

VII. Facial nerve

The seventh cranial nerve gives a motor supply to the muscles of facial expression and its sensory branch, the chorda tympani, carries taste from the anterior two-thirds of the tongue.

In clinical practice the motor supply is of most importance. Paralysis of the facial muscles may result from upper or lower motor neuron lesions. Because of bilateral cortical reprogramming of motor supply to the upper half of the face, upper motor neuron lesions, such as those caused by cerebrovascular events, will result in weakness of the face with preserva-tion of eye closure and forehead movement. In a lower motor neuron lesion, all muscles innervated by the facial nerve will be affected and this results in complete facial weakness with loss of resting tone and of facial expression (Fig. 34.14).

The causes of facial nerve damage include:

- cerebellar pontine angle lesions, such as an acoustic neuroma;
- Bell’s palsy, a mononeuritis may be related to viral infection;
- trauma to the nerve during surgery on the parotid gland.

Damage to the nerve in the face should be repaired as with other peripheral nerves. If damage or a defect occurs during the course of a cerebellar pontine angle operation, such as removal of an acoustic neuroma, then the facial nerve may be reconstituted using either a nerve graft or a piece of freeze—thawed skeletal muscle. When repair is not possible a nerve transfer of the hypoglossal to the facial nerve or cross face transfer may be carried out. Alternatively, plastic surgical procedures may be used to improve the resting state of the face.

VIII. Vestibulocochlear nerve

The eighth cranial nerve carries information from the vestibular apparatus and organ of Corn (hearing). The surgical significance of the eighth nerve is that it may be involved in fractures of the middle cranial fossa or be affected by tumors such as an acoustic neuroma.

IX. Glossopharyngeal nerve

The motor supply of the ninth cranial nerve is to the stylo-pharyngeus muscle, which cannot be tested clinically. There-fore, for the purposes of examination, the ninth cranial nerve carries sensation from the soft palate and the posterior third of the tongue. It mediates the sensory component to the gag reflex. It may be affected by fractures of the skull base or by pathology involving the lower cranial nerve roots as they
leave the brainstem.

**X. Vagus nerve**

This nerve has a small sensory supply to the ear canal, with motor innervation to the palate and vocal cords. Although the nerve may be affected throughout its course, damage to the recurrent laryngeal nerve, which may occur during a thyroid operation as a result of intraoperative traction, division or postoperative haematoma formation, is of particular note. A complete recurrent laryngeal nerve palsy results in paralysis of both abductors and adductors of the corresponding vocal cord, which therefore adopts a halfway position, the so-called cadaveric position. The opposite vocal cord can compensate, closing the glottis, but the range of the voice is impaired. Partial recurrent laryngeal nerve involvement has a predilection to the muscles of abduction leading to adduction of the vocal cord on the affected side. If this is bilateral, stridor can result, which rarely may require tracheostomy.

**XI. Accessory nerve**

This is the nerve to the sternocleidomastoid and trapezius. It may be damaged by base-of-skull fractures, but it is more commonly affected in its cervical course. It is particularly at risk during operations on the posterior triangle, for example biopsy of lymph nodes. Division of the nerve in the anterior triangle will produce paralysis of the sternocleidomastoid and trapezius muscles (Fig. 34.15). Damage in the posterior triangle will affect only the trapezius, resulting in a drooping shoulder with wasting of the trapezius and often a considerable amount of pain. If the injury is recognised early then direct repair or nerve grafting will usually allow some recovery.

**XII. Hypoglossal nerve**

This is the motor nerve to the tongue, and damage results in wasting, weakness and fasciculation on the affected side. On protrusion of the tongue, deviation occurs towards the side of the lesion. The twelfth nerve may be involved with intracranial pathology but is more often injured distally, particularly during operations such as those on the submandibular gland.

The scalp

There are five layers to the scalp: skin, dense connective tissue, galea aponeurotica, loose connective tissue and pen-cranium (Fig. 35.1). The scalp receives a rich vascular supply. This arises from both the external and internal carotid arteries with the vessels lying in the dense connective tissue layer. The anterior scalp is supplied by the supraorbital and supratrochlear arteries, and branches of the internal carotid via the ophthalmic artery. The lateral and posterior scalp is supplied by the superficial temporal, posterior auricular and occipital arteries, and branches of the external carotid. The sensory nerves run with the arteries and are derived from the trigeminal nerve at the front and sides. The posterior aspect is supplied by the greater and lesser occipital nerves with motor supply to the occipitofrontalis muscle by the facial nerve. Venous drainage of the face and anterior scalp is via the facial vein. The lateral and posterior aspects are drained by the external jugular vein and the vertebral venous plexus, respectively. The veins of the scalp and face communicate directly with the intracranial venous sinuses via emissary veins, hence infections in the nasal region have the potential to cause cavernous sinus thrombosis. Lymph drainage from the scalp is to the preauricular and occipital lymph nodes.

The walls of the vessels in the dense connective layer are bound, preventing ready retraction when divided. Wounds to the scalp therefore bleed copiously. When the underlying cranium is intact, it is a safe and simple measure to arrest haemorrhage by compression against bone until haemostasis is achieved by suturing the wound. In the presence of a penetrating wound to the scalp, it is mandatory to exclude a fracture radiologically. If no fracture is present, it is safe to explore the wound, so that foreign bodies and debris may be removed, the wound débrided and the scalp closed. This is done in layers with a resorbable suture to the galea and a nonabsorbable suture to the skin.

The scalp heals readily and therefore it is often possible for skin of questionable viability to be left in place without becoming necrotic. When a scalp wound results in loss of tissue the limiting factor to closure is often the inflexibility of the galea. By performing release incisions in the galea, a moderate-sized defect may be closed. However, when large areas of scalp are missing, more extensive rotational flaps are required. Skin grafts will only take on a layer of intact pericranium.

The loose areolar tissue under the galea aponeurotica is a dangerous zone for infections. Pus can spread freely in this layer and reach the intracranial sinuses through the emissary veins. Abscesses and haematomas under the pericranium are limited to the area of one bone because the pericranium is firmly adherent to the sutures between the skull bones. In infants, blood loss into this layer can often be underestimated leading to cardiovascular decompensation. Osteomyelitis of the skull is associated with a subperiosteal swelling and oedema of the scalp referred to as Port’s puffy tumour (Fig. 35.27). This is now a rare condition but because of the possibility of intracranial sepsis, should be aggressively investigated and treated.

Lesions that occur on the head may be identical to those occurring in the skin elsewhere (Fig. 35.2a and b). Therefore any mobile lesion occurring within the skin should be inspected, investigated and treated using the usual diagnostic criteria. However, when lesions occur in the midline or appear to be more deeply connected within the layers of the scalp, then it is mandatory that more extensive radiological investigations [ideally computerised tomography (CT) or magnetic resonance imaging (MRI)] be performed to exclude any intracranial extension.
The skull consists of several bones which are fused by means of sutures to form the cranium which encases the brain and from which the face hangs. The normal skull has a remarkable degree of symmetry about the midline. There is rapid growth of the skull during the first few years of life, a growth which is driven and shaped by the underlying developing brain and the development of the sphenoid bone. If the development of the brain is abnormal, then this can be reflected in the overall skull size. Therefore, macrocephaly may occur as a result of hydrocephalus (Fig. 35.3).

If premature closure of any of the cranial sutures occurs, this may result in loss of midline symmetry and associated developmental abnormalities of the face. The most common type of synostosis is that of the sagittal suture, which results in the characteristic keel-shaped head or scaphocephaly (Fig. 35.4 a—c).

Trigonocephaly is caused by premature fusion of the metopic suture (Fig. 35.5), whereas plagiocephaly will result from unilateral coronal or lambdoid synostosis. When more than one suture is involved in the synostotic process, this may result in elevation of the intracranial pressure. This may be as a result of not only restriction of calvarial growth but also obstruction to venous drainage at the base of the skull and respiratory problems. These are commonly associated with syndromic craniosynostosis, such as Crouzon’s and Apert’s syndrome. Surgery for craniosynostosis is undertaken in specialised units and because of the associated otolaryngological, dental and ophthalmological implications, the approach should be multidisciplinary. Surgery is directed towards increasing the volume of the skull, improving the cosmetic deformity and overcoming airway problems that may contribute to morbidity.

Congenital defects of the skull may occur at any point in the midline from the nasion to the foramen magnum as a result of incomplete fusion. Meningeal prolapses that occur with these defects may contain cerebral tissue and likewise be associated with a degree of derangement of the cerebral architecture, whereas those occurring more towards the occipital region characteristically have more severe anatomical problems with consequent mental and physical handicaps. Frontonasal encephaloceles are more common in Asiatic races and may be associated with a degree of hypertelorism. Smooth swellings seen in the roof of the mouth or in the nose in infants and dermal sinuses should be approached cautiously, as these might harbour underlying skull defects with herniation of the intracranial contents. Investigation with CT and often MRI is required to exclude intracranial communication. If this is confirmed, neurosurgical exploration may be required to prevent the risk of future ascending infection.

Bony turnouts are unusual and may present because of cosmetic deformity. The benign ivory osteoma may be either drilled down or simply excised with the defect being reconstituted by either a split cavarial graft from adjacent bone or filled with an acrylic cranioplasty. Primary malignant growths of the skull are exceedingly rare and more often these lesions are found to be secondary (Fig. 35.7). In childhood, however, lytic lesions within the skull may be as a result of histiocyotosis and therefore open biopsy with or without excision or curettage may be indicated.
Intracranial disorders

Pathophysiology of raised intracranial pressure

Introduction

The adult skull may be regarded as a rigid unyielding box containing brain, cerebrospinal fluid (CSF) and blood. At normal supine pressures of 5—15 mmHg (6—18 cmH2O), measured from the level of the foramen of Munroe, these three components maintain volumetric equilibrium. An increase in the volume of any one of the components will result in an increase in intracranial pressure (ICP) unless there is a proportionate decrease in the volume of one of the other components. These observations were first reported by Alexander Munro (Professor of Anatomy, Edinburgh, 1783) and 40 years later confirmed by Kellie — becoming known as the Munro—Kellie doctrine.

Owing to compensatory volumetric changes having physical and physiological limits, the ability to maintain a constant ICP can be exceeded by a change in volume that is too fast or too great. This intracranial pressure—volume relationship is illustrated in the curve (Fig. 35.6). Initially quite large increases in volume produce only small changes in pressure. During this phase the brain adapts by shifting CSF and moving blood from venous structures. A critical point is reached however when small changes in volume cause exponential increases in ICP.

The relationship of volume to pressure is described in terms of compliance or elastance of the intracranial space. Compliance is expressed as $\frac{dV}{dP}$ and is the amount of ‘give’ available within the intracranial compartment. Elastance is the inverse and is the resistance offered to the expansion of a mass or the brain itself. When patients initially present with symptoms of raised ICP it is invariably when brain compliance has been reduced and small volume changes have the potential to cause precipitous increases in ICP and a reduced level of consciousness.

Between physiological ranges of blood pressure, the brain is able to maintain a constant cerebral blood flow. This is achieved by a process called autoregulation (Fig. 35.9) whereby the brain adjusts the intracranial vascular resistance. With hypovolaemic shock, malignant hypertension, sub-arachnoid haemorrhage or diffuse severe head injuries, this ability is compromised and the cerebral perfusion pressure becomes virtually dependent on the mean arterial pressure.

Normal cerebral blood flow (CBF) is about 800 ml/min or 20% of the total cardiac output. The blood flow is a function of the cerebral perfusion pressure (CPP) and the cerebral vascular resistance (CVR).

$$\text{CBF} = \frac{\text{CPP}}{\text{CVR}}$$

The cerebral perfusion pressure is a function of the systemic mean arterial pressure (MAP) and the ICP.

$$\text{CPP} = \text{MAP} - \text{ICP}$$

As intracranial pressure increases, in order to maintain a constant CPP, there has to be a compensatory rise in the MAP. A hypertensive response is therefore elicited which classically is associated with a bradycardia. This is termed the Cushing reflex after the eminent American neurosurgeon.

Clinical features

These are largely determined by the underlying cause. How-ever, some of the clinical symptoms and signs will be the same:

- headache;
- nausea and vomiting;
- drowsiness;
- papilloedema.

These headaches are usually worse in the morning owing to vasodilatation caused by hypoventilation and consequent CO2 retention during sleep. They are typically progressive but relieved by an upright position and are frequently asso-ciated with nausea and vomiting. As the brain has no sensation they are caused by traction and distortion of the pain-sensitive blood vessels and dura. Compression of the reticular activating system in the brainstem results in drowsiness. In an infant, raised ICP will cause a tense bulging fontanelle.

As the eyes are extensions of the forebrain, the optic nerves carry with them the meningeal coverings. The ICP is thus transmitted directly to the optic nervehead via the CSF. This results in obstruction to axoplasmic flow in the retinal neurons causing swelling. This is seen on fundoscopy as blurring of the disc margins (Fig. 35.10), eventually retinal haemorrhages and if prolonged, optic atrophy. Traction on the abducent (sixth) nerves by caudal displacement of the brainstem may cause nerve palsies — the false localising sign.

Continuous monitoring of ICP reveals stereotyped varia-tions superimposed upon baseline fluctuations. ‘A’ waves are transient plateaux of increased pressure to greater than 50 mmHg which last for 5—10 minutes. They are abnormal and indicate low compliance within the intracranial cavity. Skull X-rays may demonstrate sutural separation in children, pronounced ‘copper-beating’ marking of the cranial vault and thinning of the dorsum sellae with erosion of the posterior clinoid processes.

Treatment

This should primarily be directed at removing the cause for the increased ICR. Intracranial volume can be mechanically decreased by removing an intracranial mass or haematoma, reducing intracranial venous blood volume by facilitating venous outflow via the jugular veins, ventilated to bring the carbon dioxide toxin (PCO2) down to 4—4.5 (avoiding vasoconstriction in patients with ischaemic disease) or by draining CSF through a ventriculostomy.

Steroids seem most effective in decreasing ICP resulting from vasogenic oedema associated with brain tumours or surgical manipulation (dexamethasone 4 mg 6 hourly). They work by stabilising the blood—brain barrier and reducing oxygen radical injury.

Mannitol, an osmotic dehydrating agent (1 g/kg 4—6 hourly), works by drawing water from parts of the brain with an intact blood—brain barrier. If this is disrupted as in a cerebral contusion, Mannitol can leach out into the brain and potentiate the mass effect. In head injuries it should therefore only be administered after consultation with a neurosurgeon. It becomes ineffective when brain osmolarity becomes...
iso-osmolar with that of the serum.

Barbiturates given as a bolus (thiopentone 3—5 mg/kg) can reduce ICP, although the exact mechanism remains obscure. Subsequent doses are titrated to give a level of 2.5—3.5 mg per cent. Infusions to control burst suppression on electro-encephalogram (EEG) have been postulated to diminish ICP by reducing cerebral metabolism. The initial response is due to vasoconstriction but it is possible to reduce CPP by causing hypotension.

Furosemide reduces ICP by reducing cerebral oedema and CSF production. It may act synergistically with mannitol. Hypothermia down to 34°C is currently undergoing assessment as a brain protection agent.

Although no randomised clinical study has ever been performed conclusively proving the value of ICP monitoring in reducing morbidity following brain injury, there is a clear relationship between raised pressure and morbidity and mortality. The vital physiological parameter in severely head-injured patients is the CPP. This is a function of the mean arterial blood pressure and the ICP and, to optimise outcome, should be maintained above 65 mmHg. This requires a close working relationship between the intensivist and the neurosurgeon.
Head injury

It has been estimated that in the UK, between 200 and 300 per 100,000 of the population are admitted to hospital each year with a head injury, making it one of the most common causes for attending accident and emergency departments. Trauma, in which severe head injury often plays a major role, is also the leading cause of death in the population below 45 years of age. Cranio-cerebral trauma is consequently a source of major disability and a huge financial and psychological burden upon society.

Despite being encased in a rigid protective skull and cushioned by CSF, the brain is still very vulnerable to trauma, having only the consistency of a well-set jelly. This trauma can take the form of translational acceleration/deceleration forces, rotational forces or direct local sharp penetrating or blunt trauma to the cranium and can involve the scalp, skull or brain, in any combination.

Scalp

Scalp lacerations are common and can give rise to exanguinating haemorrhage if not controlled. This is due to the vessels in the dense fibrous layer being held open. Scalp hair plays an important protective role and by matting into wounds can effectively assist haemostasis but likewise mask significant scalp lacerations. The scalp’s rich vascular supply plays an important role in healing, making it a very resilient structure.

Skull

Different types of skull injury may follow blunt trauma.

Simple linear fractures

These require no specific neurosurgical management but are usually markers of the force to which the head was subjected. Patients are usually CT scanned but should also be admitted for at least 48 hours’ observation.

Depressed skull fracture

These fractures are a result of blunt trauma, usually to the left-frontal region. If the pericranium has been breached the fractures are technically compound. The integrity of the dura is however more important. The dura and brain may be lacerated by the depressed fragment.

The damage done at the time of impact with subsequent risk of epilepsy is irreversible. Surgery is usually undertaken to prevent the risk of infection, to alleviate mass effect and for cosmetic purposes. Contaminated wounds require extensive debridement, a duraplasty and irrigation before closure. A full course of intravenous antibiotics should be administered.

Base of skull fracture

These are relatively frequent fractures, usually diagnosed on clinical grounds. They often result in CSF fistula which may persist but usually seal off after a few days. Anterior fossa fractures present with subconjunctival haematoma, anosmia, epistaxis and CSF rhinorrhoea and may occasionally be associated with carotidocavernous fistulae (Fig. 35.11). Periorbital haematomas or ‘raccoon eyes’ indicate subgaleal haemorrhage and not necessarily base of skull fracturing as do subconjunctival haemorrhages extending beyond the conjunctival reflections (Fig. 35.12). Middle fossa fractures present with CSF otorrhoea or rhinorrhoea via the eustachian tube, haemotympanum, ossicular disruption, ‘battle sign’ (Fig. 35.13) or VII and VIII cranial nerve palsies.

There is no evidence that prophylactic antibiotics diminish the incidence of meningitis. Administering them may just select out more virulent organisms in those that become infected, increasing morbidity and mortality. If one suspects a CSF fistula, the fluid should be screened for beta-transferrin to confirm that it is in fact CSF. Before repair of CSF fistula, it is mandatory to exclude the presence of hydrocephalus. The dura should then be sealed with autologous, vascularised grafts and fibrin glue after cranialisation of the frontal sinuses.

Ping-pong fracture

This is a smooth depression of the cranial vault usually seen in children. Also known as a ‘pond’ fracture.

Blow-out fracture

These are caused by fracturing of the orbital walls with herniation of orbital contents and subsequent tethering of the globe, resulting in pain and diplopia.
Brain injury

For both treatment and medicolegal purposes, it is important to have an understanding of the mechanisms as to how brain injuries evolve. Abrupt deceleration of a moving head is characterised by a relatively minor injury at the site of impact (coup injury) and an extensive contusion of the brain opposite the point of impact [contre-coup injury] (French-“counter-blow”). Contusions are most likely along the undersurface of the frontal lobes, the tips of the temporal lobes and along the falx.

Abrupt acceleration of an unsupported head occurs when the head is struck by a moving object. The skull accelerates against the brain causing an extensive coup injury of the brain. The remainder of the brain may remain unchanged. When a well-supported head is struck by a moving object, there is little movement of the skull and brain. Most of the force is absorbed by the skull, which will fracture. Damage to the underlying brain results from direct perforation or laceration by skull fragments.

It is thus easy to understand why most cerebral contusions occur without skull fracture and why patients with spectac-ular fractures are often awake with only minor neurological dysfunction.

Primary brain injury is caused at the time of impact and is irreversible (Fig. 35.14). Secondary brain injury develops subsequent to the impact damage (Table 35.1). The management of head injuries focuses on reducing secondary injuries.

Primary brain injury

Cerebral concussion

This is a clinical diagnosis and is manifested by temporary dysfunction that is most severe immediately after injury and resolves after a variable period. It may be accompanied by autonomic abnormalities including bradycardia, hypotension and sweating. Loss of consciousness often, but not invariably, accompanies concussion. Amnesia for the event is common and varying degrees of temporary lethargy, irritability and memory dysfunction are hallmarks.

Postconcussion syndrome can accompany head trauma and consists of headaches, irritability, depression, lassitude and vertigo. It is more frequent after minor head trauma due to people trying to return to work too quickly.

Cerebral contusion and laceration

This can be demonstrated by CT as small areas of haemorrhage in the cerebral parenchyma. They usually produce neurological deficits that persist for longer than 24 hours. Contusions may resolve together with the accompanying deficit or they may persist. Blood—brain barrier defects and cerebral oedema are common and these lesions enlarge or coalesce with time.

Even without a skull fracture, if sufficient force is delivered to the skull the brain might become lacerated as a result of rapid movement and shearing of brain tissue. The pia and arachnoid may be torn and intracerebral haemorrhage may accompany this lesion. Focal deficits are the rule.

Diffuse axonal head injury

This type of brain damage occurs as a result of mechanical shearing following deceleration, causing disruption and tearing of axons, especially at the grey/white matter interface. Severity can vary from mild confusion to coma and even death. Macroscopically, punctate haemorrhages are visible, especially in the corpus callosum and superior cerebellar peduncle. Microscopically, retraction balls reflecting axonal damage and microglial clusters (hypertrophied microglia) are found diffusely in the white matter.

Secondary brain damage

Intracerebral haematoma

Intracerebral haematoma. These appear as hyperdense lesions on CT with associated mass effect and midline shift. They are due to areas of contusion coalescing into a contusional haematoma. They may appear to have a mixed density.

Extradural haematoma occurs usually as a result of squa-mous temporal bone fractures with laceration of the middle meningeal artery. They can also arise from fractured bone edges or rarely from the dural venous sinuses. The potential space between the dura and bone is developed by the expand-ing haematoma allowing it to take on the familiar convex configuration due to the adherence of the dura to the inside of the calvarium (Fig. 35.15). The degree of trauma might not be severe and there is typically a lucid interval following the trauma. Frequently, patients present in coma and require urgent evacuation via a burr hole prior to formal craniotomy (Fig. 35.16). Patients do well if delay is minimised.

Subdural haematoma. They are the most common intracranial mass lesions resulting from head injury. Most result from torn bridging veins draining blood from the cortex to the dura. They can also arise from cortical lacerations or bleeding from the dural venous sinuses. They are usually associated with more severe, high-velocity trauma with a poorer outcome, usually in older patients. The blood follows the subdural space over the convexity of the brain and appears as a concave hyperdense lesion. Acute subdural haematomas are more rapidly evolving lesions and early evacuation is mandatory (Fig. 35.17).

Chronic subdural haematoma. These haematomas are most common in infants and in adults over 60 years of age. They present with progressive neurological deficits more than 2 weeks after the trauma. Often the initial head injury has been completely forgotten and the pathology has been attributed to either dementia or a brain tumour until patients are scanned (Fig. 35.18). The initial haematoma may be relatively small or may occur in elderly patients with large ventricles or a dilated subarachnoid space. Membranes deriving from the dura and arachnoid mater encapsulate the haematoma which remains clotted for 2—3 weeks then liquefies. The acute clotted blood initially appears white on a CT scan. As it liquefies it slowly becomes black. There is therefore a point in time where it appears isodense with brain and all that can be seen is apparent inexplicable midline shift on an otherwise normal CT. These collections can be removed by drilling burr holes and washing them out with warmed saline.

Cerebral swelling

This results from vascular engorgement, probably due to a loss of autoregulation and an increase in extracellular and intracellular fluid. The exact causative mechanisms are unclear.
**Cerebral ischaemia**

This is common after severe head trauma and is caused by a combination of either hypoxia or impaired cerebral perfusion. The brain is unable to autoregulate its blood supply with a decrease in blood pressure. Glutamate excess and free radical accumulation lead to neuronal damage.

**Infection**

Compound depressed fractures or base of skull fractures can lead to either meningitis or cerebral abscess.

**Epilepsy**

Seizures can increase brain metabolism and blood flow, thereby increasing ICR. Prophylactic anticonvulsants given acutely for the first 2 weeks are said to be of benefit. No benefit from long-term treatment has been demonstrated.

**Management**

Initial assessment of head injuries must follow Advanced Trauma and Life Support (ALIS®) guidelines with an initial primary survey, then resuscitation, followed by a secondary survey then definitive management or, more simply: airway, breathing, circulation, disability and exposure. Securing an adequate airway preventing obstructive breathing or hypoventilation is critical in unconscious head-injured patients, as is maintaining a decent blood pressure. Care must be taken to secure the neck and spine. When an intracranial haematoma is suspected, an early CT scan is essential.

In the assessment of a head injury points to determine from the history are:

- period of loss of consciousness;
- period of post-traumatic amnesia;
- cause and circumstances of the injury;
- presence of headache and vomiting.

The patient should be examined for evidence of injury (e.g. lacerations and grazes) and the findings clearly documented. Base of skull fracturing should be excluded and the conscious level determined on the Glasgow Coma Scale and monitored (Table 35.2). The pupillary response should be elicited to determine whether there is incipient transtentorial herniation with oculomotor palsy, limb movements and responses recorded.

Once any intracranial haematoma has been evacuated patients should then be admitted to an intensive care unit and ventilated to a PCO$_2$ of 4—4.5 kPa. A central line, arterial line and a urinary catheter should be inserted. The head of the bed should be positioned 40° up and the patient given analgesia (fentanyl), sedated using propofol or midazolam and paralysed (atracurium). Intravenous fluids administered should be isotonic until nasogastric feeding can be commenced. An ICP monitor (Codman or Camino) should be inserted intraparenchymally and the ICP and CPP monitored. Ideally the ICP should be maintained below 25 mmHg and the CPP above 70 mmHg. If necessary, ionotropes can be used to support the blood pressure and CPP.

Dexamethasone has no benefit. Diuretics such as mannitol and frusemide can be used to lower ICP further but the former must be used with caution in patients with large areas of blood—brain barrier breakdown for fear of potentiating the mass effect. If ICP cannot be controlled by these means alone then steps such as introducing EEG burst suppression therapy with a barbiturate (thiopentone), ventricular or lumbar CSF drainage or polar lobectomies have to be considered.

Repeat CT scan should be considered if there is a delayed deterioration in the mental state, a maintained rise in intracranial pressure or a failure to improve over 24 hours.
Hydrocephalus

Hydrocephalus is defined as a disproportionate increase in the amount of CSF within the cranium, usually in association with a rise in ICP.

Physiology and circulation of cerebrospinal fluid

The normal volume of circulating CSF is in the region of 140 ml. The fluid both protects and supports the brain and spinal cord, as well as maintaining homeostasis by acting as a transport medium for transmitters and as a method of removing the end products of metabolism. CSF is produced by an active process, 80 per cent of it being derived from the choroid plexus and the rest from the parenchyma. The rate of production is between 0.2 and 0.4 ml/minute, with a daily production rate of approximately 480 ml. This means that the turnover of CSF is approximately three times daily. Production of CSF is regulated, not only by the homeostatic environment, but also neurogenically and in response to alterations in CSF pressure. Resorption of CSF is almost entirely pressure dependent as a result of a hydrostatic gradient existing between the CSF in the subarachnoid space and the arachnoid villi, the point of reabsorption of the CSF into the venous system. There is also some absorption of CSF via the sleeves of the nerve roots.

Most fluid is produced in the lateral ventricles. Normal flow is then down through the foramina of Monro into the third ventricle and subsequently the aqueduct of Sylvius into the fourth ventricle, to pass laterally and inferiorly out of the fourth ventricle via the foramina of Luschka and Magendie, to circulate over the surface of the cortex for reabsorption at the arachnoid villi (Fig. 35.19).

Hydrocephalus means an imbalance between the ratio of the CSF to cerebral tissue within the cranium. The first condition to be excluded immediately from a physiological point of view is hydrocephalus ex vacuo. This occurs when the ratio is altered as a result of atrophy of the cerebrum with an increase in CSF, purely as a compensatory mechanism. This condition does not have treatment implications, other than being part of the differential diagnosis in a patient with suspected hydrocephalus (Fig. 35.20).

Aetiology

In those patients with the pathophysiological condition of hydrocephalus, an imbalance has occurred between the normal physiological production of CSF and its absorption. This imbalance can be as a result of overproduction of CSF or impaired absorption. Conditions in which CSF is overproduced are uncommon. Typically the choroid plexus papilloma is cited as the most common cause of overproduction and, in most cases, there is no doubt that this does occur. However, in these cases there are compounding problems, such as obstruction of CSF flow, haemorrhage and change in the protein level of the CSF, which may exacerbate the hydrocephalus. As regards conditions where CSF resorption is impaired, there is a rare congenital condition wherein there is a congenital absence of the arachnoid villi. Failure of absorption is usually as a result of alterations in the hydrostatic gradient responsible for CSF absorption or failure of the CSF to circulate adequately to allow absorption to take place.

There is a further concept of obstructive or communicating hydrocephalus. Obstructive hydrocephalus is seen where the normal pathways of CSF flow are for some reason occluded. This may be as a result of conditions such as aqueduct stenosis or as a result of local compression from a tumour. In communicating hydrocephalus no obvious obstruction to CSF flow can be observed and all of the ventricles appear to be communicating freely. In fact, these so-called cases of communicating hydrocephalus usually do have some obstructive element underlying them, the level usually being in the basal system, the subarachnoid space or at the arachnoid villi.

Hydrocephalus may be congenital and occur in conjunction with other abnormalities of the central nervous system, such as spina bifida, as a result of congenital aqueduct stenosis or as a result of intrauterine infections. Hydrocephalus acquired postnataally is commonly secondary either to intraventricular and intraparenchymal haemorrhage or to meningitis.

Clinical features

The presenting signs and symptoms related to hydrocephalus are very much dependent upon the age of the patient at presentation. In the neonatal period an increasing head circumference, tense fontanelle and failure to thrive may be the only initial signs, although feeding problems and ‘sunsetting’ (early down-turning of the eyes) associated with bradycardias may become apparent in the extreme cases (Fig. 35.21).

In older children and adults, hydrocephalus may be manifest principally by gradual development of symptoms of raised ICP, so that headache, nausea and vomiting occur, ultimately followed by a deterioration in the level of consciousness. There may also be associated ataxia and visual disturbance. With increasing age, hydrocephalus secondary to tumours becomes increasingly common and therefore in the older age group the symptoms of hydrocephalus may be combined with those symptoms attributable to the neoplasm itself.

Investigation

Records of the head circumference and its comparison with body weight and length are an integral part of the postnatal follow-up of any child. While this is an essentially somewhat crude method of determining the onset of hydrocephalus, it is nonetheless an easy and noninvasive sequential investigation with an excellent rate of diagnosis. On clinical examination, disproportion of the head to the rest of the body may immediately be evident and palpation of the head will reveal a tense fontanelle and separation of the sutures. Percussion of the head may produce the so-called ‘crack-pot sign’, while in severe cases it may be possible to transilluminate the head.

In older children and adults, the effects of chronic raised intracranial pressure may be evident on a skull radiograph with separation of the sutures and ‘copper beating’ of the skull, as well as erosion of the pituitary fossa (Fig. 35.22).

When the anterior fontanelle is patent it is possible to carry out ultrasonography to visualise the ventricular system, and this is also the way in which hydrocephalus is picked up antenatally. In older or younger children where further information is required, CT may be performed to aid in diagnosis. If a tumour is suspected then both enhanced and unenhanced tomography should be performed. The use of MRI to follow patients with hydrocephalus is attractive as no radiation dose is involved. However, accessibility, cost and time preclude this from being a routine investigation. MRI may be required when a tumour is seen to determine the surgical strategy, and when aqueduct stenosis occurs, to rule out a tectal plate tumour.

Management

Medical

Treatment of hydrocephalus is primarily directed towards methods of reducing CSF production. This can be achieved by using acetazolamide, which is a carbonic anhydrase inhibitor and may reduce CSF production by as much as 60 per cent. Frusemide also
has an effect on CSF production and both drugs, therefore, may be used in the short term. In the long term the effect of these medications appears to be relatively limited and therefore surgical intervention is required.

**Surgical**

Where an obstruction to the flow of CSF is present, removal of that obstruction, particularly if it is neoplastic in origin, should be the primary goal of surgery. In most patients with obstructive hydrocephalus secondary to tumours, removal of the tumour will result in resolution of the hydrocephalus.

In others with long-standing hydrocephalus and the chronic changes as a result of this, long-term CSF diversion will be required. Surgical management of the hydrocephalus may be directed towards reducing CSF production, bypassing a blockage to normal CSF flow drainage of CSF externally or finally drainage of CSF in another absorptive viscus. While obliteration of the choroid plexus was first described by Dandy it has failed for several reasons to act as a cure for hydrocephalus. First, the surgical procedure is directed towards the choroid plexus at the lateral ventricles and, as described above, 20 per cent of the CSF is produced by the nonchoroidal surface of the ventricles. Ablation of the intra-ventricular choroid plexus possibly has a role in the reduction in incidence of shunt obstructions. Bypassing obstruction to CSF flow may be achieved by a variety of means, such as cannulation of the aqueduct of Sylvius or third ventriculostomy, which may be performed endoscopically or at open operation. The first described bypass technique was that described by Torkildsen, where aqueduct stenosis was overcome by passing a catheter from the lateral ventricle into the cisterna magna, thereby reconstituting the normal circulatory pathway. External drainage of CSF may help in the temporary management of acute hydrocephalus but the risk of infection precludes this as a means of long term management.

The final and most common form of surgical management of hydrocephalus is by an internal diversion. Methods of CSF diversion were first tried in the nineteenth century when attempts were made to divert the CSF by the use of silver wires into the lumbar vertebral bodies. The modern era of internal CSF diversion began in the 1950s when implantable devices with regulatory valves were developed (Fig. 35.23). The proximal site of CSF diversion is usually the lateral ventricle and, while many distal sites have been attempted, the current favoured distal site of CSF absorption is the peritoneum. Two main complications can occur following shunt insertion. The first is infection and the second is shunt malfunction. Infection occurs in about 5 per cent of adult cases and approximately 10 per cent of paediatric cases depending on age mix, as the rate of infection in neonates is much higher than that in older children. Manifestations of infection usually become apparent within the first few weeks or months following implantation, and treatment of choice is to remove the infected system and treat the patient with intrathecal and intravenous antibiotics. Because infection is often with low-grade organisms, infection may take some time to diagnose. It is for this reason that the previously favoured distal shunting site at the right atrium was abandoned, as chronic bacteremia was associated with the development of immune complexes leading to renal and pulmonary damage.

Shunt obstruction may occur at any time following shunt insertion and may be due to either ventricular catheter obstruction, valve malfunction or a distal obstruction at the peritoneal catheter. Regrettably, no ideal valve mechanism for CSF diversion has been developed and together with occlusion of the system, the system may also malfunction by overdraining. This is a result of the siphoning effect of the catheter into the peritoneal cavity and can lead to symptoms of headache as a result of the low intracranial pressure and the appearances on tomography of small, slitlike ventricles.
Intracranial infection
Infections involving the central nervous system (CNS) pre-sent in a variety of ways and unless diagnosed and treated promptly can result in serious morbidity and mortality. Intracranial infections encountered in neurosurgical practice include bacterial meningitis, brain abscess and subdural empyema.

Meningitis
Bacterial meningitis, although potentially a life-threatening infection, seldom requires neurosurgical intervention. Treatment involves confirming the diagnosis and identifying the organism by obtaining a CSF sample, usually via lumbar puncture (LP). Broad-spectrum intravenous (i.v.) antibiotics with good CSF penetration should then be commenced without delay (ceftriaxone 2 g 12 hourly and metronidazole 400 mg 8 hourly) and adjusted as cultures and sensitivities become available. In situations where lumbar puncture is deemed impossible or unsafe, unless CSF can be obtained by other means, treatment might have to be empirical. Studies have demonstrated that steroids, commenced early and in combination with antibiotics, can improve outcome by reducing oxygen free radical attack on the brain. Complications are more likely to occur if treatment is not commenced early and may require neurosurgical intervention. The major complications are: cerebral oedema, seizures, hydrocephalus (communicating), subdural effusion, subdural empyema, brain abscess and ventriculitis.

Brain abscess
The treatment of brain abscess has been revolutionised by the availability of CT scanning, metronidazole and stereotaxis. Prior to these modalities, the mortality for brain abscesses ranged between 15 and 40 per cent. Pyogenic inflammation of the brain leading to cerebral abscess may result from haematogenous spread from a known septic site or occult focus (particularly in patients with right to left cardiac shunts) (Fig. 35.24); contiguous spread from an adjacent infected sinus presumably via retrograde thrombophlebitis; and direct inoculation from trauma. In 20 per cent of patients no cause can be identified (Fig. 35.25, Fig. 35.26—Fig. 35.27).

The organisms most commonly responsible vary depend-ing on the aetiology. With otitis media anaerobic strepto-cocci, *Haemophilus* and Gram-negative anaerobes are involved; with sinusitis *Streptococcus milleri* and *Staphylococcus*; with traumatic inoculation *Staphylococcus*; and with haematogenous spread various organisms are involved

Clinical features
Patients can present with either features of raised pressure, seizures, meningeal irritation or focal signs, each of which occurs in 50 per cent of patients. Systemic features of infec-tion including pyrexia are frequently absent but the history is usually short with rapid clinical progression. Diagnosis is confirmed by demonstrating a single or multiple low attenuation and smooth, symmetric, ring-enhancing mass lesions with variable oedema on CT. MRI with enhancement will demonstrate similar findings including high signal on 12-weighted images from the surrounding oedema. These lesions arise in an area of cerebritis and can often be multiloculated. Opacification of the sinuses or mastoids can be recognised on both CT and skull X-ray (SxR). Infection markers will demonstrate a leucocytosis and a raised erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), but may initially be normal.

Treatment
The principles of treatment are to identify the bacterial organism, institute intravenous antibiotic therapy (see above), drain or excise the abscess, and aggressively pursue and treat the cause. During the stage of acute cerebritis, prior to abscess formation, surgical treatment is seldom indicated. Steroids reduce oedema around these lesions and are thus invaluable in reducing intracranial pressure but can inhibit formation of the abscess capsule.

Unless very small, intracranial abscesses require surgical management. This is performed by either aspiration through a burr hole, with or without stereotaxis (repeated as neces-sary) or formal excision. The latter is undertaken if there is persistent reaccumulation of pus despite serial aspirations. Excision may also be considered if the abscess is superficial and easily accessible, and if there is a well-formed capsule which fails to collapse despite repeated aspirations. Patients should have regular follow-up CT scans with contrast until the abscess stops reaccumulating. Anticonvulsant therapy is routinely instituted.

Subdural empyemas
Subdural empyemas, although uncommon, may develop from sinusitis or mastoiditis. The infective agent is frequent-ly *S. milleri*, although other anaerobic or aerobic streptococci, other anaerobes and *Staphylococcus aureus* may also be responsible. These patients are systemically unwell with rapidly progressive neurological signs, a depressed level of consciousness and hemi paresis. Epilepsy occurs in most patients and can often progress to status epilepticus.

Despite this being a surgical emergency, diagnosis is often delayed as the collection on CT scanning is usually subtle to the untrained eye and frequently missed. Treatment is as for an intracranial abscess but the collection requires a formal craniotomy for drainage with exploration of the interhemispheric fissure. The combination of fever and seizures with a background of sinusitus is usually diagnostic of this lesion. Complications include refractory status epileptics and cortical vein/venous sinus thrombosis.

Human immunodeficiency virus (HIV) infection

Surgical management
The neurological complications of HIV infection have impli-cations for both surgeon and patient. Although transmission of HIV from patients to healthcare workers is extremely rare, the surgeon is at risk from needle stick injury and thus extra care should be taken when dealing with a population at risk. In the acquired immunodeficiency syndrome (AIDS), single or multiple lesions within the brain may develop and patients may present with focal neurological signs, symptoms of raised intracranial pressure or seizures. In the early days of AIDS management, stereotactic biopsies of these lesions were routinely carried out. However, in view of the high proportion of infective lesions, particularly toxoplasmosis, it has now become routine to treat the patient first with a full course of antitoxoplasma treatment. Should this fail or the patient’s clinical condition deteriorate, or both, then a stereotactic biopsy should be considered. The differential diagnosis is then between infection with an organism thus far not covered with the therapy given, or tumour, principally lymphomas, or the condition of progressive multifocal leukoencephalopathy (CML). The current clinical course is one of rapid and relentless deterioration and, indeed, when a stereotactic biopsy is required for diagnostic purposes in AIDS, then the overall prognosis is poor. However, biopsy and histological diagnosis allow patients, their partners and families to be counselled as regards prognosis. Furthermore, a histological diagnosis also allows a prospective study of new therapies for AIDS which, it is hoped, will lead to improved long-term prognosis.
Intracranial tumours

Introduction

Although either benign or malignant, almost all brain tumours are malignant in the sense that they may lead eventually to death if not treated. Brain tumours are responsible for 2 per cent of all cancer deaths. The annual incidence of newly diagnosed brain tumours in the USA is approximately 18 per 100 000 persons of which 30 per cent are primary. At autopsy the prevalence is 1—2 per cent. The incidence varies with age. In children tumours of the CNS comprise 20 per cent of all childhood malignancies. There is a peak at 2 years followed by a decline for the rest of the first decade. The incidence then slowly increases, peaking at 20 per 100 000 in late adulthood. The mortality rate averages 5 per 100 000. The classification of brain tumours is determined by their cell of origin. Over 50 per cent are neuroepithelial in origin, 15 per cent metastatic, 15 per cent meningiomas and 8 per cent pituitary tumours. The World Health Organization (WHO) classification is outlined in Table 35.3.

Aetiology

The aetiology of brain tumours is still not clearly understood. Although there is no genetic predisposition, chromosome abnormalities have been noted in many CNS tumours (e.g. von Recklinghausen’s). Some chemicals show carcinogenic activity in animals producing CNS tumours. Immunosuppression can markedly increase the incidence of primary CNS lymphoma. The current molecular understanding of oncogenesis involves both the addition of oncogenes to the genome and the loss of normally occurring tumour suppressor genes. Mutation in the p53 tumour suppressor gene is the most common gene alteration and found in both astrocytomas and meningiomas.

Clinical features

The clinical presentation of intracranial neoplasms will be as a result of one or a combination of raised ICP focal neurological signs, organic mental changes and seizures.

The ability of the intracranial contents to adapt to an increase in volume is limited and ultimately an increase in pressure will occur. This will manifest itself initially as a result of headache due to stretching of the dura. In the initial phase this headache is characteristically worse first thing in the morning and progressive. Nausea and vomiting may occur, followed by disturbance of vision as a result of papilloedema. Finally, a deterioration will occur in the level of consciousness as a serious and late consequence of raised ICP (Fig. 35.29).

Late-onset epilepsy, particularly over the age of 30, should prompt investigations to exclude an intracranial neoplasm.

Forty per cent of patients with supratentorial glial tumours will have experienced a seizure by the time they come to surgery. Benign tumours may also be an underlying cause of long-standing epilepsy and may render the seizures surgically remediable. Focal neurological signs associated with intra-cranial neoplasms are related to the area of cortex involved. Contralateral signs are associated with lesions in the posterior frontal area (motor) or anterior parietal (sensory) lobe. Tumours in the dominant hemisphere may cause problems with language (aphasia) and in the nondominant hemisphere apraxia. The optic pathway may be involved producing various visual symptoms, usually a contralateral homonymous hemianopia. Temporal lobe lesions frequently cause focal seizures with auras and visual field defects. Tumours in the frontal lobes can grow to considerable sizes before producing altered cognitive functioning and subtle personality changes. Subfrontal lesions may involve the olfactory nerves (anosmia). Sellar and parasellar tumours present with visual field and acuity problems due to compression of the optic chiasm. Tumours in relation to the ventricular system may obstruct CSF drainage and result in hydrocephalus, compounding raised ICR. Tumours of the brainstem and cerebellar—pontine angle may result in cranial nerve palsies and long tract signs. Tumours involving the cerebellar vermis cause ataxia, while tumours in the hemispheres produce appendicular signs such as inco-ordination and nystagmus.

Gliomas

Gliomas account for 50 pet cent of adult intracranial tumours and ate usually supratentorial. They are of neuro-ectodermal origin arising from glial cells of which there are four types: astrocytes, oligodendrogloma, ependymal cells and neuroglial precursors. The most frequent is the astrocytoma. They rarely metastasise (except for medulloblastoma and ependymoma) and spread along axonal pathways. Grading is on the basis of histological features, namely the presence of mitoses, necrosis, endothelial proliferation and nuclear atypia. Low-grade tumours have long median survival whereas high-grade tumours (glioblastoma multiforme) have a 20 per cent 2-year survival (Fig. 35.29).

CT scanning before and after contrast is able to locate and confirm the diagnosis in the majority of cases. The enhancement is often irregular around a centre of low density which may represent necrosis. Calcification may be pre-sent. MRI is more accurate in defining low-grade lesions. Tissue definition and anatomical localisation of lesions in and adjacent to eloquent areas ate also superior, facilitating surgical planning and resection (Fig. 35.30).

The aim of treatment is to obtain a pathological diagnosis and grading and to debulk the tumour, both to alleviate symptoms of raised pressure and as a precursor to adjuvant treatments. This usually involves a combination of surgery and radiotherapy and will depend on the size and location of the tumour, as well as the patient’s clinical state and age. Patients are started on dexamethasone in order to diminish cerebral oedema prior to surgery. Spread along axons makes total resection impossible unless the lesion is low grade, small and polar.

Radiotherapy is usually as an external beam (50—60 Gy fractionated over 30 days), stereotactic focal irradiation using a gamma knife or linear accelerator or brachytherapy (implantation of a radioactive source). Chemotherapy has little role for lesions other than oligodendrogliomas. Photodynamic therapy, immunotherapy and gene therapy are all currently undergoing clinical trials to determine advantages over conventional treatment. In view of the poor prognosis with high-grade lesions, conservative treatment is often appropriate for selected patients.

Metastatic tumours

Metastatic tumours comprise 15 per cent of intracranial tumours. Approximately 30 per cent of deaths are due to cancer and up to 25 per cent of these have intracranial metastatic deposits at autopsy. The common sites of origin are illustrated in Table 35.4. In 15 per cent a primary source is never found. Up to 60 per cent are multiple, with 85 per cent situated above the tentorium. The interval between diagnosis of a primary and cerebral metastasis varies considerably. Melanoma and renal carcinoma may present with haemorrhage.

Metastatic tumours appear isodense on unenhanced CT but enhance vividly after intravenous contrast. Melanoma may appear hyperdense prior to contrast. MRI will frequently reveal lesions not visible on CT. A chest radiograph is essential to exclude a source or other metastatic deposits. Steroids should be commenced to reduce peritumour oedema and if surgery is planned an anticongululant (phenytoin 300 mg nocte) started. Surgery is appropriate if there is a solitary surgically accessible lesion and no systemic spread, particularly if the primary site is unknown and the histological diagnosis in doubt. This may take the form of either resection or biopsy. Stereotactic or image-guided techniques are often employed. Radiotherapy is used to treat multiple metastases and following resection. Mote recently focused stereotactic radiosurgery is being used in the treatment of metastases smaller than 2 cm with results comparable to surgery. About 30—50 per cent of patients will
survive a year following resection.

Meningiomas

These account for 15 per cent of intracranial neoplasms and are the most common benign neoplasms. They are uncommon in children, occur more frequently in women than men and their incidence peaks in middle age. They originate from meningothelial cells that occur in the greatest abundance in the arachnoid villi, correlating with their site of occurrence. They are most commonly found along the superior sagittal sinus (patasagittal), over the free convexity and falx, along the sphenoid wing, beneath the frontal lobes (olfactory groove and tuberculum sellae), within the posterior fossa (cerebello-pontine angle and foramen magnum), the optic nerve and in the ventricles. They classically arise from a broad base along the dura, may invade bone, and derive their blood supply from the external carotid circulation (Fig. 35.31).

There is a spectrum of histological appearances but malignant meningiomas are relatively rare. Surgical treatment should be, wherever possible, total excision. If this includes the site of dural attachment, the recurrence rate is less than 10 per cent. Incomplete excision of the dural attachment will result in a recurrence rate of between 20 and 30 per cent. Subtotal excision will result in 40 per cent showing progressive growth. The role of radiotherapy is controversial and is usually reserved for tumours with aggressive histological features or recurrent tumours, or where a subtotal resection has been performed.

Nerve sheath tumours

These benign tumours originate from Schwann cells and have a predilection for sensory nerves, especially the eighth nerve (e.g. acoustic neuroma), followed much less frequently by the fifth nerve. Schwannomas of the eighth nerve arise from the superior or inferior vestibular portion in the internal auditory canal. As the tumour grows, it expands the internal auditory canal and extends into the cerebellopontine angle, compressing the pons, cerebellum and cranial nerves (Fig. 35.32). Bilateral Schwannomas of the eighth cranial nerves are diagnostic of type 2 neurofibromatosis. However, the majority of patients harbouring acoustic Schwannomas has no stigmas of this disease. Surgical intervention is aimed at total excision with preservation of neurological function. Patients frequently sustain seventh nerve palsies. More recently 'gamma knife' radiosurgery has been used effectively in the treatment of those tumours with a diameter of less than 30 mm.
Pituitary tumours

Introduction

Pituitary tumours account for 8 per cent of all intracranial tumours. Historically they were classified according to their staining characteristics seen on light microscopy. However, the three types (chromophobe, acidophilic and basophilic) did not correspond closely with the clinical syndromes of pituitary hypersecretion. The subsequent development of immunological staining techniques and electron microscopy provided a more refined classification of pituitary tumours. It is now correct to classify pituitary tumours according to their size (microadenomas, mesoadenomas and macroadenomas) and whether they are endocrine active or inactive (Table 35.5). These features will also determine their presentation.

Clinical features

Pituitary tumours arise in the sella tercica and can expand up into the suprasellar cisterns, compressing the optic chiasm above and resulting in visual failure — classically a bitemporal hemianopia. Careful assessment of the visual fields, visual acuity and optic fundi is therefore essential. They may also invade laterally into the cavernous sinuses on each side, compressing the third to fourth cranial nerves.

Endocrine disturbance is due to either hypopituitarism or excess secretion of a particular pituitary hormone. Prolactin secreting tumours are usually found in younger women and cause loss of libido, infertility, amenorrhea and galactorrhoea. Corticotrophin-producing tumours cause Cushing’s disease due to cortisol excess. The principal features are moon face, abdominal striae, buffalo hump, hypertension and diabetes mellitus.

Acromegaly is due to an overproduction of growth hormone. The disease is disfiguring, causing prognathism and overgrowth of joints, especially in the hands and feet. Systemic side effects include hypertension, cardiomyopathy, diabetes mellitus, excessive sweating, arthralgias and lassitude. Haemorrhage into a macroadenoma, known as pituitary apoplexy, can precipitate an acute presentation with headache, hypopituitarism and visual failure. Diabetes insipidus, a product of direct hypothalamic involvement, is usually indicative of a craniopharyngioma and rarely caused by pituitary tumours.

Investigation

Diagnosis is confirmed by laboratory assessment of pituitary endocrine function, neuroradiological imaging (Fig. 35.33) and formal visual assessment.

Radioimmunoassay will identify the hormone being secreted. It is important, particularly with acute presentations, to exclude a prolactinoma as the majority of these will respond rapidly to treatment with the dopamine antagonist bromocriptine. Prolactin levels above 200 ng/ml are usually diagnostic. Nonfunctioning macroadenomas may cause hyperprolactinaemia due to distortion of the pituitary stalk or impingement on the hypothalamus. This is because the latter produces prolactin-inhibiting factor, which under normal circumstances suppresses prolactin levels to below 15 ng/ml. Diagnosis of Cushing’s disease is made by radioimmunoassay of adrenocorticotropic hormone (ACTH) in the peripheral blood and petrosal venous sinus sampling.

With the exception of some patients with Cushing’s disease, MRI of the sella will confirm diagnosis of an intrasellar mass. The resolution of MRI will also detect all but the smallest (<2 mm) tumours and any extrasellar extension.

Treatment

Treatment depends on the endocrine disturbance present and the effect of compression of adjacent neural structures. For prolactinomas, bromocriptine (a dopamine agonist) is commenced. Surgical excision is reserved for macroadenomas compressing the optic chiasm, growth hormone secreting tumours causing acromegaly and ACTH secreting tumours causing Cushing’s disease. Occasionally surgery is undertaken in patients with prolactinomas not responding to medical treatment or when unwanted side effects occur. This is usually performed via a transphenoidal route although the transcranial route can be employed. The aim is to preserve normal pituitary function if possible. Surgery should be covered with parenteral hydrocortisone and frequently vasopressin is required.

Radiotherapy is used for subtotal resections and for persistent hypersecretion of pituitary hormones. The long-term follow-up of nonfunctioning pituitary adenomas has shown a recurrence rate approaching 40 per cent at 10 years indicating that there is perhaps a more extensive role for this modality and that postoperative patients should be more closely followed up.
Subarachnoid haemorrhage and aneurysms

Introduction

The blood supply to the brain enters the cranium through the skull base via the paired internal carotid and vertebral arteries. Within the subarachnoid space these vessels con-municate to form the circle of Willis and then branch out over the surface of the brain before entering into and supplying the brain parenchyma. Subarachnoid haemorrhage (SAH) occurs when a vessel ruptures into this subarachnoid layer. Patients present with a typical sudden, unusual and severe headache. They may die apoplectically or present with a range of clinical conditions varying from being moribund, to a mild residual headache. The clinical status of these patients is graded according to the World Federation of Neurological Surgeons (WFNS) scale where the Glasgow Coma Scale (GCS) is used to measure consciousness (Table 35.6). This gives a measure of severity and prognosis of the haemorrhage.

Epidemiology

The incidence of SAH is 6—16 cases per 100000 per year representing 2—10 per cent of all cerebrovascular events and can have various causes (Table 35.7). While in some countries SAH is predominantly traumatic in origin, in most, these bleeds arise from thin-walled sacculat dilatations or aneurysms situated at the bifurcation of intracranial vessels, particularly upon the circle of Willis (Fig. 35.34a and b). These are usually sacculat with a neck and fundus but may be fusiform. They are most likely to be caused by haemodynamic stresses, the result of turbulent blood flow, possibly acting on a weak point in a vessel wall. Such lesions ate found in about 7.8 per cent of individuals at post mortem examination. The total prevalence in the general population appears to be in the region of 1.5 per cent and aneurysmal SAH accounts for 0.1 per cent of deaths within the general population. The prevalence increases with each decade reaching a peak at 40—60 yeats.

Ateriovenous malformations (AVM) are vascular hamarto-nas. Several groups are recognised. The most common is the true arteriovenous malformation while the other types include cavernous angiomas, venous malformations or capillary telangiectasis. These latter types seldom bleed and ate usually incidental findings on MRI. AVMs present with either haemorrhage, epilepsy or a neurological deficit. They may also cause ischaemia by shunting blood away from cerebral tissue (‘steal phenomenon’) and are graded according to their size, situation and the direction of their venous drainage.

Clinical features

SAH is typically heralded by a severe, unusual headache of sudden onset, frequently associated with neurological symptoms and often accompanied by nausea and vomiting. This is a result of extravasation of blood under pressure into the CSF space, ventricles or into the brain itself. The accom-panying acute rise in ICP causes compromise of the cerebral perfusion pressure and the cerebral blood flow, tamponading the bleed and allowing time for a clot to develop. The patient’s level of consciousness may as a consequence be depressed to varying degrees for varied periods of time and there might be concomitant photophobia and neck stiffness from meningeal irritation. Rarely, the patient may develop back and radicular pain as blood accumulates in the spinal canal. Physical examination reveals meninges and a positive Kernig’s sign. Fundoscopy can sometimes show globular subhyloid haemorrhages, scattered retinal haemorrhages and occasionally papilloedema. A focal neurological deficit or seizures reveals concomitant parenchymal damage. Fever, leucocytosis and hypertension ate not unusual. Although the majority of aneurysms presents with rupture, they can present with symptoms of compression alone resulting in pain, dysfunction (classically a third nerve palsy) or epilepsy.

Investigations

Diagnosis is classically made by LP but all patients should be investigated with CT. This is the investigation of choice and

fifteen within the first 24 hours of the bleed has a 90 per cent sensitivity, falling to 50 per cent at 3 days. This is able to confirm the diagnosis noninvasively, detect the presence of intracerebral haematomas, exclude hydrocephalus and indicate the likely source of a bleed — directing cerebral angiography. If the CT is normal or equivocal, if the bleed is more than 72 hours old and if no contraindications to LP are present, then
the patient should undergo a lumbar puncture looking for uniformly bloodstained CSF, xanthochromia or bilirubin byproducts of haemoglobin breakdown on spectrophotometry (Fig. 35.35a and b). Acute bacterial meningitis can mimic SAH so microbiological analysis should also be requested. Confirmation of haemorrhage should be investigated with cerebral angiography to determine the cause (Fig 35.36 and Fig 35.37). This should be considered with some urgency as the potential for a ruptured aneurysm to rebleed within the first 2 weeks is 25 per cent or 60 per cent within 6 months of the initial SAH with a mortality rate of greater than 60 per cent.

Fifteen per cent of aneurysms are multiple and 15 per cent of angiograms will be negative, indicative of an occult source such as a perimesencephalic bleed, a thrombosed aneurysm or a spinal arteriovenous malformation. The first angiogram describing intracranial aneurysms was performed by Moniz in 1933. Bilateral angiography including the internal carotids and vertebral arteries is the gold standard for delineating vascular lesions. With the advent of digitised angiography, it has been possible to reduce significantly the dosage of con-trast material given. The increasing sophistication of the noninvasive imaging techniques, magnetic resonance angio-graphic (MRA) and CT angiography, enables resolution of aneurysms 3 mm in size.

Management

The clinical course of patients with SAH is frequently unpre-dictable owing to the development of complications. The most severe are

tableeding and delayed ischaemic neurological deficit (DIND) — also known as vasospasm. The risk of rebleeding is 4 per cent in the first 24 hours and 19 per cent in the first 2 weeks, and carries a mortality and morbidity of 60 per cent. Aneurysms are secured by the surgical appli-cation of a clip across the neck at craniotomy (Fig. 35.38), isolating it from the circulation. Recently, endovascular techniques have been developed enabling aneurysms to be secured by packing them with platinum coils (Fig 35.38 and 35.39).

The cause of vasospasm remains unknown and is a signif-icant cause of morbidity. Overall, 30 per cent of SAH patients will suffer DIND due to vasospasm, with the majority suffer-ing permanent neurological deficits. Treatment of vasospasm relies on maintaining an adequate blood pressure and intra-vascular volume with intravenous fluids (mixture of 3.5 litres per 24 hours of crystalloid and colloid) since cerebral per-fusion is related to arterial pressure and intracranial pressure. Cerebral blood flow is further optimised by decreasing the haematocrit and if necessary using isotropic agents to elevate the blood pressure above physiological levels. All SAH patients develop some degree of hydrocephalus. This usually resolves spontaneously but may require temporary or per-manent CSF diversion. Cardiac arrhythmias and hyponatrae-mia are also frequent complications of this condition.

The potential for rebleeding from an AVM (2—4 per cent per annum) is lower than for an aneurysm and there is therefore less urgency with treatment (Fig 35.40— Fig 35.42).
AVMs are treated by either removing the lesion surgically, endovascular embolisation of the nidus, stereotactic radio-surgery or a combination of treatments.
Epilepsy

Introduction

Epilepsy is the commonest neurological condition affecting the general population. In the UK, 300 000 people have active epilepsy, 100 000 of whom are below 15 years of age. Despite the fact that epilepsy is such a common neurological condition, the attention given to the surgical management of epilepsy has been relatively small. Following Hotzley’s initiative however, great interest was shown in the surgical management of epilepsy but it was for the most part confined to post-traumatic cases and cases with obvious neoplasms. In the 1930s, this was integrated into the preoperative evaluation and supplemented by the pioneering work of Jasper and Penfield in Montreal. Their series of patients undergoing surgery for complex partial seizures identified that, where abnormal tissue was found in the resected specimen, the outcome in terms of seizure control was generally good. With the development of effective anticonvulsant medication, epilepsy was generally confined to specialist centres or to those in whom neoplasms could be identified. Indeed, oral anticonvulsant medication is still the first-line management of seizures. However, approximately 20% per cent of patients do not have their seizures adequately controlled on oral anticonvulsants and it is these patients who may benefit from surgery. Surgery is directed towards a focal lesion, the resection of which will abolish seizures. Functional operations may also be carried out to modify seizure spread and therefore ameliorate the patient’s condition.

Preoperative evaluation

History and examination

A careful history of the onset and nature of the seizures should be made as well as the way that the seizures have changed with time, by either their nature or their frequency. Note should be made of previous medications in addition to current anticonvulsant medication. It is important that the patient should have received an adequate therapeutic trial of the first-choice anticonvulsant drugs before consideration for surgery. The examination in patients with epilepsy is frequently entirely normal. However, when focal signs do occur, they can be useful in lateralising the seizure focus. Pathology under these circumstances is commonly neoplastic or the result of previous vascular episodes. The history of the circumstances of the patient’s birth, particularly whether there were any complications in the antenatal or perinatal period, is important, while the history of febrile convulsions in childhood is frequently found in patients who have hippocampal sclerosis and associated complex partial seizures. Any associated Todd’s paralysis with the febrile convulsion may be a very useful lateralising sign. The history should include the impact that the seizures have on the patient’s activities of daily living; notably, its effect on education, employment and personal relationships.

Electroencephalography

Interictal scalp recordings may be useful in excluding a patient for surgery on the grounds of widespread abnormal activity or if a recognisable electrographic syndrome can be identified. More commonly the interictal recordings can give broad guidance in terms of lateralisation and localisation of the seizure focus as identified by slow-wave activity or interictal spikes. The information obtained from the scalp recording may be supplemented by more invasive electrodes such as sphenoidal electrodes or alternatively it may be necessary to perform video telemetry and record a seizure on video with a time-locked EEG recording. This allows analysis of the semiology of the seizure as well as the EEG changes associated with the clinical manifestations.

Neuropsychology and neuropsychiatry

Careful neuropsychological testing may reveal fixed functional deficits that lateralise and localise the site of cerebral dysfunction. An evaluation of verbal and performance IQ as well as memory function are also vital parts in preoperative evaluation of seizures arising from the mesial temporal structures. To confirm laterality of language and integrity of memory function on each side, it may be necessary to carry out a Wada test during which sodium amytal is injected under angiographic control into the internal carotid artery, effectively putting the ipsilateral cerebral hemisphere to sleep. Patients are carefully tested before injection, immediately following injection and during the recovery phase to evaluate motor, speech and memory function. Psychiatric evaluation is an essential part of the preoperative strategy, in that psychiatric morbidity is common both in relation to seizures and in the postoperative period of seizure surgery. Established psychosis is usually deemed a contraindication for surgery for epilepsy, whereas a postictal psychosis is not. Integral to the role of the psychiatrist is the counselling that is necessary before seizure surgery, as often the seizures themselves are only a portion of the patient’s morbidity and it is essential that patients and their partners and relatives understand this.

Imaging

Preoperative imaging in patients considered for epilepsy surgery has been revolutionised by the advent of MRI and by an increasing understanding of the necessary sequences and planes of acquisition required to demonstrate the patho-logical entities responsible for epilepsy. It is becoming increasingly apparent that with more sophisticated imaging techniques, pathology can be demonstrated preoperatively in an ever-increasing proportion of surgical candidates. In patients with seizures emanating from the temporal lobe, the commonest pathological substrate is hippocampal sclerosis. This can be identified on preoperative scans by careful examination of the mesial temporal structures. The volume of the affected hippocampus is reduced while the anatomy may be clearly abnormal, and both the T1 and 12 signals altered. Neoplasms lying within the mesial temporal lobe may also be readily identified and their anatomical boundaries defined, allowing some idea of the feasibility of the extent of tumour resection possible at surgery. In cases of extratemporal epilepsy, tumours may likewise be clearly identified as well as areas of cortical damage or congenital malformations of cortical architecture.

Surgical procedures

Penfield and Falconer clearly identified that, where patho-logical tissue was found in the resected specimens of patients suffering with epilepsy, then the likelihood of surgical success was high. Further studies have more recently demonstrated that the more complete the resection of pathological tissue, the higher the likelihood of a good surgical outcome. As MRI is now such a powerful investigatory tool, pathology is frequently visualised preoperatively and thus surgery for focal epilepsy is becoming more and more lesional. Thus, when neoplasms are identified, the surgical objective is to excise the lesion in its entirety, with any surrounding abnormal tissue. Where the lesion is small and circumscribed, this may be best achieved using stereotactic or minimally invasive techniques with or without intraoperative EEG.

Approximately 60% per cent of patients being treated for epilepsy suffer from complex partial seizures and their seizure focus is localised to the mesial temporal structures. Therefore resections of the temporal lobe, particularly the amygdala and the hippocampus, are the most frequently performed opera-tions for the surgical management of epilepsy. The extent of the neocortical resection is dependent on whether the lesion is on the dominant or nondominant side and may be further guided by intraoperative EEG. In order that careful dissection of the mesial temporal structures may be safely performed, this part of the procedure requires an operating microscope. Extrad temporal resections are dependent on...
the pathological entity responsible and also upon the eloquence of the brain in which the lesion is situated. Where the lesion is close to or within eloquent areas it may be necessary to carry out the surgery under local anaesthesia with cortical stimulation, so as to minimise the risk of a postoperative neurological deficit.

When an extensive area of unilateral hemisphere abnormality exists, as a result of either a congenital or an acquired lesion, consideration may be given to a multilobar or hemisphere resection. Hemispherectomy, or more correctly hemidecortication, is perhaps the most effective operation for treating epilepsy, with a near 80 per cent seizure-free rate postoperatively (Fig. 35.44). However, the inevitable neurological deficits mean that its use is limited and should be considered carefully.

The most commonly performed functional operation is section of the corpus callosum. The aim of surgery is to improve rather than eradicate the seizures. This surgical approach was initially described by Dandy in the management of tumours of the third ventricle but was applied to the management of epilepsy in the 1940s. The indications for callosal resection are far from clear but patients suffering with atonic drop attacks appear to have the best outcome. In the first instance the anterior two-thirds of the corpus callosum are usually divided to minimise the chances of a longstanding disconnection syndrome. If anterior section does not result in improvement in seizures, then the resection may be completed. The rate for extending resection is limited to approximately 10 per cent. More recently, vagal nerve stimulation is being used as an alternative to corpus callosum resection with similar success rates.

Outcome

Surgery for well-circumscribed lesions such as benign tumours and cavernomas produces seizure-free rates as high as 70—80 per cent. In the presence of hippocampal sclerosis, resection of the mesial temporal structures and temporal neocortex will result in an approximately 70 per cent seizure-free rate. Extratemporal resections have a less favourable outcome with a seizure-free rate of between 40 and 50 per cent. This is often the result of a more diffuse pathological process, such as post-traumatic gliosis or neuronal migration defects that underlie the extratemporal epilepsy. Equally important in the postoperative evaluation is an appraisal of neurological, psychological and psychiatric status, which may then be compared with preoperative status to assess the dynamic impact of the seizure surgery.
Movement disorders

Parkinson’s syndrome was first described by James Parkinson in 1817. The principal pathological disorder is a depletion of dopamine stores in the cells of the substantia nigra and neostriatum. This produces the classical triad of tremor, rigidity and akinesia. As early as 1820, Parkinson appreciated that stroke ablated contralateral tremor. Over the next century, neurosurgeons lesioned various parts of the central nervous system in an attempt to alleviate this tremor until it was thought that the surgical relief of tremor boiled down to the artificial production of paralysis. The development of stereotactic techniques and a better understanding of the circuitry of the basal ganglia led to the development of the thalamotomy procedure. By 1975, 75,000 thalamotomies had been performed world-wide. However, in 1969, the discovery of levodopa led to the cessation of surgery for Parkinson’s disease. The subsequent development of on—off phenomena, dyskinesias and dystonias in patients treated with dopamine led to a revival of interest in movement disorder surgery. New imaging techniques and work on animal models of Parkinson’s disease led to the discovery of new targets in the basal ganglia and the procedure as we know it today.

Thalamotomy is used to treat patients with drug-resistant tremor but does little to improve akinesia and rigidity, and has an inconsistent effect on levodopa-induced dyskinesias. Case series have demonstrated that pallidotomy is helpful in reducing levodopa-induced dyskinesias. Underlying parkinsonism also improves but to a lesser degree. Unilateral procedures are usually preferred to bilateral ones as some centres have reported an increase in the risk of complications with the latter such as speech impairment and neuropsychological impairment (Fig. 35.45). More recently, the subthalamic nucleus has been lesioned, alleviating akinesia in addition to tremor and rigidity. This target does however expose patients to a higher risk of haemorrhage.

Lesions are made either by radiofrequency coagulation after trial stimulation or by deep brain stimulation of any of the sites targeted for lesioning. Although stimulators do not require tissue destruction, they are expensive and prone to technical failures. They can however be turned on and off, programmed as necessary and are reversible.

Neural transplantation of foetal mesencephalon to the neostriatum of humans is a controversial experimental technique which has had variable and questionable success. In addition, the ethics of obtaining foetal tissue and the problems of immunological reactions have led to the call for a moratorium on this procedure until long-term results are available.
Pain

Pain has been described as ‘an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage’. The physician initially confronts pain as the signal of some underlying damage and, as such, an important symptom of numerous diseases. Treatment is aimed at eradicating the disorder responsible for the pain. Occasionally the underlying problem cannot be identified or eradicated. It may even represent damage to the nervous system itself. The above definition also takes account of the emotional aspects of pain which may be all consuming for the patient and suggests the importance of psychological factors in evaluation and treatment.

Patients with pain are usually divided into two groups:

- Those with diseases that limit life expectancy (e.g. malignancies) and those with chronic benign pain. The management of each group is very different. The treatment of pain follows a continuum (Table 35.8) which is determined by the severity of the pain and its response to treatment. It is also essential that chronic pain patients are managed holistically by a pain team including pain-relief specialists and nurses, physiotherapists and occupational therapists in co-junction with a neurosurgeon. Drug therapy is aimed at suppressing pain at points along the pain pathways. Steroids and nonsteroidal anti-inflammatory drugs act directly on chemoceptors. Afferent pain fibres can be anaesthetised by infiltration with local anaesthetic. Descending pain modulation circuits are influenced by narcotics and antidepressants. Psychotropic and antidepressant drugs (chlorpromazine and haloperidol) are used to treat the affective component of pain.

The optimal surgical treatment for any intractable pain would be to have its effect confined to the painful area, be simple and inexpensive to perform, and be associated with a low mortality and morbidity. In particular it should be associated with a low incidence of neurological deficit.

There are three principal methods of neurosurgical management for pain:

1. operations that interrupt nociceptive pathways by creating lesions in peripheral nerves, roots or ganglia, the spinal cord, various parts of the brain and brainstem, and the sympathetic nervous system;
2. electrical stimulation of pain suppressive systems or blocking pain pathways (peripheral nerve, spinal cord or brain);
3. administration of various drugs to the intraspinal or intraventricular compartments of the CSF pathways.

Electrical stimulation of the central nervous system

Epidual stimulation

This is achieved by either totally implanted devices which are powered by a battery with a finite lifespan, or radiofrequency powered devices which have an implanted receiver which is activated by an external stimulator. These are connected to multichannel electrodes. By activating various electrodes and adjusting the pulse width, amplitude and frequency, beneficial stimulation is sought. The electrodes are positioned epidurally over the dorsal columns or more caudally over the cauda equina roots (Fig. 35.46). If paraesthesiae can be induced in the area of pain — significant benefit is virtually assured. This location is most effective for failed back surgery syndrome, arachnoiditis, peripheral vascular disease and angina. Spinal cord stimulation is based on the gate control theory of pain with inhibition of C-fibre conduction. The exact neurochemical and neurophysiological mechanisms are poorly understood. Electrodes can also be positioned epidurally over the motor cortex for more refractory pain syndromes such as thalamic and phantom limb pain. This can be of benefit in 50 pet cent of patients.

Deep brain stimulation

Stimulation of the lateral margin of the periaqueductal and periventricular grey matter is thought to affect a pathway running from the midbrain to the dorsal horn, inhibiting nociceptive neurons. The other target area is the ventro-posteromedial/ventroposterolateral nuclei of the thalamus which ultimately inhibit spinothalamic tract neurons. These electrodes are implanted stereotactically at specialist centres.

Intrathecal drug delivery

The opiates doses required to maintain patients with chronic pain frequently result in unacceptable side effects such as respiratory depression, drowsiness, urinary retention, nausea and vomiting, and eventually progress towards tolerance. Delivery of opiates into the CSF space via the lumbar or transventricular routes has a potentiated effect directly upon the opiate receptors in the brain and spinal cord at a fraction of the previous dose. This is achieved by implanted drug delivery systems (Fig. 35.47). These can be either manually activated — pressurised systems controlled by capillary resistance utilising different concentrations — or self-activated programmable pumps delivering small aliquots.

Pain associated with spasticity following spinal cord injury can be treated with intrathecal baclofen.

Neuroablative procedures

Ablative procedures have proved effective in relieving certain types of pain but run the risk of producing a neurological deficit without relieving and potentially even exacerbating pain and are hence more suited for patients suffering from pain associated with malignant disease. Sympathectomy is used to treat causalgic and visceral pain. Coeliac ganglion blocks have been especially helpful in treating pain associated with vascular disease and angina. Spinal cord stimulation is based on the gate control theory of pain with inhibition of C-fibre conduction. The exact neurochemical and neurophysiological mechanisms are poorly understood. Electrodes can also be positioned epidurally over the motor cortex for more refractory pain syndromes such as thalamic and phantom limb pain. This can be of benefit in 50 per cent of patients.

Surgically produced dorsal root entry zone lesions in the spinal cord are especially helpful in treating phantom limb pain, brachial plexus avulsion and discrete spinal cord lesions.

Cordotomy, the surgical interruption of the spinothalamic tract, results in hemianalgesia below the level of the lesion. It is invariably effective in managing unilateral pain associated with metastatic disease but its efficacy diminishes with time. Within 1 year 20 per cent of patients will develop painful dysesthesias in the anaesthetic area. It is usually performed at C1—2 with the patient awake. Risks include sleep apnoea (Ondine's curse), bladder, bowel and sexual dysfunction. Commissural myelotomy is a longitudinal sectioning of the spinal cord in the sagittal plane to disrupt the crossing fibres of the spinothalamic tract.

Mesencephalotomy reduces the number of functioning ascending fibres in the newer specific and older nonspecific pain pathways. It is effective for pains of the neck, head and upper chest caused by cancer.

Stereotactive cingulotomy is the creation of bilateral medial frontal lesions modifying the patient’s response to pain. These central lesions do
not remove the painful sensation but alleviate the concomitant suffering.

Alcohol injection, radiofrequency lesioning, balloon compression and avulsion of various components of the trigeminal nerve are all usually effective in the treatment of trigeminal neuralgia but invariably only temporising measures. Intracranial microvascular decompression and partial trigeminal rhizotomy offer long-term relief with lower recurrence rates.
Brain death

Introduction

For as long as medical practice has existed, the layperson has required of medical practitioners that they be knowledgeable about death. For centuries, laypeople and doctors alike have accepted cessation of respiration and heartbeat as the classical signs of death. Advances in cardiopulmonary resuscitation and modern mechanical ventilation have made obsolete the traditional clinical definition of death with a small but significant harvest of irreversibly brain-damaged patients. The worst form of such damage led to the concept of ‘coma depasse’, first defined by Mollaret and Goulou in 1959. As the number of patients with artificially maintained ventilation and circulation increased, they became to be regarded as a potential source of donor organs. These two developments occurred parallel to but independently of each other, and the diagnosis of brain death did not arise because of the need for donor organs.

The presence of an irreversibly damaged brain in a body in which ventilation and circulation were being maintained by artificial means presented a state in need of a definition. Mollaret and Goulou were the first to investigate this state in their paper ‘Le coma depasse’. Many terms for this and other states for which it has been mistaken have been suggested or used, of which the following are the most commonly encountered: cerebral death, brainstem death, brain death, coma depasse, irreversible coma, cortical death, persistent vegetative state and locked-in syndrome.

The high cost of maintaining patients in intensive therapy units (ITUs) and the premium on such limited resources has led significantly to the re-evaluation and management of such states. Nursing and medical staff morale, as well as the emotional toll on relatives, are very real considerations. As these patients may now be potential essential organ donors their care has acquired medicolegal and ethical significance. It is not the primary task of a doctor to provide organs for transplantation but neither is it to deny patients in need of transplant surgery. Before a patient can be considered as having suffered irreversible brain damage, it is mandatory that a positive diagnosis be made of the pathogenesis of this damage. To produce coma, pathological processes must affect the brain diffusely or encroach upon its deep central structures.

Three major groups of lesions can be differentiated:

- supratentorial lesions;
- infratentorial lesions;
- metabolic disorders — which widely depress or interrupt brain function, including anoxia, ischaemia, infections, toxins and essential deficiencies.

The disintegration of function following progressive herniation will end in cessation of spontaneous respiration leading to hypoxic cardiac arrest. If ventilation and circulatory maintenance are maintained artificially, the heart, kidneys and liver may continue to function for some hours or days but after brainstem death has occurred, cardiac arrest will follow within 2 weeks.

Since Mollaret and Goulou, several committees and reviewers have sought to establish unequivocal and appropriate clinical and EEG criteria for brainstem death based on retrospective analysis of patients who died. The first was the Harvard group who included EEG as part of their criteria. This was later deemed unnecessary by both the Minnesota and British Groups. The latter are as follows.

Before diagnosing brain death several preconditions should be satisfied:

- there should be no doubt that the patient’s condition is due to irremediable brain damage of known aetiology (Fig. 35.48);
- the patient should be in a coma on a ventilator because spontaneous respiration has been inadequate or ceased altogether;
- conditions and drugs which simulate brain death have to be excluded and, if necessary, drug levels measured to ensure that there is no reversible cause for coma. Some drugs (e.g. thiopentone) may take days to be cleared from the system.

Potentially reversible circulatory, metabolic and endocrine disturbances must have been excluded as the cause for the continuation of unconsciousness. It is recognised that circulatory, metabolic and endocrine disturbances are a likely accompaniment of brainstem death (e.g. hypernatraemia and diabetes insipidus) but these are the effect rather than the cause of that condition and do not preclude the diagnosis.

The tests should be performed by two physicians of not less than 5 years’ registration, who are not members of a transplant team and at least one of whom is a consultant. The tests are designed to assess brainstem functioning as it is the reticular activating system in the brainstem which is responsible for activating the rest of the cerebrum.

1. The pupils should be fixed and unresponsive to changes in the intensity of incidental light.
2. There should be no corneal reflex.
3. The vestibulo-ocular reflexes should be absent. No eye movements should be observed while at least 50 ml of cold water is infused over each eardrum. Clear access to the membrane must be established by direct inspection.
4. No motor responses within the cranial nerve distribution can be elicited by adequate stimulation of any somatic area. There is no limb response to somatic pressure, bearing in mind that movements mediated at a spinal level might still be possible.
5. There is no gag reflex to bronchial stimulation by a catheter placed down the trachea.
6. No respiratory movements appear when the patient is disconnected from the mechanical ventilator. During this test it is necessary for the arterial CO\textsubscript{2} to exceed the threshold for respiratory stimulation, that is the PaCO\textsubscript{2} should reach 6.65 kPa. This should be ensured by measurement of the blood gases. The patient should first be preoxygenated with 100 per cent O\textsubscript{2} for 10 minutes (then with 5 per cent CO\textsubscript{2} in O\textsubscript{2} for 10 minutes — if CO\textsubscript{2} is available). The ventilator should then be disconnected for 10 minutes while 6 litres per minute O\textsubscript{2} via a catheter is infused into the trachea.

If no respiratory effort has been detected and other signs of brainstem dysfunction have been demonstrated the patient may be considered brain dead.

Studies of hundreds of patients in several countries have found that not a single body displaying the criteria of brain death outlined gained...
any neurological recovery. Despite full and repeated efforts at resuscitation all such reported patients have suffered asystole within days or rarely weeks of the diagnosis. Interestingly in 37 instances the EEG retained at least fragments of electrical activity at a time when the patient was diagnosed as brain dead. In contrast to this, Jennet has shown that of the patients surviving prolonged coma, none ever met the criteria for brainstem death at any stage. Although not all agree, most religious and ethical bodies have expressed themselves in sympathy with the concept that death of the brain signifies death of the person. Pope Pius XII proclaimed in 1958 that the pronouncement of death was the responsibility of the church, stating that when illnesses reached hopeless proportions, death should not be medically opposed by extraordinary measures.

It is imperative that conditions simulating brain death be excluded.

Drug intoxication

CNS-depressant drug poisoning may cause total loss of cerebral function and electrocerebral silence for more than 50 hours followed by complete recovery. Self-induced drug poisoning often involves several drugs, frequently in combination with alcohol. Toxicology screening is not always available and frequently levels do not correlate with the clinical state. Serum concentrations often lag behind brain concentrations.

Hypothermia

The core temperature tends to drop when the brainstem ceases to function. That hypothermia may cause an isoelectric EEG is a theoretical rather than a practical issue. What is important is that hypothermia should be excluded as the cause rather than the result of the coma.

Electrical injury

This may be an important cause of coma, apnoea and fixed pupils.

Brainstem encephalitis

This is a rare form of encephalitis characterised by rapid ophthalmoplegia, ataxia and areflexia with apnoea and coma in severe cases. Although the clinical state may suggest brain death, these patients do not comply with the basic prerequisite of an incontrovertible diagnosis and the physician should be concerned with diagnostic and therapeutic measures rather than speculating about irreversible coma.

Ancillary tests

Ever since the concept of brain death arose, efforts have been made to establish the diagnosis electrophysiologically, the reason being to seek an objective nonclinical mode of diagnosis free of error or bias. These tests are not available in all hospitals and those which have proved to be indisputable indicators of brainstem death have usually occurred in patients in whom the diagnosis was never in doubt. They are listed for completeness and not because they replace clinical testing:

- EEG;
- scalp electromyograms;
- evoked potentials;
- brainstem auditory evoked potentials;
- somatic evoked potentials;
- lower oesophageal contractility;
- arteriovenous O2 difference;
- cerebral blood flow;
- ocular microtremor.

There is strong evidence that EEG silence for greater than 12 hours in a normothermic patient having had no drugs is not compatible with neurological recovery. Silverman reviewed 2560 isoelectric EEGs lasting for up to 24 hours. Only three patients in this group, all of whom overdosed on CNS antidepressant drugs, recovered cerebral function. Testing in an ITU setting is technically difficult owing to interference. The presence of a few fragments of electrocerebral activity is of dubious significance. Return of EEG activity after silence has also been reported.

NB: an EEG does not measure brainstem function. Drugs may cause coma with reversible true electrocerebral silence.

Cessation of cerebral blood flow in patients with raised ICP was first described by Riishede and Ethelberg in 1953. It is a significant indicator of brain death particularly where CT scanning is not available. It is caused by ICP rising above the MAP and by progressive vascular obstruction caused by autolysis in respirator brain (Fig. 35.49).

Ocular microtremor is one of three fixational eye movements measured using the isoelectric strain gauge technique and is an indicator of brainstem activity. Studies by Coakley and Bolger (1999) have shown that this tremor is absent in patients with the diagnosis of brainstem death.

If the viability of certain organs is to be maintained for possible harvesting, mechanical ventilation can be continued and the circulation artificially supported with a clear understanding, however, that these measures are not therapeutic but continued in order to maintain a cadaver in a perfused state. A member of the transplantation team is summoned and all further medical and administrative care of the potential donor should be carried out by them. The request for organ donation must come from the transplant team and not those treating the primary pathology. The staff taking care of the patient declining to brain death have a special responsibility towards the relatives who are going through a very harrowing time. For the layperson it is still a macabre concept to speak of death of a person in whom the heart is still beating.

Friedman, A.H. and Wilkins, R.H. (1984) Neurosurgical Management for the House Officer, Williams & Wilkins, Baltimore, MD.

Periorbital and orbital swellings

Swellings related to the supraorbital margin

Dermoid cysts

Dermoid cysts are usually external angular cysts although they may occur medially (Fig. 36.1). They often cause a bony depression by their pressure, and may have a dumb-bell extension into the orbit. They can also erode the orbital plate of the frontal bone, to become attached to dura, and for this reason it is important to do computerised tomography (CT) of the area before excision.

Neurofibromatosis

Neurofibromatosis may also produce swellings above the eye. The diagnosis can usually be confirmed by an examination of the whole body, as there are often multiple lesions. Proptosis can also result (Fig. 36.2).

Swellings of the lids

Meibomian cysts (chalazion)

These are the most common lid swellings (Fig. 36.3). A meibomian cyst is a chronic granulomatous inflammation of a meibomian gland. It may occur on either upper or lower lids and presents as a smooth painless swelling. It can be felt by rolling the cyst on the tarsal plate. It is distinguished from a stye (hordeolum) which is an infection of a hair follicle, usually painful. Meibomian cysts are treated by incision and curettage from the conjunctival surface. Styes are treated by antibiotics and local heat.

Basal cell carcinomas (rodent ulcers)

This is the most common malignant tumour of the eyelids (Fig. 36.4). It is locally malignant, is more common on the lower lids, and usually starts as a small pimple which ulcerates and has raised edges. It is easily excised in the early stages, and can be treated with local radiotherapy if too big to be excised.

Other lid swellings

These can occur, but are less common. These include seba-ceous cysts, papillomas, keratoacanthosis, cysts of Moll (Fig. 36.5)(sweat glands) or Zeiss (sebaceous glands) and molluscum contagiosum. When molluscum contagiosum occurs on the lid margin, they can give rise to a mild kerato-conjunctivitis and should be curetted.

Carcinoma of the meibomian glands and rhabdomyosarcomas are rare lesions; they need to be treated radically. Meibomian cysts that recur frequently should be submitted to biopsy.

Swellings of the Lacrimal system

Lacrimal sac mucocele

This occurs from obstruction of the lacrimal duct beyond the sac, and results in a fluctuant swelling, which bulges out just below the medial canthus. It can become infected to give rise to a painful tense swelling (acute dacryocystitis). If untreated it may give rise to a fistula. Treatment is by performing a bypass operation between the lacrimal sac and the nose [a dacyrocystorrhinostomy (DCR)].

Watering of the eye can occur due to eversion of the lower lid (ectropion), which causes loss of contact between the lower punctum and the tear film, and this must be distinguished from a mucocele.

Lacrimal gland tumours

Pathologically these resemble parotid tumouts (Chapter 42). These are swellings of the gland which lie in the upper lateral aspect of the orbit, and eventually they lead to impairment of ocular movements and displacement of the globe forwards, downwards and inwards. They can be pleomorphic adenomas with or without carcinomatous change, carcinomas or mucoepidermoid tumours.

Orbital swellings

If these reach any size they result in displacement of the globe and limitation of movement. A full description of these is outside the realm of the text, but some of the most common causes include the following.

• Pseudoprotosis. This results from a large eyeball, as seen in congenital glaucoma or high myopia.

• Orbital inflammatory conditions result in orbital cellulitis (Fig. 36.6).

• Haemorrhagic lesions occur in the orbit, after trauma or retrobulbar injections.

• Neoplasia affects the lacrimal gland, the optic nerve, the nasal sinuses and glioma (neurofibromatosis) (Fig. 36.6), meningioma and osteoma (Fig. 36.7).

• Dysthyroid exophthalmos (Fig. 36.8, Fig. 36.9 and 36.10). Often unrelated to active thyroid disease but can start after thyroidectomy and may need urgent tarsorrhaphy, large doses of steroids or even orbital decompression, if the eyeball is threatened by exposure. This is most easily done into the nasal sinuses (Chapter 44). CT and magnetic resonance imaging (MRI) scans are useful in diagnosis.

• Pseudotumour, or malignant lymphoma.

• Haemangiomas of the orbit (Fig. 36.11).

• Tumour secondaries or metastases. These are rare. In children they usually come from neuroblastoma of the adrenal gland, whereas in adults, the oesophagus, stomach, breast and prostate can be sites of primary lesions.
**Diagnostic aids**

Diagnostic aids include: radiography, tomography, orbital venography, ultrasonography, CT and MRI.

**Treatment**

*Treatment* is directed to the cause of the lesion if at all possible, taking care to prevent exposure of the eye and discomfort from diplopia.
Intraocular tumours

Children

Retinoblastoma is a multicentric malignant tumour of the retina, which can be bilateral. Some are sporadic, but many are hereditary. Children with a family history should be carefully monitored from birth. It is often not spotted until the tumour fills the globe and presents as a white reflex in the pupil (Fig. 36.12). Differential diagnosis is from retinopathy of prematurity, primary hyperplasic vitreous and intraocular infections. If the tumour is large, enucleation may be required, but radiotherapy, cryotherapy or laser treatment can cure small lesions.

Adults

Malignant melanoma is the most common tumour, and it originates in the pigment cells of the choroid ciliary body (Fig. 36.13 and Fig. 36.14) or iris. It can present a reduction in vision, a vitreous haemorrhage or by the chance finding of an elevated pigmented lesion in the eye. Growth can be rapid or fairly slow; as a general rule, the more posterior the lesion the more malignant it is likely to be. Malignancy is ultimately related to the cell type. Spread is often delayed for many years, and often goes to the liver, hence the advice ‘beware of the patient with a glass eye, and an enlarged liver’. Treatment is by light or laser coagulation, radioactive plaques, radio-therapy, enucleation and in selected cases it is by local excision using hypotensive anaesthesia. Note: a blind painful eye may hide a malignant melanoma. Diagnosis is made either by direct observation or by ultrasound which shows a solid tumour (Fig. 36.15).
Injuries involving the eye and adjacent structures

Corneal abrasions and ulceration

The cornea is frequently damaged by trauma and foreign bodies (Fig. 36.16). Ulceration can occur with infection or after damage to the facial nerve (Chapter 34). Post herpetic ulceration is common and serious if not treated. Fluorescein instillation can show up corneal ulceration at an early stage. Treatment is by protection (eye pads, tarsorrhaphy or a bandage contact lens), and antibiotics topically and systemically. 0.5 per cent chloramphenicol or ofloxacin eye drops are commonly used. The eye is made more comfortable by the use of mydriatics such as homatropine or cyclopentolate. Herpes simplex ulcers are treated with acyclovir ointment. In countries in the Far and Middle East chronic infection with trachoma can cause corneal opacification and blindness. Cornea grafting is the only cure for an opaque cornea. Osteo—odontokeratoprosthesis can be done in very severe cases of opaque corneas which are not suitable for grafting. Acanthoemeba is a serious cause of corneal infection. This fungal corneal infection usually follows the use of contact lenses. These rare cases need specialist treatment.

Blunt injuries to the eye and orbit

The floor of the orbit is its weakest wall, and in blunt trauma, such as fist injuries, it is often fractured without fractures of the other walls. This is called a blow-out fracture. Clinical signs are enophthalmos, bruising around the orbit and limitation of upward gaze and diplopia. This occurs when the extraocular muscles become trapped in the fracture, and can be identified as a soft tissue mass in the antrum on a radiograph (Fig. 36.17), although tomograms or CT scans may be necessary. Surgical repair of the orbital floor with freeing of the trapped contents may be necessary if troublesome diplopia persists. Large doses of steroids sometimes relieve symptoms in acute cases. If an orbital haemorrhage is too extensive to examine the eye, it may be necessary to examine the eye under anaesthesia because there may be a hidden perforation of the globe. Injuries to the lids and lid margins must be repaired, and if the lacrimal canaliculi are damaged they should be repaired if possible, especially the lower canaliculus, because 36 per cent of tear drainage goes through it.

Blunt injuries can also cause damage to the optic nerve which can result in blindness and a total afferent nerve defect (Fig. 36.18 and Fig. 36.19).

Concussional injuries

Concussional injuries of the eye can give rise to several problems, which include the following.

- **Hyphaema** (blood in the anterior chamber) (Fig. 36.20). Bed rest and sedation are advised because the main danger in this condition is secondary bleeding, resulting in an acute rise in intraocular pressure and blood staining of the cornea. The use of antifibrinolytic agents (e-aminocaproic acid) has been advocated and, if the pressure rises, surgery to wash out the blood may be necessary.

- **Subluxation of the lens** can be suspected if the iris, or part of the iris, ‘wobbles’ on movement.

- **Secondary glaucoma** often associated with recession of the angle.

- **Retinal haemorrhages and choroidal tears** (Fig. 36.21).

- **Retinal dialysis**, which may lead to a retinal detachment and permanent damage to vision (Fig. 36.22).

Penetrating eye injuries

These occur when the globe is penetrated, often in road traffic and other major accidents (Fig. 36.23), and also in injuries from sharp instruments. In the UK, the seat belt law has reduced this type of eye injury by up to 73 per cent in some series. The presence of an irregular pupil suggests prolapse of the iris, and should arouse the suspicion of a penetrating injury. Treatment is immediate surgery to restore the integrity of the globe. If a perforation is suspected, extensive eye examination should not be attempted before anaesthesia because this may lead to further extrusion of the intraocular contents. In severe corneal and intraocular injuries, primary cornea) grafting, lensectomy and vitrectomy have considerably improved the visual prognosis; these must be done by an experienced eye surgeon. Injuries to the optic nerves must also be excluded in severe accidents.

Intraocular foreign bodies

**Intraocular foreign bodies** must always be excluded when patients attend the accident and emergency department with a history of working with a hammer and chisel. Radiography of the orbits should always be performed, and ferrous and copper foreign bodies should always be removed. Beta-scan ultrasonography can also assist in localising foreign bodies when a vitreous haemorrhage is present. CT can be used, but MRI is contraindicated for orbital lesions.

**Burns**

**Radiation burns**

These occur after exposure to ultraviolet radiation after arc welding or excessive sunlight (snow blindness) and sun lamps. Such burns cause intense pain and photophobia due to a keratitis, which may start some hours after exposure. Mydriatic and local steroid drops ease the condition, and healing usually occurs after 24 hours.

**Thermal burns**

If these involve the full thickness of the lids, corneal scarring may occur, and immediate skin grafting to the lids is necessary. A splash of molten metal may cause marked local necrosis, and may lead to permanent corneal scarring. Treatment is to remove any debris by irrigation, and to instil local atropine, antibiotics and steroids to prevent superadded infection and scarring.

**Chemical burns**

Chemical burns, and especially alkali burns, can be serious because ocular penetration occurs quickly and ischaemic necrosis can result. Immediate irrigation will ensure that the chemical is diluted as much as possible, and all particles should be removed from the fornices. Treatment can then be continued as with thermal burns. Well-fitting goggles should prevent such injuries (Fig. 36.24).
Differential diagnosis of the acute red eye

The importance of this is in the management of minor ocular complaints, and the recognition of conditions requiring expert attention. Possible causes of the acute red eye can be divided into:

• conjunctivitis;
• keratitis;
• uveitis;
• episcleritis and scleritis;
• acute glaucoma.

 Conjunctivitis

Symptoms are grittiness, redness and discharge. Causes are infective, viral, traumatic or allergic. In the newborn it can be serious, and gonococcal and chlamydial infection must be excluded. Vernal conjunctivitis (Fig. 36.25) is a form of allergic conjunctivitis, usually worse in the spring and early summer, and often associated with other allergic problems such as hay fever. Clinically, most signs are under the upper lid which may have a cobblestone appearance instead of a smooth surface. Giant papillary conjunctivitis with large papilli under the upper lid may be seen in soft contact lens wearers. This is usually due to an allergy to the sterilising solutions and may be helped by either using a preservative-free solution or using daily wear disposable lenses where these are applicable. Viral conjunctivitis has become much more common. Chlamydial and adenovirus infections must be considered. Adenoviral infections usually affect one eye much more than the other and are often associated with a palpable preauricular gland. Kaposi’s sarcoma can present like a subconjunctival haemorrhage (Fig. 36.26).

Considerable conjunctival irritation can be caused by the lids turning in (entropion) (Fig. 36.27) or turning out (ectropion) (Fig. 36.28 and Fig. 36.29) and by ingrowing lashes. The lids should be repaired surgically to their normal position.

Vision is not affected in conjunctivitis, but with some virus infections a keratitis may be present, and result in visual loss and pain. All of the other conditions are painful, and usually affect vision. Herpes simplex infection is the most serious, and presents itself as a dendritic (branching) ulcer, shown easily by staining with fluorescein or Bengal rose. It is treated with acyclovir ointment five times a day. The use of steroid drops must be avoided as this can make the condition much worse (Fig. 34.30).

Corneal ulceration may occur due to ingrowing lashes or corneal foreign bodies, marginal ulceration and infected ulcers. Infected ulcers can occur in patients wearing soft contact lenses. Herpes zoster (shingles) affects the ophthalmic division of the fifth nerve, and can give rise to a keratitis and uveitis. It is important to exclude the use of steroid drops until a diagnosis has been made. Local anaesthetic drops should also not be given on a regular basis.

Uveitis

This can be anterior (inns) or posterior. In anterior uveitis the pupil will be small, sometimes irregular, there is circumcorneal injection and there may be keratic precipitates (KPs) present on the posterior surface of the cornea. Pain, photophobia and some visual loss are usually present. Posterior uveitis can present with a white eye and blurred vision. It usually takes a chronic course. Granulomatous diseases, Behçet’s disease, toxoplasmosis and cytomegalovirus infection should be excluded. Systemic steroids and cytotoxic drugs are sometimes useful in treating these conditions.

Episcleritis and scleritis

Episcleritis or inflammation of the episcleral tissue often occurs as an allergic reaction following an eye infection (Fig. 36.31).

Scleritis is a more serious condition in which the deeper sclera is involved. There is often an associated uveitis and thinning of the sclera. It may require the use of systemic steroids in order to treat adequately

Scleritis is often associated with severe rheumatoid conditions.

Acute glaucoma

This usually occurs in older, often hypermetropic patients. The cornea becomes hazy, the pupil oval and dilated, the vision very poor and the eye feels rock hard. In severe cases the pain may be accompanied by vomiting, and the pain can be mistaken for one of an acute abdomen. In doubtful cases the use of the tonometer to measure the intraocular pressure is a useful diagnostic procedure. Urgent treatment to reduce the pressure by pilocarpine, acetazolamide and mannitol should be started followed by a surgical iridectomy or laser iridotomy. The condition is usually bilateral, and the second eye usually needs treatment at the same time.

Except for a simple conjunctivitis, which is self-limiting, these conditions require expert treatment and a specialist opinion should be sought.

A painful eye with a third nerve palsy often signifies an intracranial aneurysm and should be investigated immediately.
Painless loss of vision

This may occur in one or both eyes, and the visual loss may be transient or permanent. Possible causes are:

• obstruction of the central retinal artery (Fig. 36.32);
• obstruction of the central retinal vein (Fig. 36.33);
• cranial arteritis;
• ischaemic optic neuropathy;
• migraine and other vascular causes;
• retrobulbar neuritis and papillitis;
• vitreous and retinal haemorrhages;
• retinal detachment (Fig. 36.34);
• macular hole, cyst or haemorrhage;
• cystoid macular oedema often after surgery;
• hysterical blindness.

Specialist help should be sought in any case of loss of vision. The erythrocyte sedimentation rate and C-reactive protein should be measured immediately if cranial arteritis is suspected, and the carotid system should be examined for bruits and other signs of arteriosclerosis in cases of ischaemic optic neuropathy and central retinal artery occlusion. Glaucoma, hypertension, myeloma and diabetes should be looked for in cases of central vein thrombosis.
Recent developments in eye surgery

In the last two decades, eye surgery has become a micro-surgical speciality. Cataract surgery has been transformed by changes in local anaesthesia, implants, phakoemulsification and small incision surgery which allows compressible silicone or acrylic implants to be inserted through a 3-mm incision. The implant power can be more accurately measured by new formulae and the use of A-Scan ultrasonography.

The developments in vitreous surgery have enabled membranes to be peeled off the retina and macular holes to be repaired and have also increased the success rate in retinal detachment surgery with the additional use of gases and silicone oil inserted into the vitreous cavity.

Some paralytic squints can be helped by the use of adjustable sutures or injections of botulinum toxin into the overacting muscles. Refractive error can be treated either by surgery (radial keratotomy) or by the excimer laser. This can be combined with LASIK surgery (laser in situ keratomileusis) which involves removing a cornea flap and doing the laser surgery at a deeper level. There have been some concerns about defective contrast sensitivity and problems with night vision after laser correction of myopia. Phakic implants have also been used to correct high refractive errors.

Corneal topography can help in making corneal and refractive surgery more accurate, and the increased use of CT and MRI scans helps to diagnose orbital and intracranial lesions involving the optic pathways. Fluorescein angiography and indocyanine green angiography help in the diagnosis and occasional treatment of macular lesions. The only advantage of indocyanine green is that the vascularisation of the choroid is much easier to see.
Lasers in ophthalmology

These were originally used as coagulators. The ruby laser was superseded by the argon blue—green laser and then the argon green-only laser, as the blue light was dangerous both to the operator and to the patient’s macula. Yellow and red wavelengths are also used and the doubled frequency YAG (yttrium—aluminium—garnet) laser can be used as a coagulator with a frequency of 533. The YAG laser was developed together with extracapsular surgery and is used for capsulotomies, iridotomies and cutting anterior vitreous bands. In its continuous mode it can be used to treat severe glaucomas.

Holmium and erbium lasers have been used to create subconjunctival drainage in glaucoma and the holmium laser can also be used in lacrimal obstruction during a DCR (dacrystocystorhinostomy) operation. CO₂ lasers are used to remove external lesion of the eyelids and excimer lasers are used for refractive surgery. The diode laser can be used both as a photocoagulator and for treating the ciliary body in advanced cases of glaucoma. Lasers combined with phakoemulsification to liquefy the human lens are being developed. Laser surgery is making rapid advances and no doubt many new forms of lasers will be developed for use in ophthalmology in the next few years.
Surgical procedures

Excision of an eyeball

Indications include a blind, painful eye, a blind, cosmetically poor eye, intraocular neoplasm and in cadavers for use in corneal grafting. The operation. The speculum is introduced between the lids and opened. The conjunctiva is picked up with toothed forceps and divided completely all round as near as possible to the cornea. Tenon’s capsule is entered, and each of the rectus tendons hooked up on a stabismus hook and divided close to the sclera. The speculum is now pressed backwards and the eyeball projects forwards, blunt scissors, curved on the flat, are insinuated on the inner side of the globe, and these are used to sever the optic nerve. The eyeball can now be drawn forwards with the forceps, and the oblique muscles, together with any other strands of tissue which are still attaching the globe to the orbit, are divided. A swab moistened with hot water and pressed into the orbit will control the haemorrhage. If an orbital implant is inserted to give better eye movement, the muscles are sutured to the implant at the appropriate sites.

Evisceration of an eyeball

As a result of the danger of opening up lymphatic spaces at the back of the globe, and thus favouring meningitis, evisceration is to be preferred to excision in panophthalmitis. The sclera is transfixed with a pointed knife a little behind the corneosclerotic junction, and the cornea is removed entirely by completing the encircling incision in the sclera. The contents of the globe are then removed with a curette, care being exercised to remove all of the uveal tract. At the end of the operation the interior must appear perfectly white.

Incision and curettage of chalazion (meibomian cyst)

The lid margin is everted to allow the application of a meibomian clamp. The ring of the clamp is placed on the palpebral conjunctiva with the granuloma in the centre. An incision is made with a sterile blade in the axis of the gland. The herniating granulomatous tissue is removed with a curette and the gland is scraped clear. Recurrent cysts may have to have the cyst wall dissected away with scissors. A biopsy may be necessary in recurrent cysts to exclude malignant change.
Acquired immunodeficiency syndrome (AIDS) and the eye (See Chapter 9).

**Kaposi’s sarcomas**, purplish or brown nonpruritic nodules or macules, are a frequent early manifestation of AIDS. Commonly affecting the face, especially the tip of the nose, the lesions may involve the eyelids and the conjunctiva.

**Fundus lesions** are divided into ‘noninfective’ and ‘infective’ categories. Noninfective changes consist of cotton-wool spots, haemorrhages and vascular sheathing. These occur in up to 40 per cent of patients with the disease. Infective lesions are usually caused by a cytomegalovirus infection. These lesions may have been described as tomato ketchup and salad cream retinopathy’, but the pattern is now changing and not so florid. Herpes zoster, toxoplasmosis, pneumocystis and candidiasis lesions can also occur in the retinae. Cytomegalovirus retinitis can be prevented from spreading by treatment with ganciclovir or foscarnet or a combination of the two. These are, however, toxic in the doses required: ganciclovir to the leucocytes, foscarnet to the kidneys.

Intravitreal injections of ganciclovir twice a week until the condition regresses is an alternative if systemic treatment is not tolerated. Intravitreal implants of ganciclovir or foscarnet are now being used.

**Neuro-ophthalmological complications** in AIDS have been reported, most frequently as nerve palsies associated with intracranial infections with cryptococci and toxoplasmosis, or as a manifestation of an intracranial lymphoma.

Cleft lip and palate

Clefts of the lip, alveolus, hard and soft palate are the most common congenital abnormalities of the orofacial structures. They frequently occur as isolated deformities but can be associated with other medical conditions particularly congenital heart disease. They are also an associated feature in over 300 recognized syndromes.

All children born with a cleft lip and palate need thorough paediatric assessment to exclude other congenital abnormalities. In certain circumstances genetic counselling must be sought if a syndrome is suspected.

Incidence

The incidence of cleft lip and palate is one in 600 (1:600) live births, and 1:1000 live births for isolated cleft palate. The incidence increases in Oriental groups (1:500) and decreases in the black population (1:2000). The highest incidence reported for cleft lip and palate occurs in the Native American tribes of Montana, USA (1:276).

Although cleft lip and palate is an extremely diverse and variable congenital abnormality, several distinct subgroups exist, namely cleft lip with/without cleft palate (CL/P), cleft palate alone (CP) and submucous cleft palate (SMCP).

The typical distribution of cleft types is:

• cleft lip alone — 15 per cent;
• cleft lip and palate — 45 per cent;
• isolated cleft palate — 40 per cent.

Cleft lip/palate predominates in males whereas cleft palate alone appears more common in females. In unilateral cleft lip, the deformity affects the left side in 60 per cent of cases.

Aetiology

Contemporary opinion on the aetiology of cleft lip and palate is that cleft lip and palate (CL/P) and isolated cleft palate have a genetic predisposition and a contributory environmental component. A family history of cleft lip and palate in which the first-degree relative is affected increases the risk to one in 25 live births. Genetic influence is more significant in cleft lip/palate than cleft palate alone where environmental factors exert a greater influence.

Environmental factors implicated in clefting include maternal epilepsy and drugs (e.g. steroids, diazepam, phenytoin), although the benefit of antenatal folic acid supplement to prevent cleft lip and palate remains equivocal.

Although most clefts of the lip and palate occur as an isolated deformity, the Pierre Robin sequence remains the most common syndrome. This syndrome comprises isolated cleft palate, retrognathia and a posteriorly displaced tongue (glossoptosis), which is associated with early respiratory and feeding difficulties.

Isolated cleft palate is more commonly associated with a syndrome than cleft lip/palate and cleft lip alone. Over 150 syndromes are associated with cleft lip and palate, although Stickler (ophthalmic and musculoskeletal abnormalities), Shprintzen (cardiac anomalies), Down’s, Apert’s and Treacher Collins’ are most frequently encountered.

Classification

Any classification for such a diverse and varied condition as cleft lip and palate needs to be simple, concise, flexible, exact but graphic. It must be suitable for computerisation but descriptive and morphological. An example of such a classification is the LAHSHAL system which is able to describe site, size, extent as well as type of cleft (Fig. 37.1).

Complete clefts of the lip, alveolus, and hard and soft palate are designated capital L, A, H and 5, respectively, whereas incomplete clefts are recorded in small letters; microform clefts are documented with asterisks. Hence, LAHSHAL is the anatomical paraphrase of a complete bilateral cleft lip and palate. Another example, lahSh, represents an incomplete right unilateral cleft lip and alveolus with a complete cleft of soft palate extending partly on to the hard palate.
Primary management

Antenatal diagnosis

An antenatal diagnosis of cleft lip, whether unilateral or bilateral, is possible by ultrasound scan after 18 weeks of gestation. Isolated cleft palate cannot be diagnosed on an antenatal scan. When an antenatal diagnosis is confirmed, referral to a cleft surgeon is appropriate for counselling to allay fears. Photographs of cleft lip shown to parents ‘before and after’ surgery are invaluable. Introduction to a parent support group and meeting parents of a child with a similar cleft who has undergone surgery may also be extremely helpful.

Feeding

Most babies born with cleft lip and palate feed well and thrive provided appropriate advice is given and support available. Some mothers are successful in breastfeeding, particularly when the cleft is incomplete and confined to the lip. Good feeding patterns can be established with soft bottles (e.g. Mead Johnson) and modified teats (orthodontic, Nuyk). Simple measures, such as enlarging the hole in the teat, often suffice. Feeding plates, constructed from a dental impression of the upper jaw, are rarely necessary to improve feeding. Some babies are provided with an active plate which aims not only to improve feeding but also reduce the width of the cleft lip and palate prior to surgery. The long-term benefit of such a regime remains unproven.

Airway

Major respiratory obstruction is uncommon and occurs exclusively in babies with Pierre Robin sequence. Hypoxic episodes during sleep and feeding can be life threatening. Intermittent airway obstruction is more frequent and man-aged by nursing the baby prone. More severe and persistent airway compromise can be managed by ‘retained nasopharyngeal intubation’ to maintain the airway. Surgical adhesion of the tongue to the lower lip (labioglossopexy) in the first few days after birth is an alternative but less commonly practised method of management.

Principles of cleft surgery

The ultimate goal in cleft lip and palate management is a patient with normal appearance of lip, nose and face, whose speech is normal and whose dentition and facial growth fall within the range of normal development.

Surgical techniques are aimed to restore normal anatomy. With the exception of rare conditions such as holoprosencephaly, there is no true hypoplasia of the tissues involved either side of the cleft. There is, however, displacement, deformation and underdevelopment of the muscles and facial skeleton. Emphasis is placed on muscular reconstruction of the lip, nose and face, as well as muscles of the soft palate. Normal or near-normal anatomy promotes normal function, thereby encouraging normal growth and development of lip, nose, palate and facial skeleton. An in-depth understanding of the anatomy of the cleft is invaluable if the surgeon is to achieve normal, or near-normal, anatomical reconstruction.

Anatomy of cleft lip and palate

Cleft lip

The abnormalities in cleft lip are the direct consequence of disruption of the muscles of the upper lip and nasolabial region. The facial muscles (Fig. 37.2) can be divided into the three muscular rings of Delaire.

Unilateral cleft lip. In the unilateral cleft lip, the nasolabial and bilabial muscle rings are disrupted on one side resulting in an asymmetrical deformity involving the external nasal cartilages, nasal septum and anterior maxilla (premaxilla) (Fig. 37.3). These deformities influence the mucocutaneous tissues causing displacement of nasal skin on to the lip and retraction of labial skin, as well as changes to the vermilion and lip mucosa. All of these changes need to be considered in planning the surgical repair of the unilateral cleft lip.

Bilateral cleft lip. In the bilateral cleft lip, the deformity is more profound but symmetrical. The two superior muscular rings are disrupted on both sides producing a flaring of the nose (due to lack of nasolabial muscle continuity), a protru-sive premaxilla and an area of skin in front of the premaxilla, known as the prolabium, devoid of muscle (Fig. 37.4). As in the unilateral cleft lip, the muscular, cartilaginous and skeletal deformities influence the mucocutaneous tissues, which must be respected in planning the repair of the bilateral cleft lip.

Cleft palate

Embryologically, the primary palate consists of all anatomical structures anterior to the incisive foramen, namely the alveolus and upper lip. The secondary palate is defined as the remainder of the palate behind the incisive foramen divided into the hard palate and, more posteriorly, the soft palate.

Cleft palate results in failure of fusion of the two palatine shelves. This failure may be confined to the soft palate alone or involve both hard and soft palate. When the cleft of the hard palate remains attached to the nasal septum and vomer, the cleft is termed incomplete. When the nasal septum and vomer are completely separated from the palatine processes, the cleft palate is termed complete.

Soft palate. In the normal soft palate, closure of the velo-pharynx, which is essential for normal speech, is achieved by five different muscles functioning in a complete but coordinated fashion. In general, the muscle fibres of the soft palate are orientated transversely with no significant attachment to the hard palate.

In a cleft of the soft palate, the muscle fibres are orientated in an anteroposterior direction, inserting into the posterior edge of the hard palate (Fig. 37.5).

Hard palate. The normal hard palate can be divided into three anatomical and physiological zones (Fig. 37.6). The central palatal fibromucosa is very thin and lies directly below the floor of nose. The maxillary fibromucosa is thick and contains the greater palatine neurovascular bundle. The gingival fibromucosa lies more lateral and adjacent to the teeth.

In performing surgical closure of cleft palate the changes associated with the cleft must be understood to obtain an anatomical and functional repair. In complete cleft palate the median part of the palatal vault is absent and the palatal fibromucosa is reduced in size. The maxillary and gingival fibromucosa are not modified in thickness, width or position.
Surgical techniques

There have been many different surgical techniques and sequences advocated in cleft lip and palate management. Cleft lip repair is commonly performed between 3 and 6 months of age, whereas cleft palate repair is frequently performed between 6 and 18 months.

The Delaire technique and sequence (Table 37.1) is one of many regimes currently practised.

Cleft lip surgery

Skin incisions (Fig. 37.7 and Fig. 37.8) are developed to restore displaced tissues including skin and cartilage to their normal position, whilst gaining access to the facial, nasal and lip musculature.

Muscular continuity is achieved by subperiosteal undermining over the anterior maxilla. Nasolabial muscles are anchored to the premaxilla with non-resorbable sutures. Oblique muscles of orbicularis oris are sutured to the base of the anterior nasal spine and cartilaginous nasal septum. Closure of the cleft lip is completed by suturing the horizontal fibres of orbicularis oris to achieve a functioning oral sphincter (Fig 37.9 and Fig. 37.10).

Cleft palate surgery

Cleft palate closure can be achieved by one- or two-stage palatoplasty. The surgical principle is mobilization and reconstruction of the aberrant soft palate musculature (Fig. 37.11), together with closure of the residual hard palate cleft by minimal dissection and subsequent scar formation (Fig. 37.12). Excess scar formation in the palate adversely affects growth and development of the maxilla. The philosophy of two-stage closure encourages a physiological narrowing of the hard palate cleft to minimize surgical dissection at the time of the second procedure.
Secondary management

Following primary surgery, regular review by a multi-disciplinary team is essential. Many aspects of cleft care require long-term review.

Hearing

Eustachian tube dysfunction plays a central role in the pathogenesis of otitis media with effusion in babies and children born with a cleft palate. Children with a cleft lip alone exhibit the same frequency of otitis media as their age-matched non-cleft counterparts. It has been recently recognised that a child with a craniofacial anomaly including cleft lip and palate is at increased risk of a sensorineural hearing deficit. All children born with a cleft lip and palate should undergo assessment before 12 months of age for sensorineural and conductive hearing loss by auditory brainstem responses (ABR) and tympanometry, respectively.

Sensorineural hearing loss is managed with a hearing aid, whilst the management of secretory otitis media remains more controversial. Early (6—12 months old) prophylactic myringotomy and grommet temporarily eliminates middle ear effusion. Regular audiological testing may be appropriate, reserving surgery for established secretory otitis media with infection. No firm evidence is available to support the interventional approach over the conservative regime. Nevertheless, the relationship between hearing loss and potential speech problems remains important. Regular audiological assessment during childhood is of utmost importance.

Speech

Initial speech assessment should be performed early (18 months) and repeated regularly to ensure that problems are identified early and managed appropriately.

Common speech problems associated with cleft lip and palate are:

- Velopharyngeal incompetence — this is associated with increased nasal airflow and resonance producing a nasal or ‘hypernasal’ quality to speech. It frequently reflects poor function of soft palate associated with inadequate muscle repair.
- Articulation problems — these either arise as a compensatory mechanism to overcome velopharyngeal incompetence or, less commonly, are due to jaw/dental and occlusal abnormalities.

Investigation by:
- videofluoroscopy
- nasal airflow studies (aerophonoscopy)
- nasendoscopy

is helpful in defining the exact mechanism of the problem which aids management.

Speech problems are managed by:

- speech and language therapy;
- secondary palatal surgery:
  - intravelar veloplasty (muscular reconstruction of soft palate);
  - pharyngoplasty;
- speech-training devices.

Dental

Dental anomalies are common findings in children with cleft lip and/or palate. Various phenomena include delayed tooth development and delayed eruption of teeth; morphological abnormalities are also well documented. The number of teeth may be reduced (hypodontia) or increased (hyperdontia), and occurs most commonly in the region of the cleft alveolus involving the maxillary lateral incisor tooth. These abnormalities can occur in both primary and secondary dentition. All children with cleft lip and palate should undergo regular dental examination. Dental management should also include preventive measures such as dietary advice, fluoride supplements and fissure sealants.

A well-maintained and disease-free dentition in childhood is an absolute prerequisite for orthodontic treatment.

Orthodontic management

Many children with cleft lip and palate require orthodontic treatment.

Orthodontic treatment is commonly carried out in two phases:

- mixed dentition (8—10 years) — to expand the maxillary arches as a prelude to alveolar bone graft;
- permanent dentition (14—18 years) — to align the dentition and provide a normal functioning occlusion. This phase of treatment may also include surgical correction of a mal-positioned/retrusive maxilla by maxillary osteotomy (Fig. 37.13).

Secondary surgery for cleft lip and palate

Good outcome in cleft lip and palate is directly attributable to the quality of primary surgery. Poorly executed primary surgery leads to residual deformity of the lip and nose, together with poor speech. Impaired growth of the midface (maxilla) is now attributed to poor and traumatic primary surgery. Surgical techniques must endeavour to minimize scarring.
Despite adequate primary surgery, residual problems do occur and are managed with appropriate secondary procedures (Table 37.2).

The management of children with cleft lip and palate is complex, requiring the skill of a multidisciplinary team. Each team should include professionals who are appropriately qualified with specialist training, treating an adequate number of patients per year. Meticulous record-keeping of photography, radiology, dental casts and speech recording are indispensable, and permit regular audit and improved outcomes.
Developmental abnormalities of the face, palate, jaws and teeth

Treacher Collins’ syndrome (Fig. 37.14)

Ttreacher Collins’ syndrome or mandibular facial dysostosis has a variable presentation. The cardinal features are of an anti-mongoloid palpebral fissure with a coloboma or groove in the outer portion of the lower lids with deficiency of the eyelashes. There is generally hypoplasia of the midface and zygomatic bones, and occasionally of the mandible. There may be malformation of the external ear unilaterally or bilaterally. Macrostomia and facial clefts may accompany this condition.

Crouzon’s disease (Fig. 37.15)

This is also known as craniofacial dysostosis and may occur together with syndactyly. This is a genetic disease characterised by protruberant frontal bones, a hypoplastic maxilla with relative mandibular prognathism. The hypoplasia may be so severe that the globes of the eye are protruberant to a degree that corneal ulceration and loss of sight can occur. There may well be a hypertelorism and divergent strabismus. Most patients have a normal cerebral function.

Pierre Robin’s syndrome

This condition is characterised by micrognathia (small lower jaw) and glossoptosis. There is almost always a cleft palate. The overall impression is of bird faces. It does not appear to be an inherited syndrome and it has been thought that extreme flexion of the neck during foetal life may contribute to the disorder: the tongue is thrust upwards between the palatal shelves which fail to fuse so causing the cleft palate to develop. Recent work on gene function suggests that deficiences one of the transformation growth factors (TGFβ3) is responsible. Respiratory obstruction due to poor control of the tongue and difficulties with sucking require careful neonatal management.

Hemifacial microsomia (first arch syndrome — Fig. 37.16)

In this condition tissues which seem to have been derived from the first branchial arch are deficient. A better understanding of the embryology, and experimental work by Poswillo, have indicated that there may be haemorrhage from the stapedial artery around the sixth week of intrauterine development. Tissues that were in development at that time are damaged by the haemorrhage and the subsequent reorganisation so that tissues are smaller or fail to develop completely. The expression is variable but there is always hypoplasia or absence of the mandibular condyle and part of the ramus of the mandible. The masticatory muscles are deficient, and the external, middle and inner ear may fail to develop. Thus, there is the appearance of hypoplasia or the affected side of the face and head with the pinna absent and the external auditory meatus rudimentary or absent. Skin tags over the side of the face beneath the ear are common. The child is almost always deaf in the affected ear. As the growth centre at the mandibular condyle is deficient, the deformity progresses throughout early life and particularly at puberty. The patient requires expert craniofacial surgery that is delayed as long as possible but is generally carried out at the age of 8 years. Further surgery is usually required postpuberty.

Maxillomandibular disproportion

Angle, an American orthodontist, put the occlusion of the teeth into three classes:

- **class I** — normal relationship of the lower to the upper teeth in the molar area;
- **class II** — the lower molar teeth are placed posterior to the normal position;
- **class III** — the posterior molar teeth are placed anterior to the normal position.

This classification has been extended to include the facial skeleton such that:

- **skeletal II** — small mandible is placed posterior to the normal position in relation to the maxilla;
- **skeletal III** — mandible is placed anterior to the norms position relative to the maxilla.

It is a helpful description of a facial skeletal deformity, but it only describes the mandible in relation to the maxilla which itself may be hyperplastic or hypoplastic. Thus, the ‘Hapsburg jaw’ which described the familial features of the royal houses of Europe in the nineteenth century describes large lower jaw, a hyperplastic mandible, which is frequently associated with a hypoplastic maxilla which accentuates the deformity in the mandible.

The most common deformity of the facial skeleton in the Caucasian is the hypoplastic mandible — skeletal class II—which gives the impression of a hyperplastic maxilla as the upper teeth are very prominent. A hyperplastic maxilla alone is very unusual. Bimaxillary protrusion is a racial characteristic of the African races. Occasionally the mandible may grow large and asymmetric owing to hyperplasia of the mandibular condylar neck. Rarely, a hemimandible may be hypoplastic.

Orthognathic surgery

Orthognathic surgery is the term given to the correction of deformities of the teeth and jaws. It should always be under-taken in close co-operation with consultant orthodontists and consultant oral and maxillofacial surgeons. Correction of maxillomandibular disproportion is frequently directed towards changing the position of both the maxilla and the mandible, usually at the end of the growth period. It is essential that there should be a team approach, with treatment planning usually commencing at the age of 12—13 years. Treatment of the syndromes, some of which are described above, may require much earlier treatment (see below). The orthodontist prepares the dental arches for their new position preoperatively, and continues postoperatively with the ultimate goal of a perfect dental occlusion within 6 months of the surgery.

The orthognathic surgery is generally carried out through incisions within the mouth avoiding skin incisions where possible. The upper and lower jaws are mobilised individually and fixed by means of small stainless steel or titanium plates and fixed by means of stainless steel or titanium miniplates. Splitting of the upper and lower teeth by various means is undertaken intraoperatively to achieve an accurate and planned occlusion. Usually it is possible to leave the mandible free for the mouth to be opened at the dangerous times in the first 24 hours postoperatively. An example of maxillomandibular disproportion may be seen in Fig. 37.17, with the effect of bimaxillary surgery in Fig. 37.18.

Craniofacial surgery

Craniofacial surgery is undertaken in a few designated centres in the UK where the team of an orthodontist and a maxillofacial surgeon is augmented to include a craniofacial surgeon (usually with plastic surgery training), neurosurgeons and ear, nose and throat (ENT) surgeons.
The whole team includes dedicated nursing staff, both in the ward and in the operating theatre, speech therapists and audiologists. The principles of treatment are to correct deformities from the cranium downwards. Thus, in Crouzon’s disease (see above) the craniofacial surgeon with the neurosurgeon will correct the cranial deformity in the first 2—3 years of life, and will return to deal with the midface by the age of 6 or 7 years, often in co-operation with the maxillofacial surgeon. Final correction will be to the mid and lower face with the patient in their mid-teens where they may be treated much like a more straightforward orthognathic case. The surgical principles involve dividing the various bones of the face and skull, inserting bone grafts where appropriate, and maintaining the position of the bones by miniplates or microplates made of stainless steel or titanium. The surgery to the cranium as far forward as the nose and lateral border of the orbits may be carried out through a coronal incision, pulling the scalp downwards and forwards over the face. For access to particular areas, incisions are made through the skin around the orbits at sites where the scarring is barely noticeable.

New developments in osteogenic distraction in the early growth period in the severe abnormalities may greatly change and reduce the major surgery that is currently undertaken on patients with facial deformity.
Other developmental abnormalities in the face and jaws

Failure of fusion, or inclusions of epithelium where various processes meet during development, can lead to cysts and fistulae around the face, the jaws and the neck. Cysts may develop and then become infected, leading to persistent sinuses. Examples are as follows.

- **Pre-auricular cyst** — fusion of the six tubercles around the external auditory canal can lead to formation of one or more narrow, blind pits or, perhaps, a cyst. Infection of the cyst may lead to a persistent discharging sinus which would need to be excised.

- **Periauricular dermoid cyst** — these may develop from under the puma as a fluctuant swelling, usually posteriorly. They occur in the position where the two adjacent auricular tubicles should merge.

- **Globulomaxillary cyst** — cysts may develop in the alveolus in the position where the globulomaxillary processes should fuse with the frontonasal process. The cyst occurs lateral to a vital second upper incisor and canine. These have to be differentiated from a radicular cyst developing on a nonvital lateral incisor.

- **Nasolabial cyst** — these occur in a similar position to the globulomaxillary cyst, but in the soft tissues of the upper lip. They are extremely rare.

- **Cysts of the incisive canal** — the two palatal shelves fuse with the premaxilla at the site of the exit from the palate of the nerve of the incisive canal. This canal may form a cyst or be patent, leading to recurrent infections in this area. Those that have a patent canal may enjoy the party-trick of producing a high-pitched squeaking or whistling sound as they raise the pressure in the mouth, discharging air into the nose.

- **Oral dermoids** — these are derived from embryonic epithelium and can occur anywhere where the facial processes fail to fuse completely. They are rare, but the most common site is the midline of the floor of the mouth. They should not be confused with the ranula, which is a mucous extravasation cyst derived from the lingual gland.

- **Branchial cysts** — these occur in the lateral aspect of the upper neck of young adults as a slow-growing fluctuant swelling. It had been assumed that these occur as a result of failure of fusion branchial arches. They are lined with lymphoid tissue, and the current view is that they are derived from cystic transformation of glandular epithelium included in lymphoid aggregates during embryogenesis. The current nomenclature is lymphoepithelial cyst.

- **Oral tori** ([Fig. 37.19](#) and [Fig. 37.20](#)) — it is uncertain as to whether these are true developmental abnormalities. They occur at two major sites, the most common lies on the medial side of the mandibular alveolus in the region of the premolar teeth. Less frequently midline palatal tori occur, again in line with the premolar teeth. These are dense, bony swellings that cause no problem apart from occasional ulceration, particularly if dentures are to be worn. They are only removed if they cause difficulty in the wearing of dentures.

- **Cysts in the thyroglossal tract** — the thyroid gland develops as an evagination of the epithelium at the junction of the anterior two-thirds and the posterior third of the tongue, the foramen caecum. A vestigial epithelial remnant may remain and cysts may occur along the line of this duct. They may be anywhere on a line from the surface of the tongue ([Fig. 37.21](#)), down to and behind the hyoid bone or to the isthmus of the thyroid gland. Occasionally thyroid tissue may develop and remain at the site of origin in the base of the tongue.

**Surgical treatment**

Cysts are, by definition, epithelial lined cavities, and where swellings cause difficulty, embarrassment or recurrent infections the lining has to be removed. Where infection may cause sinus formation, the epithelial track has to be removed. The surgery may be major and complex, or minor, according to site.
Congenital and developmental anomalies of the teeth

Dental lamina

Teeth develop from the dental lamina, a strand of epithelium originating from the oral mucosa, which migrates backwards from the incisor region of both mandible and maxilla beginning in the sixth week of intrauterine life. As it migrates backwards tooth buds are formed which eventually develop into the teeth and roots, each with its characteristic shape, according to the position in the jaw. Abnormalities in its migration may lead to abnormalities that are laid out below. The concept of the dental lamina, however, has changed in recent years, as it would seem that the epithelium responsible for developing the teeth is not the dental lamina as such but modifications of the oral mucosa. This invaginates beneath the alveolus progressively posteriorly from the incisor region under the influence of genes and activators, which are specific for each part of the mouth, in a time-window of 2—3 days.

The total number of the secondary dentition is 32. The third molar or wisdom tooth may fail to develop in any of the four quadrants. Lack of space may cause them to impact into the second molars or backwards into the ramus. These may lead to pericoronal infection later in life and the third molars may require removal. The upper lateral incisors may fail to develop or develop as small, peg shaped teeth. This is normally associated with an impaction of the canines and is thought to be associated with faults in the dental lamina or gene deficiencies during development.

Failure to develop a large number of primary and secondary teeth is known as hypodontia. It may be associated with other forms of ectodermal dysplasia where there is a lack of sebaceous and sweat glands. Considerable problems are encountered in providing a functional dentition, particularly during the growth period.

Supernumerary teeth and odontomes

Supernumerary teeth tend to occur in the same areas where teeth may be absent — the lateral incisor, second premolar and the third molar areas. Generally they are smaller than the normal teeth in the same area and seldom develop little more than a crown and a vestigial root. They may be multiple. In the incisor region they may be responsible for the failure of eruption of adjacent permanent teeth, particularly the central and lateral incisors and canine. They generally lie palatal to their normal counterparts. They have to be removed to allow eruption of the permanent teeth to occur. Rarely, in the third molar region, dentigerous cysts may develop around the crown. These are characterised by a radiographic appearance of a cyst enveloping the crown of the tooth that is displaced.

Odontomes are aggregations of tooth-like material and may take the form of multiple small teeth (denticles, a compound complex odontome) or irregular masses of dentine, cementum and enamel (complex composite odontome). They lie within the alveolus, frequently inhibiting the eruption of the adjacent teeth and are encapsulated. The most common site is the premolar region of the mandible. Odontomes are, in effect, hamartomas. Once formed they do not increase in size. Occasionally they become infected.

Developmental disturbances in the structure of the teeth

The enamel of primary and secondary dentition may be affected by a number of genetic or congenital conditions. There may be effects due to local problems such as trauma during birth or infection. The most notable change affecting all teeth is the result of amelogenesis imperfecta which is genetic and may be dominant or recessive. It is an ectodermal disturbance and the anomalies can range from pits in the teeth to failure of enamel development. It may be associated with osteogenesis imperfecta. By contrast, dentinogenesis imperfecta affects the mesodermal portion of the odontogenic apparatus. The appearance of the teeth is variable with the poorly supported enamel taking on a opalescent tinge. The enamel is readily damaged. Both amelogenesis and dentinogenesis imperfecta result in rapid early tooth loss.

Odontogenic cysts and tumours

Abnormalities in the dental lamina may form benign cysts and odontogenic tumours (keratocyst, odontogenic myxoma). A malignant form, ameloblastoma, is variable between cystic and solid, and is locally invasive. The most common site for these to occur is in the third molar region and ramus of the mandible.
Congenital and developmental abnormalities of the gums

Congenital epulis of the newborn

This uncommon tumour is seen in the anterior mandible and can reach a relatively large size. It is pedunculated and mobile, and can cause extreme concern to parents. It is simple to remove and has no long-term consequences.

Predeciduous teeth

At birth, or shortly afterwards, hard tooth-like structures may be detected in the lower alveolus and can cause the mother considerable discomfort during breastfeeding. These do not represent primary dentition or ‘a third set of teeth’ as the structures, although calcified, do not take the form of normal teeth. Simple removal is advised where breastfeeding is undertaken.
Further reading

Injuries to the face are common but the majority is relatively minor. A few are major and complex, requiring exacting technique and infinite care in management. It must be remembered always that an intact and unscarred face is important to the well-being of the individual, and thus all injuries, however trivial, should be treated thoughtfully and sympathetically, with every effort always to produce an optimal outcome. In addition, even trivial blows to the face may:

- cause injuries which compromise the airway;
- directly or indirectly cause a head injury (a fall to the ground so banging the head, for instance);
- cause injuries to the cervical spine.

Injuries to the face and facial bones result from both sport- and accidents and accidents, and intentional violence. The major injuries in the past were as a result of road traffic accidents, but the compulsory wearing of seat belts, car air bags, head restraints and laminated windscreens have reduced all of these greatly. However, the reduction in damage from this source has been almost matched by the increase in deliberate injury from bodily violence where ‘putting the boot in’ has become a fashion with appalling results.

Clinical effects

The mouth and nasal passages are the upper airway, and lacerations and fractures of the facial skeleton may give rise to immediate or delayed respiratory obstruction. Immediate obstruction may arise from inhalation of tooth fragments, accumulation of blood and secretions, and loss of control of the tongue in the unconscious or semiconscious patient. To avoid this, the patient should always be nursed in the semi-prone position (Fig. 38.1) with the head supported on the bent arm, and never lying on their back. Damaged teeth, blood and secretions can then fall out of the mouth and gravity pulls the tongue forward. As the patient is manoeuvred into the correct nursing position, the neck should be supported and held in a neutral position — a protective collar is advisable until a fracture of the cervical spine has been excluded. Under no circumstances should the chin be pulled up to straighten the airway. An intracranial injury should always be considered as a possibility, however minor the injury to the face.

Initial haemorrhage after a facial injury can be dramatic. Sustained bleeding is unusual but emergency surgery to stabilise the facial fractures and control bleeding may be required. The most likely causes of circulatory failure in a bad facial injury are accompanying skeletal injuries or a ruptured viscus, and these should always be actively sought for in the shocked patient. Oedema is a particular feature of all fractures of the face skeleton and tends to develop within 60—90 minutes. Thus, a patient with a shattered face may appear to have a choke airway immediately after the blow, but that airway may rapidly change and become occluded by swelling of the tongue facial and pharyngeal tissues. This problem must always be borne in mind when the middle third of the face is involved. In Le Fort III fractures (see below) the facial bones may be thrust downwards and backwards along the base of the skull. As it does so, the posterior teeth of the upper and lower jaw contact first and the mouth is held open giving the impression of a good airway (Fig. 38.2). As swelling supervenes, the soft palate and the tongue may swell to meet, so closing the pharyngeal airway and leading to acute respiratory obstruction (Fig. 38.3). Whenever this is suspected, the ‘golden hour’ must be used to insert an oropharyngeal airway, even though the patient may appear conscious and unobstructed. If this is not done an emergency tracheostomy may have to be undertaken later with great risk to the patient.

Examination of the injuries

The examination of the patient should be under a good light with consideration of the airway and other collateral injuries always in mind. It is easy to be deviated from examining the whole patient by the dramatic effects of the facial injury. The rapid onset of oedema may make the examination of the face and routine head injury observations difficult — occasionally it is impossible to prise the eyelids apart to examine the pupil, for instance. Lacerations should be explored gently first and, if necessary, cleaned using sterile saline, aqueous antiseptic solution and/or dilute hydrogen peroxide.

Once the pattern and extent of soft-tissue injury has been established, attention should be given to the hard tissues. Regardless of the apparent site of the injury, the whole head should be examined visually and by palpation starting with the vault of the skull. A blow to the face may result in the head being thrown back against a hard object and a bruise or laceration on the occiput missed. The face should be examined from in front. Any asymmetry and displacements should be noted, although oedema may make this difficult. Gentle palpation, using both hands and wearing surgical gloves, gives the most information in searching for step deformities. Tenderness over sites of known weakness and potential for fracture (see below) is a very good guide for the possibility of fracture of the bone beneath. A suitable system is to examine from above downwards — the supraorbital and infraorbital ridges, the nasal bridge, the zygomas including the zygomatic arch. The mandible should then be examined starting at the condyles bilaterally and then following the posterior and lower border of the mandible as far as the midline. All middle third injuries are accompanied by bleeding from the nose, and Le Fort II and III injuries frequently have a cerebrospinal fluid (CSF) leak with anterior or posterior CSF rhinorrhea. All fractures of the maxilla lead to mucosal tears with bleeding from the nose. A particularly useful sign in the fractured zygoma is the frequent subconjunctival haemorrhage which will be found to have no posterior border when the patient is asked to look to the opposite side (Fig. 38.4). This gives a positive indication of a fracture of the bone behind.

The patient should then be examined orally with good illumination; a pen torch is insufficient. The lips should be parted and the occlusion of the teeth examined. The upper and lower teeth normally ‘fit’ together even if the occlusion is naturally irregular if they do not a fracture of the jaws is likely. All fractures of the alveolus (the bone holding the teeth) tear the gingiva and are compound into the mouth: the examiner should ask the patient to look to the opposite side (Fig. 38.4). This gives a positive indication of a fracture of the bone behind.

If a fracture of the maxilla is suspected, the upper dental arch should be grasped between index finger and thumb of one hand in the molar region, while the other is placed on the forehead. A gentle pull on the maxilla forward and backward, or side to side, will reveal movement between the examining hands. With the mandible, gentle manipulation across the suspected site of a fracture will confirm the presence of the fracture if ‘spinging’ is felt and seen. Confirmation of a fractured zygoma may be made by palpating the fractured antral wall above the upper molar teeth in the buccal sulcus.

The facial examination should be completed by testing for sensation over the face. Anaesthesia or paraesthesia suggests a fracture proximally along the path of the nerve. Thus, anaesthesia of the cheek and upper lip suggests a fracture going through the infraorbital foramen, while anaesthesia of the lower lip suggests a fracture of the mandibular body. It is important to confirm that the patient has sight in both eyes. This may be difficult in the very oedematous patient with circumorbital haematoma, but a pen torch shone through the lids will confirm that the optic nerve is intact. Where possible, vision should be checked for diplopia by asking the patient to follow the light of the pen torch in both central and extremes of gaze. Diplopia may mean that there is damage to the thin orbital plates of bone, particularly the infraorbital plate.

All findings should be recorded accurately, preferably with diagrams to include measurements of lacerations and displacements. Photographs
of the initial injury can be very helpful if litigation is likely to follow.

**Investigations**

**Blood tests**

Baseline full blood picture and serum electrolytes should be recorded, and the blood should be grouped when it is thought that much bleeding has occurred and more bleeding is likely.

**Radiographs**

Posteroanterior occipitomental radiographs taken at 10 and 30 degrees are the best initial radiographs to illustrate the site and displacement of the maxilla; an opaque antrum is a good indication that there may be a fracture of the maxilla. A panoramic oral radiograph (orthopantomogram) is the radiograph of choice for the mandible as it shows the whole bone from condyle to condyle. If the patient cannot be positioned in the machines to achieve these views, radiographs should wait until the patient is fit enough. Poor radiographs can be misleading, and treatment can only be carried out on good ones. The orbital floor may be visualised best by a computerised tomography (CT) scan in the coronal plane, and may also be used to identify the presence and site of other middle third fractures. If a CT scan is to be made, always consider including the upper cervical spine in addition to the face.
Fractures of the facial skeleton

Fractures of the facial skeleton may be divided into those in the upper third (above the eyebrows), the middle third (above the mouth) and the lower third (the mandible). Fractures tend to occur through points of weakness — the sutures and foramina, and in thin unsupported bone.

The upper third

The patterns of fracture of the skull tend to be random but there are points of weakness, mainly involving the frontal sinuses and the supraorbital ridges.

The middle third

Fractures of the middle third of the face have been studied extensively and René Le Fort in 1911 classified fractures according to patterns which he created on cadavers using various degrees of force. The Le Fort classification is used extensively today throughout the world. While Le Fort classified the fractures from superior to inferior, the custom today is that the classification runs inferiorly to superiorly (Fig. 38.9).

The Le Fort I fracture effectively separates the alveolus and palate from the facial skeleton above. The fracture line runs through points of weakness from the pyriform aperture, through the lateral and medial wall of the maxillary sinus running posteriorly to include the lower part of the pterygoid plates.

The Le Fort II fracture is pyramidal in shape. The fracture involves the orbit, running through the bridge of the nose, and the ethmoids whose cribiform plate may be fractured, leading to a dural tear and CSF leak. It continues to the medial part of the infraorbital rim, through the infraorbital foramen and through the infraorbital fissure. The orbital floor is always involved. It continues posteriorly through the lateral wall of the maxillary antrum at a higher level than the Le Fort I to the pterygoid plates at the back. The nasal septum is displaced and lateral walls of the nose are fractured.

The Le Fort III fracture effectively separates the facial skeleton from the base of the skull — the fracture lines run high through the nasal bridge, septum and ethmoids, again with the potential for dural tear and CSF leak, and irregularly through the bones of the orbit to the frontozygomatic suture. The zygomatic arch fractures, and the facial skeleton is separated from the bones above at a high level through the lateral wall of the maxillary sinus and the pterygoid plates. The nasal septum will be fractured and may be displaced.

These fractures are seldom confined exactly to this classification and may be combinations of any of the above.

The zygoma

This is the most common fracture of the middle third of the face apart from the nose, as the patient turns the cheek to approaching danger. The fractures occur through points of weakness — infraorbital margin, the frontozygomatic suture, the zygomatic arch and the anterior and lateral wall of the maxillary sinus. Tears on the mucosa of the antrum lead to bleeding from the nose. The infraorbital plate of bone is always involved to a greater or lesser extent and may cause entrapment of the orbital contents.

Blow-out fractures of the orbit

Direct trauma to the globe of the eye may push it back within the orbit. The globe is a fairly robust structure and as it is thrust backwards, the pressure increases within the orbit and the weaker plates of bone may fracture, without necessarily fracturing the bones of the orbital rim. Such injuries can occur where a pointed object hits the globe of the eye — for example, a bent elbow of a standing man inadvertently being thrust into the orbit of a person sitting. A finger deliberately thrust into the eye may have the same effect. The weakest plate of bone, commonly the infraorbital plate, ruptures and the orbital contents herniate downwards into the maxillary antrum. On rebound, as the pressure within the orbit is reduced, the small fractured pieces of bone may entrap the orbital contents, particularly the inferior oblique and inferior rectus muscles, leading to failure of the eye to rotate upwards. Enophthalmos and profound diplopia can follow although initially both may be concealed by oedema. Anaesthesia over the distribution of the infraorbital nerve may be an important clue to the blow-out fracture. Pain is experienced on movements of the eye as the entrapped muscle is stretched. There may be enophthalmos although this may be masked in the early stages by oedema. Any fracture that may involve the orbital floor (Le Fort II and zygomatic bone) must be considered a potential for orbital content entrapment too.

Fractures of the mandible

These are usually as a result of blows from the side or from the front to the lower third of the face. The condylar neck is the weakest part of the bone and is the most frequent site of fracture (Fig. 38.6) while other fractures tend to occur through unerupted teeth (the impacted wisdom tooth) or where the roots are long (the canine tooth). Blows from the side may fracture at the point of injury but, as the force is transmitted to the base of the skull via the condylar neck, this may fracture first. Blows from the front may cause fracture in the midline and fractures of both condyles. Individual sharp blows with a blunt instrument may fracture a segment away from the mandible. Blows from below may cause the mandible to be thrust upwards fracturing the alveolus and teeth as they hit their fellows in the maxilla. Fractures of the mandibular body may also fracture the teeth in the fracture line.

Much has been made in the past of the ‘butterfly’ fracture of the mandible. Here a segment of mandible in the midline with fractures in the canine regions. The segment of bone takes on the appearance of a butterfly, and this will include the anterior insertion of the tongue (geniohyoid and genioglossus). Conceptually, the tongue may fall back and occlude the airway. First, the fracture is extremely rare, and second, the patient can still control the tongue, if allowed to by a good nursing position (see above).
Treatment

Soft-tissue injuries

Facial soft tissues have an excellent blood supply and heal well. They should be sutured as soon as possible after the injury after careful exploration, debridement and cleaning, particularly where glass or plastic may be embedded. The tissues should be meticulously clean and scrubbed, as retain-ed dirt may cause tattooing and hypertrophy of the scar. Many lacerations may be closed using local anaesthesia, injecting into the edges of the wound. If the patient is due to have a general anaesthetic and there is a delay, the wounds should be closed in advance by local anaesthesia. Tissue sufficiently traumatised to have lost its blood supply should be removed with a sharp scalpel, and the edge to which it is to be apposed trimmed to fit as appropriate.

Great care should be taken to replace tissues very accurately, particularly in cosmetically important landmarks such as the vermilion border of the lips, the eyelids and nasal contours. Haemostasis is important. Muscle and underlying layers should be brought together with absorbable sutures so that the edges of the wound lie passively within 2 mm of their final position. Then fine monofilament sutures (5-0 or 6-0) are used to bring the wound edges together (Fig. 38.7). All sutures should be placed so as to avoid compromising the blood supply of the apices of small flaps. Vacuum drains are used where there is concern over dead space beneath the wounds. The lacerations should be covered by antibiotic ointment and this should be replaced two to three times per day. This prevents the sutures causing scarring of the skin. Intravenous dexamethasone 8 mg twice daily for 2 days and broad-spectrum antibiotics should be prescribed. Sutures may be removed from the third day.

Facial nerve injury

The facial nerve may be severed in the depth of a lateral facial wound. If this is suspected, primary repair should be attempted, particularly where clinical signs suggest that a main division is involved. Locating the divided branches in oedematous and damaged tissue may be extremely difficult. Proximal and distal flaps in relatively normal adjacent tissue may have to be raised to identify the nerve on each side of the laceration. The severed nerve may then be traced towards the laceration and the ends approximated using an operating microscope, and the nerve and laceration sutured. Attempt at primary repair is always worthwhile, although extremely difficult, as secondary repair is generally unsatisfactory.

Parotid duct

Lacerations in the same vicinity as those that transect the facial nerve may also transect the parotid duct. The suggested management is to insert a small cannula in the parotid duct from within the mouth and then pass it distally until it appears in the wound. The position of the duct is identified and the proximal end may be found from the site of the distal end as the tissues are approximated and the cannula runs into it. The laceration of the facial tissues may be sutured in the normal way avoiding any tendency to displacement across the ends of the duct. Some advise that the parotid duct is sutured side to side to avoid stricture. Two days of intravenous dexamethasone (8 mg twice a day) should follow the surgery. Antibiotics are recommended.

The lacrimal apparatus

The lacrimal apparatus may be involved in damage to the eyelids and nasal bones in Le Fort II and III injuries. The tissues are generally grossly oedematous and the manipulation required to reduce the fractures adds to the difficulties of identifying the cannaliculae. Most surgeons do not attempt repair primarily but refer to an appropriate plastic or ophthalmic surgeon if epiphora become a problem later. Surprisingly, few patients suffer epiphora after a year has elapsed from the injury.

Injuries to the facial bones

The fractured nose

This is the most common fracture of the face. Best results are achieved when oedema has been allowed to settle so that accurate reduction can be achieved. Reduction of oedema may be assisted by intravenous or intramuscular dexamethasone 8 mg twice daily preoperatively. However, surgery should not be left for longer than a week, as reduction may become difficult or impossible. Accurate reduction always requires a general anaesthetic and an endotracheal tube. A throat pack should always be inserted. Reduction should be directed first to repositioning the nasal bones, disimpacting with Walsham’s forceps with the external blade covered with rubber tubing so as to avoid damage to the skin. The nasal bones are first taken laterally to disimpact them, and then medially to reposition them. It is wise to start on the side opposite to the blow which broke the nose. The septum is then grasped with Asch’s forceps, manipulated until it is straight, and then positioned in the groove of the nasal crest and vomer. Asch’s forceps may be used to pull the disimpacted nasal bones forward to their previous unfractured position. If there is a suggestion that the insertion of inner canthi has been involved, or the nasal bones have been thrust into the ethmoid sinuses, then open reduction may be required (see treatment of Le Fort III). The nasal bones may need supporting by a pack within the nasal bridge. This is best done using ribbon gauze inserted into the finger(s) of a rubber surgical glove previously placed beneath the reduced nasal bones (to reduce the discomfort of pack removal at 3 days). A protective nasal plaster may be placed and removed at 1 week.

Fractures of the maxilla

Treatment of fractures of the maxilla should be undertaken in a maxillofacial unit. They always require a general anaesthetic given through auffed nasotracheal tube. Careful intubation is required ensuring that the tube is directed posteriorly, not superiorly, on insertion. Correctly placed tubes are of no risk to the cranial base however extensive the fracture. Occasionally it may be necessary to begin the operation with an oral tube, and then transfer to a nasal tube once the maxillae reduced and held. Final positioning of a concomitant fractured nose may be left until the end of the operation, just after the nasal tube has been removed. Conversely, if it is necessary to leave in a nasopharangeal airway, a second airway should be inserted in the other nostril, so as to keep the nares equally distended. A tracheostomy may be required occasionally.

The principle of reducing and stabilising fractures of the frontal and facial bones is that the surgeon starts at the top and works down. Where there are extensive lacerations, these may be used, perhaps with small extensions, to approach the fracture lines. Where there are no convenient lacerations, fractures of the frontal bone and supraorbital ridges and fractures of the nasal root may be approached through a coronal incision at the vault of the skull, high in the hair line. The incision is taken from just in front of each ear across the vault of the skull and reflected forwards until the supraorbital ridges are exposed. The supraorbital nerve is identified and freed and the flap extended as required. The nasal root, the lateral orbital rim and zygomatic arch may be exposed through this route. All of the fractured bones may be reduced and held by stainless steel or titanium miniplates or microplates and wires, under direct vision. Bone deficiencies in this area or in the infraorbital plate may be made up with free cranial cortical bone grafts, with the donor sites available through the coronal incision. Where the nasal bones are spread, leading to an orbital hypertelorism, the root of the medial canthal ligaments may be identified and sutured to the opposite side to restore canthal width.

When the stabilisation of the upper part of the face is complete, attention may be given to the midface. Incisions in the lower eyelid
For this to be done properly, the lower eyelid should be retracted and the inferior rectus muscle grasped in the lower fornix. The globe can then be checked by palpating the bony prominences of the arch, and the lateral and inferior orbital rims. As all fractures of the zygoma involve the orbital floor, it is essential to apply a forced duction test to the globe to ensure that the inferior oblique or inferior rectus muscle is not trapped.

Second to the fractured nasal bone, this is the most common fracture of the maxilla. Displacement is usually posteriorly, but it is important to assess the actual displacement by studying the occlusal radiographs. Most fractures may be reduced by the Gillies approach. This entails an incision in the hairline superficial to the temporal fossa about 15 mm long, at 45° to the vertical. It is deepened down to and through the temporal fascia. A channel is prepared behind the fascia and down to the body of the zygoma and arch. A Bristow’s or Rowe’s elevator is then inserted beneath the body of the zygoma or arch, according to the site of fracture. Considerable force is applied in the opposite direction to that calculated to have been delivered by the blow which caused the fracture. After reduction, the position of the zygoma can be checked by palpating the bony prominences of the arch, and the lateral and inferior orbital rims. As all fractures of the zygoma involve the orbital floor, it is essential to apply a forced duction test to the globe to ensure that the inferior oblique or inferior rectus muscle is not trapped. For this to be done properly, the lower eyelid should be retracted and the inferior rectus muscle grasped in the lower fornix. The globe can then be explored through intra oral or extra oral incisions according to the access required, and the fractures reduced and fixed with miniplates and/or wires. Any fractured teeth should be removed and also those previously compromised by extensive caries or infection. It is possible so that it matches the previous occlusion with the lower teeth. To achieve accurate location, dental arch wires or eyelet wires (see below) may be used. Each splint is wired to the respective jaw  the mandible, with wires going around the mandible (circumferential wires) and the maxilla, with wires going around the zygomatic arches. The circumferential wires around the mandible are sited to stabilise the fracture line. The hooks placed on the buccal surfaces of the plastic arch are used to apply IMF when the patient has recovered from the general anaesthetic. IMF is retained for 3—4 weeks.

Fractures of the mandible frequently are reduced and then fixed with intermaxillary fixation (IMF). IMF is a means of splinting the upper and lower arches of teeth together. First, eyelet wires or arch bars are fixed to the upper and lower teeth. Eyelet wires consist of a small loop about 4 mm in diameter twisted in the centre of a length of 0.35-mm stain-less steel wire. Each loop is threaded between and around pairs of teeth, and the wire then is pulled through the buccal slit of the inferior arch. The loops are then tied to the tooth preparation, the teeth are separated by eyelet wires, and the eyelet wires are required for each dental arch. These are most suitable where there is a full, or near full, arch of teeth in each jaw. Where there has been tooth loss with irregular gaps around the mouth, then arch bars may have to be used. These are prefabricated lengths of stainless steel tape or wire, with hooks coming off at 8—10-mm intervals. These are wired to individual teeth so that there are two arch bars opposing one another in each jaw. IMF is applied between the loops of the eyelet wires or the hooks of the arch bars. In the past, custom-made silver cap splints were used, cemented to the opposing jaws. These are rarely used now.

For future comfort of the patient, it is very important to restore the dental occlusion to its original position. With simple minimally displaced fractures, eyelet wiring is all that is required (Fig. 38.8). This may be achieved without general anaesthetic. Undisplaced fractures and fractures of the mandibular condyle may require no active treatment.

Displaced fractures, or fractures which have markedly dis-turbed the occlusion, will require a general anaesthetic. A cuffed nasotracheal tube is required without a throat pack (a throat pack may make it difficult to achieve the correct occlusion). Fractures of the body of the mandible may be explored through intra oral or extra oral incisions according to the access required, and the fractures reduced and fixed with miniplates and/or wires. Any fractured teeth should be removed and also those previously compromised by exten-sive caries or infection. It is unnecessary to remove healthy teeth in the fracture line. To be sure of achieving a correct occlusion it is wise to use temporary intraoperative IMF. There are occasions when the best results can be achieved with IMF alone. In this event, it is necessary to remove the IMF during recovery, so as not to risk complications involving the airway. IMF may be inserted after 12 hours when the patient has recovered from the general anaesthetic. It is retained for 4—6 weeks.

Fractures of the edentulous mandible generally are plated using miniplates. In the atrophic mandible, the raising of periosteum should be kept to a minimum as the blood supply to the jaw may be compromised. Where there is fear that the blood supply may be seriously disadvantaged by the insertion of plates, Gunning’s splints may be constructed. These require dental impressions and are then constructed in the laboratory. In effect, these are like upper and lower dentures, but with the teeth replaced with plastic in which hooks are placed (the patient’s dentures may be used). Each splint is wired to the respective jaw the mandible, with wires going around the mandible (circumferential wires) and the maxilla, with wires going around the zygomatic arches. The circumferential wires around the mandible are sited to stabilise the fracture line. The hooks placed on the buccal surfaces of the plastic arch are used to apply IMF when the patient has recovered from the anaesthetic. The IMF is released after 4—6 weeks.

Fractures of the mandibular condyle may cause disturbance to the occlusion with deviation of the mandible to the side of the fracture. In unilateral fractures, this disturbance may correct spontaneously in a few days. If it is still present at 10 days, or where both condyles are fractured, open surgery may be required to one of the condyles to prevent an anterior open bite developing. The open bite occurs due to the vertical pull of the muscles of mastication shortening the ramus. The posterior teeth contact first and the anterior teeth remain apart. If there is a unilateral fracture, this disturbance may correct spontaneously in a few days. If it is still present at 10 days, or where both condyles are fractured, open surgery may be required to one of the condyles to prevent an anterior open bite developing. The open bite occurs due to the vertical pull of the muscles of mastication shortening the ramus. The posterior teeth contact first and the anterior teeth remain apart. Functionally and cosmetically, this is very undesirable and is almost impossible to counteract by sec-ondary procedures. Simply to fix the mandible in IMF, with or without posterior block to overcome the tendency to open bite, is insufficient. Direct surgical approaches to the condylar neck are difficult owing to the parotid gland and facial nerve lying in close proximity. Preauricular incisions combined with incisions at the lower border of the mandible do give access but reduction of the bones is difficult through these approaches. A simple and effective approach is via a tangential incision at the angle of the mandible that gives access to the bone beneath, between the facial and cervical branches of the facial nerve. The angle of the mandible is identified and the periosteum raised up both sides of the ramus as if it is the fracture line. Access to the displaced condyle is achieved by removing the posterior border of the mandible with a vertical subsigmoid cut, running from the sigmoid notch of the mandible down to the angle of the jaw. The condyle may then be removed and offered up to the excised segment of the mandible. Fractures of the zygoma may be explored through intra oral or extra oral incisions (blephoroplasty incisions) or lower con-junctival sac are used to explore fractures of the infraorbital margin. These also give access to the orbit reconstituted with bone, titanium or alloplastic material according to choice, held by wires or screws.

The principle of treatment is to restore the fragments to their original position. To achieve this, usually it is necessary to reduce the maxilla first with Rowe’s disimpaction forceps which grasp the palate between the nasal and palatal mucosa. Considerable force is sometimes required in a series of downward, forward and sideways movement to free it, particularly where the operation has been delayed. After 3 weeks, full disimpac-tion is often impossible.

With the advent of miniplates and microplates, indirect fixation with pins and halo frame is seldom used. If the fragments are multiple and the whole restored maxilla remains unstable, external fixation may be the only answer. Then the principle is that the mandible is fixed to the cranium, with the maxilla as a sandwich between the two. Cranial fixation is by a halo or supraorbital pins, and mandibular fixation is by pins inserted in the body on each side. All of the pins are con-ected together with connecting bars secured by universal joints. When the teeth of each jaw are fixed together with intermaxillary fixation (see below) the anteroposterior position of the face is likely to be correct. The vertical dimension is adjusted through the connecting bars fixed by universal joints on to the pins. This means that the jaws are fixed together during recovery, and careful attention should be given to advising the recovery staff on how to release the apparatus in an emergency.
be rotated upwards and should move freely. Any restriction in movement suggests entrapment of intra orbital tissues and the floor of orbit should be explored as for a blow-out fracture (see below). It is essential to warn the anaesthetist that this manoeuvre is being done, as it can lead to a severe bradycardia.

Should the fracture seem unstable, direct wiring or plating may be necessary. The frontozygomatic suture should be exposed by a small incision just behind the lateral part of the eyebrow and visualised. Displacements may be reduced and generally the fracture becomes stable once this fracture is fixed. Occasionally it is necessary to explore and fix fractures of the infraorbital rim (see above).

If the fragments are very unstable owing to comminution, packing the antrum via a Caldwell—Luc incision in the mouth may be necessary. The antrum should be first examined using a fibre-optic light source, with particular attention given to the orbital floor. Then, with the orbital floor reduced and protected, and the body of the zygoma supported by an assistant, the antrum may be packed from above down with a 2-inch ribbon gauze soaked in Whitehead’s varnish. Great care must be exercised not to overpack the antrum and displace the orbital contents. The incision is closed with a tail of ribbon gauze sutured into the wound to allow drainage. The pack is removed at 3 weeks.

All patients who have had operations around the orbit should be observed formally at 15-minute intervals for 9—12 hours. The condition of the eye, the pupil size and the appreciation of light should be recorded. Occasional complications arise, the most serious of which is a developing haematoma in the peri orbital tissues or the cone between the ocular muscles. Increasing exophthalmous and loss of vision constitute a postoperative emergency requiring immediate action to reduce the pressure of the haematoma.

**Blow-out fractures**

The mechanism has been explained above. The floor of the orbit is approached either through a blephoroplasty incision in the lower eyelid or through the inferior fornix. Keeping superficial to the tarsal plate of the lower lid, the infraorbital margin is identified and the periosteum raised, being careful not to displace the delicate fragments of bone constituting the fracture. The peri orbital tissues are gently separated from the bones of the fracture and freed so that no trapping remains. The apex of the orbit should not be explored for fear of damage to the optic nerve or spasm of the retinal artery. Defects of the orbital floor may be made up with bone from the cranium (see above) or the opposite antral wall, titanium mesh, or other suitably rigid materials. Reinforced silastic sheet is no longer thought adequate. The materials are fixed with wires, screws or plates and the wound is closed.

**General**

Fractures of the facial skeleton are almost always compound and prophylactic antibiotics are important. Penicillin and metronidazole singly or in combination are ideal for those patients who are not allergic. The cephalosporins are an alternative. Where there is the possibility of a CSF leak from a dural tear above a fractured cribriform plate of the ethmoid bone (Le Fort II and III), suitable antibiotics which cross the blood—brain barrier (chloramphenicol, for example) should be given to avoid the risk of meningitis or later intracranial abscess. All patients with fractures of the facial skeleton bene-fit from intraoperative and postoperative dexamethasone, to reduce swelling.

Intermaxillary fixation makes it impossible to chew. It is important that the patient receives the advice of a dietician so that high calorific value food may be taken through the IMF. It is surprising how patients find a way to take fluid and semi-solids through clenched teeth. In the badly injured, parenteral feeding may be required. It is wise to leave a nasogastric tube in place, inserted at the time of operation, for as long as food cannot be taken normally.

**Dislocation of the mandibular condyles**

Dislocation of the mandibular condyles is a relatively uncommon condition and occurs usually after a wide opening of the mouth. Occasionally it may accompany a blow to the face, particularly a blow to the jaw with the mouth already open. The patient is unable to close the mouth as the condyles have translated in front of the articular eminence and spasm of the closing muscles traps them there. It may be very painful. An attempt should be made to reduce the dislocation by manual manipulation. This is achieved by standing in front of and above the seated patient and grasping the mandible with gloved hands with the thumbs on the occlusal surfaces of the teeth, and the index and middle fingers below the lower border of the mandible. It is wise to wrap the thumbs each in a gauze square. Sudden downward and backward movement is applied bilaterally with an assistant supporting the head. If this fails, one repeat attempt concentrating on one side at a time may then succeed. Reduction may be assisted by injecting local anaesthetic around both joints. Occasionally it may be necessary to sedate the patient with intravenous midazolam or even resort to a general anaesthetic.

Surgical anatomy of the nose

The supporting structures of the nose are shown in Fig. 39.1. The paired nasal bones join in the midline with a suture and are supported by the septum, which consists of the anterior quadrilateral cartilage, the perpendicular plate of the ethmoid and the vomer (Fig. 39.2). In children the length of the nasal bone equals its width, whereas in the adult the length is three times the width. The lateral wall of the nasal cavity contains the superior, middle and inferior turbinates (Fig. 39.3). Opening on to the lateral nasal wall are the ostia of all the nasal sinuses except for the sphenoid sinus (Fig. 39.4). The nasolacrimal duct opens into the inferior meatus beneath the inferior turbinate approximately 3 cm posterior to the external nasal opening. Below the middle turbinate is the middle meatus into which the nasofrontal duct, the anterior ethmoid cells and the maxillary antrum open (Fig. 39.5). The superior meatus between the middle and superior turbinates contains the opening for the posterior ethmoid cells. The sphenoid ostium lies at this level on the anterior wall of the sphenoid sinus. The nasal cavities and sinuses are lined by respiratory epithelium. The olfactory mucosa, innervated by fibres from the olfactory nerve, lines the area of the olfactory cleft and the cribriform plate. The nasal fossae and sinuses receive their blood supply via the external and internal carotid arteries. The external carotid artery supplies the interior of the nose via the maxillary and sphenopalatine arteries. The greater palatine artery supplies the anteroinferior septum via the incisive canal. The contribution from the internal carotid artery is via the anterior and posterior ethmoidal arteries which are branches of the ophthalmic artery (Fig. 39.6). All of these arteries anastomose to form a plexus of vessels (Kiesselbach’s plexus) on the anterior part of the nasal septum. Venous drainage is via the ophthalmic and facial veins and the pterygoid and pharyngeal plexus. Intracranial drainage into the cavernous sinus via the ophthalmic vein is of particular clinical importance because of the potential for intracranial spread of nasal sepsis. The nasal cavity and sinuses have a sensory nerve supply provided by the first and second branches of the trigeminal nerve. The olfactory epithelium is supplied by the olfactory nerve. Autonomic innervation comprises sympathetic fibres to the blood vessels via the cervical and pterygopalatine ganglia. Parasympathetic fibres also synapse in the pterygopalatine ganglion before passing to the mucous glands.
Investigation

Plain X-rays are of limited value in the assessment of sinus disease. A minimum of four views namely occipitomental, occipitofrontal, submentovertical and lateral views—are required to demonstrate the paranasal sinuses adequately. Computerised tomography (CT) scanning is far superior in demonstrating sinus pathology. Coronal and axial scans are necessary for detailed assessment.

Nasal airway resistance can be assessed by means of rhinomanometry which can be performed by either active or passive techniques. It may be used to quantify pre- and post-medical and surgical treatment for nasal obstruction and for the assessment of response to treatments for rhinitis.

Both rigid and flexible naso endoscopes can be used for direct visualisation of the nasal fossa and the paranasal sinuses. Endoscopic techiques can be used for diagnosis and treatment.
Injuries to the nose are commonly sustained in fights, sporting injuries and road traffic accidents. A blunt injury of moderate force may lead to springing of the nasal septal cartilage with separation of the overlying mucoperichondrium. Bleeding into this potential space will cause a septal haematoma which may be unilateral or bilateral. The haematoma will give rise to nasal obstruction and can be easily overlooked in the presence of extensive facial injuries. It is, however, an important diagnosis not to miss because untreated, a septal haematoma will progress to abscess formation and ultimately result in necrosis of the septal cartilage. Robbed of this support the tip of the nose will collapse. A septal haematoma should be treated by incision and evacuation of the blood clot. The insertion of a small silicone drain and packing of the nasal fossa will prevent reaccumulation and encourage the mucoperichondrium to re-adhere to the septal cartilage. A broad spectrum prophylactic antibiotic should be prescribed.

A more violent blunt injury to the nose can fracture the nasal bones. This may be a simple crack of the nasal bones without displacement, but greater force may result in deviation of the bony nasal complex laterally (Fig. 39.7) or depression of the bony pyramid if the blow is directly from the front. Greater impacts from this direction may cause a comminuted fracture and widening of the nasal bones or involve the lacrimal bones causing a nasoethmoidal fracture. Lateral injuries with displacement of the nasal bones may also be associated with a C-shaped fracture of the septal cartilage and the anterior portion of the perpendicular plate of the ethmoid (Jarjavay fracture). Nasal bone fractures can extend into the lacrimal bone tearing the anterior ethmoidal artery to produce catastrophic haemorrhage. This may be delayed, occurring only as the soft-tissue swelling subsides and the torn artery opens up.

Violent trauma to the frontal area of the nose can result in a fracture of the frontal and ethmoid sinuses extending into the anterior cranial fossa. Dural tears and brain injuries are then at risk from ascending infection through the fracture line from the nose or sinuses which may progress to meningitis or a brain abscess.

Cerebrospinal fluid (CSF) rhinorrhoea is a certain sign of a dural tear. There may be associated surgical emphysema, proptosis with or without loss of vision or frontal pneumoencephalocele. Anosmia occurs in 75% of patients with these injuries, and cranial nerves II—VI may be injured. A clear discharge from the nose may be confirmed to be CSF by a simple stix test demonstrating the presence of glucose, which is not present in nasal mucus. Such injuries are managed by neurosurgical exploration to remove bone fragments, repair the skull base and close the dura. Late complications of this injury include CSF fistula, recurrent late meningitis, brain abscess, osteomyelitis and the formation of mucopyoceles.

**Management of fractured nasal bones**

Fractured nasal bones are often accompanied by extensive overlying soft-tissue swelling and bruising which may hinder the assessment of the underlying bony deformity. Reviewing the patient 4—5 days later will give time for the soft-tissue swelling to subside and make subsequent assessment of any deformity much easier. If a fracture to the nasal bones has caused a significant degree of nasal deformity then this should be corrected by manipulation of the nasal bones under general anaesthesia. This must be carried out within 10 days of the injury while the bony fragments are still mobile. The deviated nasal bones are repositioned to restore the correct alignment of the nose or, in the case of a depressed fracture, the fragments are elevated and supported if necessary with anterior nasal packing. Often a satisfactory result can be obtained by simple manipulation, but should this fail then a rhinoplasty procedure (see later) may be necessary at a later date to obtain further improvement in the appearance of the nose. Any blow to the nose may cause displacement or fracture of the cartilaginous septum giving rise to post-traumatic nasal obstruction. Unlike the nasal bones, the nasal septum cannot be manipulated back into position and requires a formal septoplasty to restore the anatomy and the patency of the nasal airways (see later).

**Nasal trauma — summary**

- Do not overlook a septal haematoma
- Displaced nasal bone fractures should be reduced within 10 days of injury
- Severe epistaxis suggests lacrimal bone fracture and anterior ethmoid artery injury
- CSF rhinorrhoea indicates fracture involving frontal or ethmoid sinuses with a dural tear
Epistaxis

Although in the majority of patients this is a relatively easy clinical problem to deal with, this may not always be the case and in certain situations the haemorrhage may be life threatening. The most common site of bleeding is from Kiesselbach’s plexus in Little’s area of the anterior portion of the septum (Fig. 39.6). The usual cause is microtrauma to these blood vessels sandwiched between the mucosa and the underlying cartilage. In young children, heavy bleeding sometimes occurs from an engorged retro-columellar vein. Less often bleeding arises from the lateral nasal wall. Anterior bleeding is common in children and young adults as a result of nose blowing or picking. In the elderly, arteriosclerosis and hypertension are the underlying causes of arterial bleeding from the posterior part of the nose. The degeneration of the muscle layer of small arteries with age and the gradual replacement with collagen and calcification hinder post-traumatic vasoconstriction and prolong bleeding. Less common causes are trauma, foreign bodies within the nose, blood diseases, disorders of coagulation and malignant tumours of the nose or sinuses. Nasopharyngeal angiofibroma is a rare condition that affects boys and may lead to massive life-threatening attacks of bleeding. Hereditary haemorrhagic telangiectasia (Osler’s disease) gives rise to recurrent multifocal bleeding from thin-walled vessels deficient in muscle and elastic tissue (Fig. 39.8).

Management of epistaxis

Bleeding from Kiesselbach’s plexus may be controlled by silver nitrate cautery under local anaesthesia. Bleeding from further back in the nose, as seen in the elderly, may require anterior nasal packing with Vaseline-impregnated ribbon gauze. The packing is inserted in layers starting on the floor of the nasal cavity. Sometimes hypoxia can be induced by nasal packing and may be exacerbated in patients with chronic obstructive airways disease. The packing is usually kept in place for 48 hours and the patient commenced on a broad-spectrum antibiotic. An alternative to anterior packing is the use of an epistaxis balloon catheter (Fig. 39.9). The catheter is inserted in the nose and the distal balloon is inflated first within the choana to secure the catheter and then the proximal balloon, which is sausage shaped, is inflated within the nasal cavity proper. These catheters are usually effective but can be quite uncomfortable.

Sometimes anterior nasal packing alone is not sufficient to control haemorrhage and posterior nasal packing may be required. This is usually carried out under general anaesthesia inserting a gauze pack into the nasopharynx, which is then secured by tapes passed through each side of the nose and tied together across a protected columella. A third tape is brought out through the mouth and taped to the patient’s cheek. The nasal fossae are then packed with anterior nasal packs. All packs are left in for 48 hours and prophylactic antibiotics are given. The tape attached to the cheek is to facilitate removal of the pack usually without a general anaesthetic.

In uncontrolled life-threatening epistaxis where the above methods have proved ineffective, haemostasis is achieved by vascular ligation. Depending on the origin of bleeding it may be necessary to ligate the internal maxillary artery in the pterygopalatine fossa and the anterior and posterior ethmoidal arteries within the orbit. An alternative measure is external carotid artery ligation above the origin of the lingual artery.

In Osler’s disease anterior nasal packing is best avoided if at all possible because it is most likely to lead to further mucosal trauma and bleeding. High-dose oestrogen induces squamous metaplasia of the nasal mucosa and has been used effectively in treating this condition. In some cases however, it may be necessary to resort to excision of the diseased nasal mucosa via a lateral rhinotomy and replace it with a split skin graft—a procedure known as septodermoplasty. It is not unknown, however, for the grafted skin to undergo similar abnormal vascular change over time.

Epistaxis — summary

- Young people bleed from the anterior septum — Kiesselbach’s plexus
- Older people bleed from the posterior part of the nose
- Silver nitrate cautery is good for controlling anterior septal bleeding
- Moderate bleeding may require anterior nasal packing
- Severe bleeding may require anterior and posterior nasal packing
- Persistent bleeding will probably require arterial ligation
Nasal polyps

Nasal polyps are benign swellings of the ethmoid sinus mucosa. Histologically polyps consist of a water-logged stroma infiltrated with eosinophils. The cause of polyp formation is unknown but it is thought that it may be related to a disorder of arachidonic acid metabolism. Nasal polyps are erroneously linked to allergic rhinitis, but many patients with allergic rhinitis never have polyps and many patients who suffer from nasal polyposis have no evidence of nasal allergy. Approximately a third of patients with nasal polyps also have asthma, while the triad of nasal polyps, aspirin allergy and asthma is not uncommon.

The vast majority of nasal polyps arises from the ethmoid sinuses, each individual ethmoid air cell giving rise to a single polyp as its swollen mucosal lining prolapses out of the air cell to hang down inside the nasal cavity. Polyps can arise from the other nasal sinuses, and a single large polyp arising from the maxillary antrum is referred to as an antrochoanal polyp. This usually fills the nose and eventually prolapses down into the nasopharynx. The diagnosis can often be made by looking into the patient’s mouth and observing the fundus of the polyp hanging down beyond the free margin of the soft palate. Ethmoid polyps are usually bilateral but when unilateral in an adult or associated with bleeding then malignancy must be excluded. Nasal polyps are unusual in children and if multiple often occur in conjunction with cystic fibrosis in 10 per cent of cases. A unilateral nasal polyp in a child must be distinguished from a meningocele or encephalocele by high-resolution CT scanning of the anterior cranial fossa.

Clinical features

Polyps cause nasal obstruction associated with watery rhinorrhea and often anosmia. They are easily identifiable within the nose as pale, semitransparent grey masses which are mobile and insensitive when palpated with a fine probe, allowing them to be distinguished from turbinate hypertrophy. Extensive nasal polyposis often gives rise to secondary pan sinusitis, by occluding the ostia and interfering with sinus ventilation. If left untreated they will eventually result in expansion of the nose and prolapse through the nasal vestibule (Fig. 39.10).

Management of nasal polyps

Polyps are best treated by surgical removal either by avulsion with a nasal snare or with a powered nasal microresector (Fig. 39.11). Antral lavage should be performed at the same time. Benign transitional cell papilloma (inverted papilloma) can be mistaken for simple nasal polyps (see later) and therefore the polyps should always be submitted for histological examination.

Polyps often recur in a seemingly random and unpredictable way. There is evidence to suggest that long-term treatment with low-dose topical nasal steroids (beta-methasone) postoperatively lessens the tendency for polyps to recur. After multiple recurrence external ethmoidectomy should be considered. Although polyp formation may still occur after the procedure, the interval between recurrences will be longer. Polyps usually shrink while a patient is taking oral steroids but recur when treatment is stopped.

Nasal polyps — summary

• Polyps are insensitive to touch
  • Transitional papilloma may be mistaken for simple polyps
• Polyps can be removed by nasal snare or powered nasal microresector
• Recurrent polyps, may require external ethmoidectomy
  • Meningocele and encephalocele should be excluded in children with polyps
• Bleeding polyps may indicate malignancy
Nasal septum

The nasal septum consists of the quadrilateral cartilage anteriorly and the bony perpendicular plate of the ethmoid and vomer posteriorly. Few, if any, people are born with an entirely straight septum and symmetrical nasal airways. In some individuals a naturally occurring deviated nasal septum gives rise to significant nasal obstruction. In others minor nasal trauma is responsible for displacement of the septum and restriction of the nasal airway (Fig. 39.12). Further encroachment of the anterior nasal airway can occur if the ventral edge of the septal cartilage is dislocated from the columella and projects into the nasal vestibule. Inferior turbinate hypertrophy is frequently seen on the concave side of a deviated nasal septum. This is particularly likely to occur after nasal injury. The physical obstruction of the nasal airway by a deviated septum is readily apparent on anterior rhinoscopy.

Septal deformity can be corrected by means of a septo-plasty procedure or by a submucus resection of the septum (SMR). In the former procedure the septal cartilage is preserved but the anatomical abnormalities giving rise to its deformity such as a twisted maxillary crest or inclination of the bony septum are corrected, permitting the septal cartilage to be repositioned in the midline with the restoration of nasal airway patency. In the SMR procedure the deformed septal cartilage is excised, while preserving a dorsal strut along with the anterior 5 mm of septal cartilage in order to support and maintain the normal shape of the nasal tip. Both operations are performed through a vertical incision of the septal mucosa with elevation of mucoperichondrial flaps.

Postoperatively, the nose is packed for 24—48 hours to prevent haematoma formation. Complications of septal surgery include septal perforation giving rise to excessive crusting within the nose, nasal obstruction and epistaxis. If too much cartilage is excised in the SMR procedure the loss of support to the dorsum of the nose may result in a saddle deformity or drooping of the tip of the nose.

Septal perforation

The causes of septal perforation are listed in Table 39.1. The commonest cause is a complication of septal surgery. Septal perforations seldom heal spontaneously. They give rise to extensive crusting at the margins of the perforation, often with mucosal bleeding. If situated towards the front of the septum embarrassing whistling can occur. Patients also often complain of a sensation of nasal obstruction.

Crusting can be controlled to a degree with nasal douches or the use of topical antiseptic creams to minimise mucosal drying. A great variety of operations has been described to close septal perforations but none of them has met with universal success. A more certain option is to occlude the perforation by inserting a sialastic biflanged prosthesis (Fig. 39.13).
Rhinitis

Rhinitis is inflammation of the nasal mucous membranes and can be of various types (Table 39.2). A clinical diagnosis of rhinitis can be made if a patient has two or more of the following symptoms: anterior rhinorrhoea, postnasal catarrh, nasal obstruction, nasal itch or irritation, and sneezing. The management of these conditions is determined largely by the type of rhinitis and the predominant symptom and lies within the province of the otolaryngologist, seldom requiring surgery and therefore not referred to further in this chapter.
External nasal deformity

Anomalies of the shape of the nose may be congenital or acquired. The latter may be the result of trauma, previous nasal surgery or destructive processes such as Wegener’s granulomatosis. Correction of a deformity of the bony nasal complex is referred to as a rhinoplasty procedure and if combined with a procedure to correct a deviation of the nasal septum the procedure is known as a septo rhinoplasty. In a standard rhinoplasty procedure the nasal bones are approached through an intercartilagenous incision between the upper and lower lateral cartilages within the nasal fossa and the soft tissues covering the nasal skeleton are elevated. Superior and lateral osteotomies are used to mobilise the nasal bones, which are then repositioned to produce a pleasing shape to the nose. This procedure can also be carried out through an external approach where the skin of the columella is divided allowing elevation of the soft tissues of the tip of the nose to provide access to the nasal bones and septum. With adequate exposure by either method a dorsal hump can be removed with hammer and chisel and a saddle nose deformity can be corrected by dorsal augmentation using either bone from the iliac crest, harvested septal cartilage or a suitably shaped silastic implant. Cosmetic deformities of the soft tissues of the tip of the nose require the specialised surgical techniques of a facial plastic surgeon.
Tumours of the nose

Benign tumours

Osteomas of the nasal skeleton are not uncommon and are usually detected on X-ray as an incidental finding. They are usually seen in the frontal and ethmoid sinuses (Fig. 39.14). Some may produce symptoms such as headache or recurrent sinusitis if the location interferes with the drainage of one of the paranasal sinuses. Plain X-rays demonstrate a calcified, well-demarcated tumour of variable size. In symptomatic individuals the osteoma can be removed via the frontal sinus or an external ethmoidectomy.

Transitional cell papilloma (inverted papilloma) can occur in both the nasal cavity and the nasal sinuses. They can be quite extensive (Fig. 39.15) and give rise to nasal obstruction and sometimes epistaxis. Although usually unilateral, red, firm and vascular they can sometimes look like simple nasal polyps, and in 25 per cent of cases the diagnosis is made by the pathologist after a routine nasal polypectomy. When large they can erode the lateral nasal wall and infiltrate the antrum and ethmoid. Calcification within the tumour may be seen on CT scanning along with sclerosis of bone at the margins of the growth. Transitional cell papilloma can undergo malignant change; synchronous lesions occur in 5—10 per cent, while metachronous lesions develop in 1 per cent of cases.

For this reason more radical surgery is employed than for simple polyps to ensure complete removal of all papillomata and will usually involve a partial maxillectomy.

Benign nasal tumours —summary

• Osteomas are frequently asymptomatic
• Transitional papilloma may undergo malignant change

Malignant tumours

Skin tumours involving the nose are not uncommon. Basal cell carcinomas (rodent ulcer) are confined to the head in 86 per cent of cases and of these 26 per cent occur on the nose. Adequate surgical excision may require some form of reconstructive flap procedure to eliminate the resulting defect. Keratinising squamous cell carcinoma is the second most common tumour of the external nose, which should be adequately excised with a generous margin of healthy skin and the defect reconstructed with a local flap. About 10 per cent of all melanomas occur in the head and neck. Wide surgical excision is mandatory, frequently requiring the skills of a plastic surgeon for reconstruction (see Chapter 13 on ‘Plastic surgery’).

The most common tumours to occur within the nasal cavity and paranasal sinuses are squamous cell carcinoma (Fig. 39.16), adenoid cystic carcinoma and adenocarcinoma. (Table 39.3). Presenting symptoms include unilateral nasal obstruction, chronic nasal discharge, which is often haemor-rhagic and offensive, and loss of skin sensation on the face (trigeminal nerve). There may be swelling of the cheek, buccal sulcus or the medial canthus of the eye and a feeling of fullness or pressure within the nose or face. Suspicious signs of invasion of neighbouring tissues include diplopia, proptosis, loosening of the teeth (Fig. 39.17), trismus, cranial nerve palsies and regional lymphadenopathy. Biopsy via nasal endoscopy will permit a tissue diagnosis, while assessment of bone erosion and the extent of the disease can be determined by CT scanning (Fig. 39.18). If invasion of the skull base is suspected then angiography will be required, and distant metastases to lung, bone, brain and liver should be excluded.

Patients with sinus or intranasal malignancy are best managed in a combined clinic where the expertise of ear, nose and throat (ENT) surgeons, maxillofacial surgeons and radiotherapists can be employed. Detailed surgical management is outside the scope of this book, but the adequacy of any surgical resection will need to be confirmed by frozen section control of soft-tissue margins. Inevitably reconstruction will require the use of myocutaneous flaps or free grafts with microvascular anastomosis. Surgery is followed by radiotherapy. At present chemotherapy is reserved for palliation of inoperable tumours.

Malignant nasal tumours —summary

• Skin cancer of the nose requires wide excision and expert reconstruction
• May present late with signs of invasion
• Should be managed by ENT and maxillofacial surgeons with a radiotherapist
Paranasal sinus infection

Patients with paranasal sinusitis will usually only be referred to an ENT surgeon if they have failed to respond to conservative treatment with antibiotics or if complications are developing.
Maxillary sinusitis

Patients with persistent maxillary sinusitis have postnasal discharge, headache which is variable in severity and location, nasal obstruction and usually general malaise. The nasal mucosa is swollen and bathed in mucopurulent secretions. Plain sinus X-rays may show a fluid level in the antrum or complete opacity (Fig. 39.19).

The most likely causative organisms are *Streptococcus pneumoniae* and *H. influenzae*. As the infection becomes chronic the likelihood of anaerobic infection increases. The consideration of a *Branhamella catarrhalis* as a primary pathogen and the possibility of 3-lactam-producing strains of *H. influenzae* will also influence the choice of antibiotic.

Adequate penetration of antibiotics into chronically inflamed sinus mucosa is doubtful, and therefore treatment may need to be given for several weeks. Topical nasal decongestants such as ephedrine nasal drops will often encourage the sinus to drain. About 10 per cent of infections of the maxillary antrum are due to dental sepsis from anaerobic organisms. The resultant mucopurulent nasal secretion has a foul smell and taste. Maxillary sinusitis from any cause may, through irritation of the superior alveolar nerve, give rise to referred upper toothache.

Antral lavage under local or general anaesthesia allows confirmation of the diagnosis and provides the opportunity to obtain samples for bacteriology. The antrum is entered through the inferior meatus below the inferior turbinate where the bone separating the antrum from the nasal fossa is extremely thin and can be penetrated by a trocar and cannula (Fig. 39.20).

If infection has caused a significant degree of inflammation and fibrosis of the lining of the antrum then the natural ostium may be completely obstructed. In this situation an intranasal inferior meatal antrostomy may be fashioned to facilitate drainage from the antrum. Alternatively, intranasal endoscopic techniques may be employed to create a middle meatal antrostomy. The middle turbinate is lifted and the infundibulum is located and enlarged anteriorly, sometimes requiring the excision of the anterior end of the uncinate process under direct endoscopic control. The antrum itself can be inspected through the antrostomy using a combination of 30degree and 70degree rigid endoscopes (Fig. 39.21). For persisting disease a Caldwell—Luc radical antrostomy may be performed, whereby the entire diseased maxillary sinus mucosa is removed through an opening in the anterior wall of the antrum via an incision in the upper gum. Once the diseased antral mucosa is removed a large window is created in the lateral nasal wall allowing drainage into the inferior meatus.

Endoscopic nasal surgery allows a more functional approach to disease’s of the paranasal sinuses and the indications for radical antrostomy are on the decline. Areas of chronically diseased mucosa and infected granulation tissue hinder mucociliary transport and lymphatic drainage leading to retained secretions and the perpetuation of infection. Intranasal endoscopic operations permit the precise removal of diseased mucosa with minimal trauma to adjacent tissues. By removing scar tissue from the narrow recesses within the nose, ventilation and internal drainage can be restored allowing permanent resolution of the chronically inflamed mucosa. In this way precise endoscopic surgery directed towards the middle meatus and the ethmoid system restores the normal physiological function of the paranasal sinuses with minimal mucosal resection (Fig. 39.22).

Complications of maxillary sinusitis

Untreated chronic maxillary sinusitis can lead to acute cellulitis or Osteitis and rarely, if there is a breach in the roof of the antrum, infection may spread into the orbit.

Maxillary sinusitis — summary

- Commonest organisms *S. pneumoniae* and *H. influenzae*
- May result from dental sepsis
- Antral lavage is diagnostic and therapeutic
- Intranasal antrostomy or endoscopic middle meatal antrostomy may be needed
If treated promptly with antibiotics and topical nasal decongestants this type of sinus infection is unlikely to be a long-term problem. If allowed to persist chronic frontoethmoiditis gives rise to mucopurulent catarrh, frontal headaches, pressure feeling between the eyes, nasal obstruction and hyposmia. Nasal endoscopy will confirm pus issuing from the middle meatus. The ethmoid sinuses can only be properly assessed radiologically by CT scanning, including coronal as well as axial sections. If frontoethmoiditis fails to settle with conservative treatment then frontal drainage may be required. The frontal sinus is entered through its anterior wall via a small incision below the medial end of the eyebrow. After pus is drained a small sialastic tube is left in the wound to allow regular irrigation of the sinus. Where the disease is more extensive intranasal endoscopic ethmoidectomy may be required. Removal of the uncinate process provides access to the osteomeatal complex, so that if necessary the entire ethmoid complex can be cleared and the frontonasal recess opened. If endoscopic nasal equipment is not available then the tried and tested radical external ethmoidectomy through a Lynch—Howarth incision provides excellent access to the frontal, ethmoid and sphenoid sinuses. Chronic frontal sinus disease can be cleared by means of an osteoplastic flap procedure. Using an X-ray template, the boundaries of the frontal sinus are marked out and a fissure burr is used to cut through the frontal bone along the outline of the sinus. The front wall of the sinus is then prised downwards and forwards to produce an inferiorly based osteoplastic flap. The diseased lining can then be removed and the sinus obliterated with fat taken from the anterior abdominal wall.

Complications of frontoethmoiditis

These are potentially extremely serious. Quite often infection can spread to involve the other sinuses because of the close proximity of their ostia. Orbital cellulitis is not an uncommon complication (Fig. 39.23) and may progress to an extra-periosteal abscess, which typically displaces the eyeball down forwards and laterally. If unrecognised and untreated this can lead to blindness. Treatment consists of intravenous broad-spectrum antibiotic and an orbital decompression by an external approach. Orbital cellulitis may progress to cavernous sinus thrombosis and septicemia. Spread of infection by direct bone penetration or via the diploic veins can give rise to either extradural, subdural or frontal lobe abscess formation.

Frontoethmoidal sinusitis — summary

• May require open surgical drainage
• Chronic frontal sinusitis may require obliterative osteoplastic flap procedure
• Orbital complications may threaten sight
• Intracranial complications include cerebral abscess and cavernous sinus thrombosis
Further reading

The external ear consists of the pinna and the ear canal. The pinna is made of yellow elastic cartilage covered by tightly adherent skin. The external and middle ear develop from the first two branchial arches. The external ear canal is 3 cm in length, the outer two-thirds is cartilage and the inner third is bony. The skin on the lateral surface of the tympanic mem-brane and the inner two-thirds of the ear canal is highly specialised. It does not simply shed like the skin from the rest of the body. It migrates outwards from the tympanic membrane and along the ear canal. As a result of this migration most people’s ears are self-cleaning. Disorders of skin migration can result in ear disease (e.g. cholesteatoma). The external canal is richly innervated and the skin is tightly bound down to the perichondrium so that oedema in this region results in severe pain.

The lymphatics of the external ear drain to the retro auricular, parotid, retropharyngeal and deep upper cervical lymph nodes.

The middle ear contains the ossicles. Laterally it is bound-ed by the tympanic membrane, medially by the cochlea, anteriorly by the eustachian tube and posteriorly it communicates with the mastoid air cells (Fig. 40.1). Entwined in this tiny space is the facial nerve which pursues a tortuous course through the middle ear and exits the skull base at the stylomastoid foramen. Knowledge of the anatomy of the middle ear is important because infection can spread through it to the cranial cavity which lies millimetres away.

The tympanic membrane has three layers: an inner mucosal layer, a dense fibrous middle layer and the outer stratified squamous epithelium (skin). The upper portion that lies above the lateral process of the malleus is called the pars flaccida. The lower portion, making up the majority of the drum, is called the pars tensa (Fig. 40.2).

The tympanic membrane and ossicles act as a transformer system converting vibrations in the air to vibrations within the fluid-filled inner ear (perilymph). The evolution of the middle ear is interesting. Fish do not have one, whereas amphibians (e.g. salamanders) have a single strut for an ossicle. At an air—water interface there is a 30 decibels loss of sound energy. The mammalian middle ear overcomes virtually all of this potential loss of sound energy.

The inner ear comprises the cochlea and vestibular laby-rinth (saccule, utricle and semicircular canals). These struc-tures are embedded in dense bone called the otic capsule. The cochlea is a minute spiral of two and three-quarter turns. Within this spiral, perilymph and endolymph are parti- tioned by the thinnest of membranes (Reissner’s membrane). The endolymph has a high concentration of potassium similar to intracellular fluid, and the perilymph has a high sodium concentration similar to extracellular fluid. Maintenance of the ionic gradients is an active process and is essential for neuronal activity.

There are approximately 15 000 hair cells in the human cochlea. They are arranged in rows of inner and outer hair cells. The inner hair cells act as mechanicoelectric transducers, converting the acoustic signal into an electric impulse. The outer hair cells contain contractile proteins and have an efferent nerve supply from the brain. They serve to tune the basilar membrane on which they are positioned.

Each inner hair cell responds to a particular frequency and when stimulated it depolarises and passes an impulse to the cochlea nuclei in the brainstem.

The vestibular labyrinth consists of the semicircular canals, the utricle and saccule, and their central connections. The three semicircular canals are arranged in the three planes of space at right angles to each other. As in the auditory system, hair cells are present. In the lateral canals the hair cells are embedded in a gelatinous cupula, and shearing forces, caused by angular movements of the head, produce hair cell movements and generate action potentials. In the utricle and saccule the hair cells are embedded in an otoconial membrane which contains particles of calcium carbonate. These respond to changes in linear acceleration and the pull of gravity.

Impulses are carried centrally by the vestibular nerve, and connections are made to the spinal cord, cerebellum and external ocular muscles.

The sensory nerve supply of the ear is complex. The exter-nal ear is supplied by the auriculotemporal branch of the trigeminal nerve (V), and this supplies most of the anterior half of the pinna and the external auditory meatus. The greater auricular nerve (C2,3), together with branches of the lesser occipital nerve (C2), supply the posterior part of the pinna. The VIIth, IXth and Xth cranial nerves also supply small sensory branches to the external ear; this explains why the vesicles of herpes zoster affecting the VIIth nerve appear in the concha (see Fig. 40.29 later). The middle ear is supplied by the glossoopharyngeal nerve (IX).

This complicated and rich sensory innervation means that referred otalgia is common and may originate from the nor-mal area of distribution of any of the above nerves. A classic example is the referred otalgia caused by a malignancy in the pyriform fossa of the pharynx or a cancer of the larynx.

Anatomy of the ear

• Referred otalgia has many causes (e.g. cancer of the larynx)
• Middle ear is intimately related to the cranial cavity
• The VIIth nerve has a tortuous course through the ear
Conditions of the external ear

Congenital anomalies

Congenital anomalies can range from total absence of the ear through to mild cosmetic deformities such as tiny accessory auricles or skin tags. External ear anomalies can be isolated or may be associated with middle ear deformity. The external and middle ear originate from the first and second branchial arches, whereas the cochlea is of neuroectodermal origin. This means that an individual may have no pinna or ear canal but a normal cochlea may well be present. In these circumstances, sound can be transmitted from a hearing aid connected to an osteo-integrated peg that is screwed into the mastoid bone. (Tab 40.1)

Children who have a significant deformity of the pinna (microtia) can be helped with osteointegrated implants to which a prosthetic ear is connected (Fig. 40.3). The ear can be unclipped prior to playing violent sport (e.g. rugby) and this unsettles the opposition. Preauricular sinuses are a common congenital abnormality and occasionally need excising because of recurrent infections and discharge. The sinus usually ends near the external canal but occasionally the track is very extensive and is closely related to the facial nerve, which makes life exciting.

Prominent ears are a common deformity which usually results from the absence of the antihelix curve. Various carilage scoring methods are available to correct this deformity.

Trauma

Trauma often affects the external ear. A haematoma of the pinna occurs when blood collects between the pen-chondrium and the cartilage. The cartilage receives its blood supply from the perichondrial layer and will die if the haematoma is not evacuated (cauliflower ear). An extensive excision, under general anaesthetic, with a pressure dressing and antibiotic cover is recommended (see Fig. 40.4).

Foreign bodies in the ear canal need to be treated with the greatest respect. If an object is not simply removed at the first attempt, it is better to do it with the aid of a microscope and general anaesthesia. An active 2-year-old with a bead in the ear can be a formidable opponent (Fig. 40.5).

Inflammatory disorders

Inflammatory disorders of the external ear are extremely common. Otitis externa frequently presents to general prac-tice and to ear, nose and throat (ENT) surgeons. There is generalised inflammation of the skin of the external auditory meatus. It can occur as an acute episode or can run a more chronic course. The cause is often multifactorial but includes general skin disorders, such as psoriasis and eczema, and trauma. Common pathogens are pseudomonas and staphylococcus bacteria, and amongst fungi, candida and aspergillus. Once the skin of the ear canal becomes soggy and oedematous, skin migration stops and debris collects in the ear canal which acts as a substrate for the pathogens. The hallmark of acute otitis externa is severe pain (evidently on a par with childbirth). Unlike otitis media, movement of the pinna elicits pain. The condition is often bilateral.

The initial treatment is with topical antibiotics and steroid ear drops, together with analgesia. If this fails meticulous removal of the debris with the aid of an operating micro-scope is required. Regular cleaning of the canal, together with topical steroids, needs to be continued until normal skin migration resumes. If fungal infection is present it can easily be recognised by the presence of hyphae and spores within the canal (Fig. 40.6). Fungal infection causes irritation and itch, and the treatment is meticulous removal of the fungus and any debris, as well as stopping any concurrent antibiotics.

Systemic antibiotics are rarely required for otitis externa but should be used if cellulitis of the pinna occurs (Fig. 40.7).

Necrotising otitis externa is a rare but very important con-dition. It presents as a severe, persistent, unilateral otitis externa in an immunocompromised individual, for example it is important to think of the diagnosis in an elderly diabetic. Osteomyelitis of the skull base occurs and usually the infect-ing organism is Pseudomonas aeroginosa. Several cranial nerves (VII, IX and X) may be destroyed by the progressing infection. Intensive systemic antibiotic treatment is required and the disease process is monitored by high-resolution imaging.

A furuncle of the external ear is an infection of a hair follicle and is due to a staphylococcal infection. Moving the pinna causes extreme pain. Local treatment of the ear canal (oto-wick and steroid drops) together with systemic antibiotic therapy is required.

Neoplasms

Benign neoplasms

Benign neoplasms of the external ear are common if osteomas are included. These arise from the bone of the ear canal in individuals who have done a lot of swimming in cold water. No treatment is required unless they obstruct the migration of skin out of the canal. Other benign tumours include papillomas and adenomas.

Malignant primary tumours

Malignant primary tumours of the external ear are either basal cell or squamous cell carcinomas (Fig. 40.8). Both may present as ulcerating or crustulating lesions which grow slowly and may be ignored by elderly patients. Squamous cell carci-nomas may metastasise to the parotid and/or neck nodes and need radical surgical clearance. The ear canal may be invaded by tumours from the parotid and postnasal space carcinoma which ‘creep’ up the eustachian tube. All resectable malig-nant tumours of the ear are treated primarily with surgery with or without the addition of radiation therapy.

The external ear

• Otitis externa responds to topical medication
• Unilateral otitis externa in a diabetic may be fatal
• Auricular haematoma needs a robust incision, drainage and pressure dressing
• Think osteo integration for congenital malformations
Conditions of the middle ear (Tab 40.2)

Congenital anomalies

Congenital anomalies of the middle ear may be isolated or may be associated with other ear or general congenital deformities. There is a number of branchial arch syndromes — for example Pierre Robin’s syndrome, craniofacial dysostosis, Down’s syndrome and Treacher Collins’ syndrome. If there is an external ear abnormality, it should raise suspicion of an underlying middle ear deformity. Middle ear deformity can be assessed by high-resolution computerised tomography (CT) scanning and, if the inner ear is normal, reconstructive surgery of the middle ear can be very successful.

Trauma

Trauma to the middle ear can result in a perforated tympanic membrane (Fig. 40.9a). Such perforations usually heal spontaneously (Fig. 40.9b). Trauma can result in ossicular discontinuity and typically it is the incus that is displaced. Various operations termed ‘tympanoplasties’ are available to reconstruct the damaged ossicular chain and repair the tympanic membrane if necessary.

Inflammatory disorders

The most common inflammatory condition of the middle ear is acute suppurative otitis media. It is extremely common in childhood and is characterised by purulent fluid in the middle ear. Mastoiditis may be associated with otitis media because the mastoid air cells connect freely with the middle ear space. The tympanic membrane is hyperemic and bulges owing to pressure from the pus in the middle ear (Fig. 40.10). The child suffers extreme pain until the tympanic membrane bursts. The most common infecting organisms are Streptococcus pneumoniae and Haemophilus influenzae. Appropriate systemic antibiotics should be given for 10 days.

The incidence of acute mastoiditis has diminished with the widespread use of antibiotics for otitis media. Sometimes, however, a child will have had a number of courses of anti-biotics, none of which completely resolves the middle ear infection. In such cases the pain and swelling behind the ear may not be quite so apparent as in Fig. 40.11. When mastoiditis is present, if the tympanic membrane can be seen, there is always a rag in the posterior superior part of the drum. (Conversely, a normal tympanic membrane excludes mastoiditis.) Treatment requires hospital admission and intensive parenteral antibiotics. If this does not resolve the infection quickly a cortical mastoidectomy is required, together with a myringotomy.

Mastoiditis

* Sequelae of acute otitis media
* May be masked by antibiotics
* Requires intensive antibiotics and/or drainage

Otitis media with effusion (glue ear) is very common with the majority of children experiencing at least one episode of it during development. Many factors have been implicated, although it is primarily thought to be due to poor eustachian tube function. Oxygen is continually being absorbed by the middle ear mucosa and this results in a negative middle ear pressure unless the eustachian tube opens to replenish the air. This negative middle ear pressure initially results in transudation of fluid into the middle ear space (Fig. 40.12). If the hypoxia continues, a mucoid exudate is produced by the glands within the middle ear mucosa. This sticky exudate is referred to as ‘glue ear’.

The following symptoms may be associated with glue ear:

* hearing impairment which often fluctuates;
* delayed speech;
* behavioral problems;
* recurrent ear infections — this occurs because the exudate is an ideal culture medium for microorganisms;
* reading and learning difficulties at school.

If these symptoms are present for a short time only, it is likely that no long-term sequelae will develop. However, if symptoms persist, particularly a long-term bilateral conductive hearing loss, the child will miss out on educational opportunities and may not fulfill his or her academic potential. The otoscopic findings of exudative glue ear are of a dull drum that is immobile on pneumatic otoscopy (Fig. 40.13). The tympanic membrane is retracted and radial blood vessels may be present (Fig. 40.14). Of children first presenting with bilateral glue ear, 50 per cent of the effusions will resolve spontaneously within 6 weeks of onset. Initially, a ‘wait and watch’ policy is therefore appropriate. If the bilateral glue ear persists with a significant hearing loss then treatment is required.

There is no substantial evidence for medical treatment. Use of the Otovent device (Fig. 40.15) may improve eustachian tube function and is worth trying while waiting for resolution of the effusion. However, surgical intervention is the only effective way of curing glue ear. Both ventilation tube (groin-mets) and adenoidectomy are effective. The controversy is not whether surgery works but when to intervene. Insertion of ventilation tubes and/or an adenoidectomy require a general anaesthetic. The ventilation tube is placed in the anterior inferior portion of the tympanic membrane because there is no important clockwork behind this part of the drum. The ventilation tubes stay in position for approximately 6—18 months and are then extruded because of the migratory behaviour of the tympanic membrane. There is no reason why children with ventilation tubes should not be allowed to swim (Fig. 40.16).

Otitis media with effusion (glue ear)

* Very common, peaks at 18 months and 5 years
* Majority of children need no treatment
* Prolonged hearing loss treated with ventilation tubes and/or adenoidectomy

A middle effusion in adults is relatively rare and when it occurs does not usually last long. The condition is often associated with an upper
Otosclerosis

A per-sistent unilateral effusion in an adult should always be viewed with suspicion. A nasopharyngeal carcinoma may cause the effusion by blocking the opening of the eustachian tube in the postnasal space. This is the most common carcinoma in males in southern China.

**Chronic suppurative otitis media**

Chronic suppurrative otitis media (CSOM) is classified into two types: tubotympanic disease, in which there is a perforation of the pars tensa; and atticocentral disease, in which a retraction pocket develops from the pars flaccida.

CSOM of the tubotympanic type. CSOM of the tubo-tympanic type can result from trauma or infection. When perforated the tympanic membrane usually repairs itself, but occasionally the outer layer of the tympanic membrane fuses with inner mucosa and a chronic perforation results (Fig. 40.17). With this type of disease the patient's main symptoms are of an intermittent or chronic mucoid discharge associated with a mild conductive hearing loss. It is rare for this type of disease to be associated with intracranial complications.

A diagnosis is made on otoscopy and the tuning forks usually suggest a conductive hearing impairment. The first-line treatment is topical antibiotic and steroid drops, and on occasion microsuction. If medical treatment fails, the patient may request an operation to graft the tympanic membrane in order to give a dry ear. This operation is termed a myringoplasty (type I tympanoplasty). The edges of the perforation are freshened and a small piece of temporalis fascia is inserted under the tympanic membrane to graft the drum. The raw epithelial edges then grow across the graft to repair the tympanic membrane.

CSOM of the atticotympanic type. CSOM of the attico-antral type is important because of the complications associated with it. Cholesteatoma is the alternative name and means a cyst or sac of squamous epithelium that is present in the attic part of the middle ear. The exact aetiology of cholesteatoma is not known, although poor eustachian tube function is implicated (e.g. patients with cleft palates have relatively poor eustachian tube function and have a higher incidence of cholesteatoma).

A retraction pocket develops in the pars flaccida and, if the squamous epithelium cannot migrate out of this pocket, a cholesteatoma results. The expanding ball of skin causes a low-grade osteomyelitis which results in the release of fatty acids from the bone. This gives the discharge its characteristic faecal smell. Invariably the discharge is accompanied by hearing loss and mild discomfort. The patient may simply put up with the symptoms until a severe complication occurs.

The hearing loss that is caused by cholesteatoma may be conductive due to erosion of the incus or sensori neural due to direct erosion of the cochlea or migrations of toxins into the inner ear. Vestibular symptoms may occur because of erosion of the semicircular canals or the migration of toxins into the vestibule. Pressure or erosion of the facial nerve is relatively unusual.

The close proximity of the middle ear and mastoid to the middle and posterior cranial fossae means that intracranial sepsis can result from chronic ear disease. The infection spreads to the dura via emissary veins which connect the middle ear mucosa to the dura or by direct extension of the disease through the bone. Meningitis, extradural, subdural or intracerebral abscess, or a combination of these may occur. The main causes of intracranial sepsis in the UK are chronic ear disease and chronic sinus disease.

Diagnosis should be suspected on otoscopy (Fig. 40.18). Pus, crusts, granulations or a whitish debris in the attic are hallmarks of the disease. Examination under the microscope, audiometry and, sometimes, CT scanning are indicated.

The treatment is surgical and follows the principle of exposing the disease, excising the disease and then exteriorising the affected area. Two commonly applied operations for this disease are an atticotomy and a modified radical mastoidectomy.

An atticotomy or modified radical mastoidectomy is performed by making an incision behind the ear (post auricular), or between the tragus and the pinna (end auricular). The attic part of the bony ear can is drilled away and the retraction pocket is followed back into the mastoid until the end of the disease is found. An attempt is made to excise totally the pocket and then the resulting cavity is usually lined with temporalis fascia. A mastoid cavity heals with normal skin that does not migrate, and for this reason patients with a mastoid cavity need to be seen in an out-patients' clinic on a regular basis. Any skin that collects in the mastoid cavity needs to be removed with the aid of a sucker and a microscope (Fig. 40.19).

**Chronic suppurative otitis media (CSOM)**

- In tubotympanic CSOM there is a perforated tympanic membrane and frequently a mucoid discharge
- Atticoantral CSOM:
  - Is skin in an attic retraction? = cholesteatoma
  - Presents with hearing loss and smelly discharge
  - Is a common cause of intracranial sepsis

Tuberculous otitis media is an important cause of suppuration in some countries. The diagnosis should always be considered in any ear which fails to respond to standard therapy. A swab for appropriate culture studies, coupled with chest radiography, will usually confirm the diagnosis.

Otosclerosis is a condition in which new abnormal spongy bone is laid down in the dense otic capsule. Of particular importance is the bone that is laid down around the footplate of the stapes which impedes the mobility of the stapes and results in a conductive hearing loss (Fig. 40.20). Toxins released from the new bone formation may also cause a gradual sensorineural hearing loss. Otosclerosis is more common in women, and in 50 per cent of patients there is a family history. The typical presentation is of a conductive hearing loss in a young woman with the condition being exacerbated by the hormonal flux of pregnancy. A similar type of stapes fixation occurs in osteogenesis imperfecta and is known as Van der Hoeve's syndrome. Otosclerosis is often bilateral. A diagnosis should be suspected in any patient with a conductive hearing loss and a normal tympanic membrane.

The treatment options are simple reassurance, a hearing aid or a stapedotomy operation. In the stapedotomy operation, the stapes crura are removed and a small hole is drilled in the fixed stapes footplate. A vein graft is then inserted over the hole and a piston linking the incus to the vein graft is delicately placed in position (Fig. 40.21). In 90 per cent of cases the operation is highly successful, but rare complications include severe sensorineural hearing loss and balance disturbance.

- Hearing aid;
- Stapedotomy

Neoplasms

Neoplasms of the middle ear are rare, the most common being a glomus tumour (Fig. 40.22). Glomus tumours arise from nonchromaffin paraganglionic tissue. The carotid body tumour arising in the neck is an example of this type of tumour. In the temporal bone three types of glomus tumour are recognised and classification depends on the location:

- glomus tympanicum (arising in the middle ear),
- glomus jugulare (arising next to the jugular bulb),
- glomus vagal (skull base).

Pulsatile tinnitus is a classic symptom of these tumours. Hearing loss occurs and may be either conductive or sensorineural, and paralysis of the VIIth, IXth, Xth, XIth and/or XIIth nerves may occur. The classic sign is a cherry-red mass lying behind the tympanic membrane. An audible bruit may be heard with a stethoscope over the temporal bone. The treatment of choice is preoperative embolisation followed by surgical excision. Radiotherapy is also effective.

Squamous cell carcinoma may also occur within the middle ear. It usually presents with deep seated pain and a blood-stained discharge. The facial nerve may be paralysed. Squamous carcinomas usually arise in a chronically discharging ear and can certainly arise in a chronically infected mastoid cavity. Radical surgical excision with or without radiotherapy provides the only chance of cure.
Conditions of the Inner ear (Tab 40.3)

Congenital

Congenital inner ear disorders may be associated with external or middle ear abnormalities or exist on their own. The most common anomaly is dysplasia of the membranous labyrinth, although dysplasia of the bony labyrinth and even total aplasia of the ear may occur. Intrauterine infections, including rubella, toxoplasmosis and cytomegalovirus, can cause inner ear damage. Perinatal hypoxia, jaundice and pre-maturity are also risk factors for a hearing loss. After birth, meningitis may cause profound sensorineural hearing loss.

If a child’s parents suspect a hearing impairment it is important to believe them, especially when clue ear has been excluded. In children in whom there is a suspicion of sensorineural hearing loss, brainstem evoked audiometry is used to establish hearing thresholds (Fig. 40.23). If some hearing is present, the early fitment of hearing aids can maximise the neural plasticity that is present in the developing brain. If a child has a profound hearing loss, then early intervention with a cochlea implant may be appropriate (Fig. 40.24). Most cases of profound sensorineural hearing loss are due to loss of cochlear hair cells so that an implant inserted through the round window can selectively stimulate the cochlear neurons which usually remain intact.

Degenerative

Presbycusis, a degenerative disorder, is a term used to describe the hearing loss of old age. It is characterised by a gradual loss of hearing in both ears, with or without tinnitus. The hearing loss usually affects the higher frequencies and a classical audiogram is shown in Fig. 40.25.

The consonants of speech lie within the high-frequency range which makes speech discrimination difficult. Examination of an elderly person's cochlea shows loss of hair cells, particularly at the basal turn of the cochlea. With age the dynamic range of hearing is also reduced so that elderly people often find loud noises uncomfortable. This phenomenon is known as ‘recruitment’.

Many patients with presbycusis are concerned that they may lose their hearing completely and need reassurance. Hearing aid technology has improved dramatically and most patients now benefit (Fig. 40.26). Care and attention to detail when fitting the hearing aid are essential, together with monitoring the patient’s progress. If this does not occur the hearing aid ends up in the bedroom drawer.

Tinnitus describes an abnormal noise that appears to come from the ear or within the head. It may have an extrinsic cause, for example the pulsatile tinnitus of a glomus jugulare tumour. Usually, however, the tinnitus is generated within the cochlea, and most people will experience tinnitus at some time in their life.

Tinnitus frequently accompanies presbycusis, as well as any condition that damages the inner ear structures. Most individuals adapt to the presence of tinnitus but in some patients it proves intrusive. Reassurance and relaxation therapy are highly effective, as is a hearing aid for patients who also have presbycusis. An ENT surgeon who was a keen fisherman found that he could not hear his tinnitus when fishing next to a waterfall. From this observation tinnitus maskers have been developed (Fig. 40.27). A masker provides a similar noise to the tinnitus and ‘blanks it out’.

Trauma

Trauma to the inner ear can be caused by noise or direct injury. Hair cells within the cochlea are damaged by sudden acoustic trauma (blast injury or gun fire) or by prolonged exposure to excessive noise. The sensorineural hearing loss that results is greatest at high frequencies (particularly 4000 Hz) and is often accompanied by tinnitus (Fig. 40.28). The law in the UK requires that workers are protected from noise, but in a disco an individual relies on common sense!

The otic capsule is the hardest bone in the body but if trauma to the head is severe temporal bone fractures may occur. These tend to be either longitudinal (80 per cent) or transverse (20 per cent). Transverse fractures usually involve the labyrinth and lead to a sensorineural hearing loss which is permanent. Profound vertigo occurs initially followed by gradual compensation. In about 50 per cent of cases there is an associated facial nerve paralysis. When assessing a severely injured patient, it is important to record the facial nerve function and, in particular, whether any facial weakness is partial or total. Total facial paralysis immediately following a head trauma suggests a major injury to the nerve and under certain circumstances exploration of the facial nerve to decompress it or repair it may be appropriate. Longitudinal fractures usually spare the labyrinth but frequently involve the external meatus and roof of the middle ear. Important physical findings that may accompany a skull base fracture include a haematoma over the mastoid bone (Battle’s sign), blood in the external ear or a laceration along the roof of the external canal. Cerebrospinal fluid (CSF) otorrhoea or CSF rhinorrhoea (if the tympanic membrane is intact) may occur. A conductive hearing loss may be present because of fluid in the middle ear or disruption of the ossicular chain. A high-resolution CT scan is required to assess skull base fractures.

Facial paralysis

• Think complete or partial
• Protect the eye
• Otoneurological examination to find cause
• Early treatment with steroids and/or antiviral therapy dependent on aetiology
Barotrauma is a rare cause of a sudden sensorineural hearing loss (SNHL) or acute vestibular disturbance. Rapid changes in pressure across the labyrinthine membranes may occur with diving or flying and may allow air to be forced into the cochlea. Any individual with a sudden sensorineural hearing loss requires urgent hospital admission, and in those with a history of barotrauma it may be appropriate to raise the tympanic membrane and to search for a leak of pen-lymph in the region of the oval or round window.

Drug ototoxicity is a form of trauma that may damage the inner ear. Some drugs differentially affect the cochlea causing hearing loss and tinnitus while others pick out the vestibular system causing vertigo. Aminoglycosides are well known to be ototoxic, as is cisplatinum.

Recognition of risk factors,

such as poor renal function in patients being treated with aminoglycosides, is most important. Although many topical ear drops contain aminoglycosides, there is little evidence that such topical treatment causes sensorineural hearing loss if used for short periods.

Benign paroxysmal positional vertigo (BPPV) may follow head or neck trauma. Vertigo is an illusion of movement and BPPV is characterised by intermittent attacks of vertigo that occur when the head is moved in a certain position. Typically the vertigo only lasts for a few seconds and is not associated with other otological symptoms. Positional testing can evoke nystagmus and helps in the diagnosis of this condition. The condition is usually self-limiting and special manoeuvres described by Epley help the majority of patients (Fig. 40.29).

Vascular occlusion

A reduction in labyrinthine blood flow with associated hypoxia is the most likely cause for most cases of sudden onset of severe sensorineural
hearing loss. All patients with a sudden sensorineural hearing loss should be referred immediately for specialist treatment. The treatment consists of bed rest, steroids and, in some centres, the administration of Carbagene (an oxygen and carbon dioxide mixture). Five per cent of acoustic neuromas present with a sudden sensorineural hearing loss and therefore radiological investigation, preferably with magnetic resonance imaging (MRI), is required to exclude this tumour.

Inflammatory disorders

Inflammation caused by a viral infection is thought to account for acute vestibular failure (vestibular neuritis). This condition is characterised by a sudden onset of vertigo. The vertigo is so severe that the patient often takes to his or her bed for between 2 and 5 days. Central compensation then occurs, although recurring episodes of vertigo for up to 18 months can occur. This is thought to be due to incomplete compensation for the original vestibular damage.

The aetiology of Ménière’s disease is not known. The condition is characterised by a triad of symptoms. Intermittent attacks of vertigo, a fluctuating sensorineural hearing loss and tinnitus. The patient often has a sensation of pressure in the affected ear before an attack. The hearing loss typically affects the lower frequencies and is virtually the only type of sensorineural hearing loss that fluctuates. The time-course of the vertigo characteristically lasts between 30 minutes and 6 hours. It is often accompanied by nausea and vomiting. Although the cause of the condition is unknown, the pathology is well documented. There is an excessive accumulation of endolymphatic fluid (hydrops) and it is thought that the distension of the endolymphatic compartment may rupture Reissner’s membrane which leads to mixing of endolymph and perilymph. This is the basis for the cochlear—vestibular failure which characterises the condition. The investigations include pure tone audiometry, electrophysiology and MRI scan if available. The latter is required to exclude an acoustic neuroma which may mimic the symptoms of Ménière’s disease.

Viral infections that involve the facial nerve are possibly one of the most common causes of facial weakness (80 per cent). Bell’s palsy results from viral infection of the facial nerve. The nerve swells and is compressed in its labyrinthine portion as it passes from the internal auditory meatus towards the middle ear. If the patient presents within the first 48 hours, treatment with high-dose steroids is appropriate. Not all facial nerve palsies are due to viral infection and a thorough oto-neurological examination is required. The facial nerve can be damaged within the brainstem at the cerebellopontine angle, within the internal auditory meatus, within the middle ear, at the skull base and within the parotid. It is essential to consider these potential sites of facial nerve damage in any patient with VIIth nerve paralysis.

Ramsey Hunt’s syndrome is caused by herpes zoster virus. It is characterised by a facial palsy and is often associated with facial pain and the appearance of vesicles on the ear drum, ear canal and pinna (Fig. 40.30). Vertigo and sensorineural hearing loss (VIIIth nerve) accompany it. Treatment with aciclovir is effective if given early.

Metabolic causes

The metabolic causes of inner ear damage include diabetes mellitus and thyroid disease, both of which may cause sensorineural hearing loss.

Neoplasms

Tumours of the inner ear are uncommon but can present with sensorineural hearing loss, tinnitus and vertigo. Acoustic neuromas, which are actually Schwannomas of the vestibular division of the VIIIth nerve, are the most common, followed by meningiomas. Acoustic neuromas grow slowly and somewhat unpredictably and as they expand can cause cranial nerve palsies, brainstem compression and raised intracranial pressure. The early symptoms are a unilateral sensorineural hearing loss or unilateral tinnitus, or both. It is important to diagnose these tumours early and remove them when they are small. The morbidity and mortality from surgery is directly related to tumour size. If the tumour is removed when it is small, there is an extremely good chance of preserving facial nerve function.

The investigation of choice for detecting acoustic neuromas is MRI (Fig. 40.31). In many centres patients with any unilateral otological symptoms are screened using MRI. If MRI is not available, CT scanning is the next best diagnostic tool. Occasionally, in an elderly patient, ‘a wait and see’ policy may be adopted. In such patients repeat MRIs can be used to monitor the tumour. There are three main surgical approaches for resecting acoustic neuromas. A translabyrinthine approach is entirely through the ear and does not breach the dura. The neurosurgeon and ENT surgeon work together. There is minimal disturbance to the patient, although the hearing is completely destroyed. A suboccipital approach is performed by a neurosurgeon doing a cranotomy with the ENT surgeon removing bone at the internal auditory meatus. Traction on the cerebellum is required. This increases the morbidity. In some cases, however, what remains of the hearing can be preserved using this approach. The physiological monitoring of the facial nerve and auditory nerve during surgery has improved acoustic nerve surgery results.

The inner ear

- Presbycusis: bilateral high-frequency loss
- Unilateral tinnitus or sudden sensory neural hearing loss needs to be investigated for possible acoustic neuroma
- Sudden sensory neural hearing loss needs immediate treatment

Oral and oropharyngeal cancer

In global terms, oral—oropharyngeal cancer is the sixth most common malignancy. In the Western world it accounts for only 2—4 per cent of all malignant tumours, although there is now good evidence to show that the incidence is increasing particularly in younger people. By contrast, in Asia oral—oropharyngeal malignancy is the commonest malignant tumour which in parts of India accounts for no less than 40 per cent of all malignancy. It is estimated that globally there are nearly 500 000 new cases annually and that by the year 2000 there will be 1.5 million people alive with oral cancer at any one time.

Oral—oropharyngeal cancer is an almost entirely preventable disease being caused by tobacco either with or without alcohol. In the West this is mostly cigarette smoking combin-ed with alcohol abuse, the risk of both in combination being greater than the summation of the risks of each individually.

In Asia and the Far East the use of Pan and reverse smoking are the major aetiological agents. Epidemiological evidence strongly suggests that again it is the presence of tobacco in the betel quid which is the major agent, although there seems also to be some relationship to the source of slaked lime and the areca nut itself.

The incidence in women appears to be increasing and there is a worrying cohort of young patients, mostly male and particularly with tongue cancer, who show a sharp increase in incidence after a gradual fall earlier in the twentieth century. This recent trend seems not to be related to tobacco and alcohol consumption and has been observed throughout Europe and North America.

Local control of disease at the primary site and the management of neck disease have improved, yet despite this cure rates and survival rates have not improved during the last 40 years remaining at approximately 55 per cent survival at 5 years.

Both recurrence of local disease and failure to control lymphatic metastases in the neck are early events and clearly have a negative effect on 5-year survival figures. There is no doubt, however, that during the past 20 years great advances have been made in the management of oral cancer, and persistence of local disease and lymphatic metastasis are now less common events. Why then have cure rates not improved?

Field changes in the upper aerodigestive tract result in the phenomenon of multiple primary cancers. The longer a patient survives his or her index tumour, the greater the risk of developing a second or third primary tumour either else-where in the oral cavity or in the larynx, bronchus or oesophagus.

Even if the patient does not develop a second primary tumour, he or she is then at risk of developing distant metasta-static disease. It is probable that although until recently rarely recognised during life, metastasis via the bloodstream is a relatively early event in oral cancer. Currently, 20 per cent of all cancer-related deaths in patients with a tumour in the oral cavity or oropharynx are due to distant metastasis with no evidence of disease in the head or neck. Thus, oral cancer is a ‘systemic’ disease from an early stage.

Reconstruction

Surgical advances have been primarily in techniques of access surgery and in reconstruction. The widespread adoption of lip splitting and mandibulotomy has facilitated safe three-dimensional resections of tumours in the tongue and floor of mouth incontinuity with the lymphatics in the neck. A better understanding of the patterns of invasion of the mandible by adjacent tumour has allowed the development of rim resections, avoiding the sacrifice of mandibular continuity in many cases, without risking local recurrence. In recent years there has been the development of skull base access surgery using well-established oral and facial osteotomy techniques which have rendered previously inoperable tumours operable. This is particularly true for tumour extending into the pterygoid, infratemporal and lateral pharyngeal regions.

Reconstruction

Primary reconstruction is now the rule to the great advantage of patients. Previous reconstruction techniques were often unreliable, and when bony reconstruction was involved they were often staged. It was reasonably felt that before embarking on such prolonged and insecure techniques a period of time should be allowed to elapse to demonstrate that local recurrence was unlikely before reconstruction was attempt-ed. With current techniques based largely on muscle flaps —pectoralis major, trapezius and latissimus dorsi — and free tissue transfer, based on microvascular techniques, primary reconstruction is not only reliable but produces acceptable functional and cosmetic results.

Radiotherapy

High-energy beams, computerised planning and simulation have greatly reduced the morbidity of radiotherapy by reducing the dosage to the adjacent tissues. Teeth are no longer routinely extracted prior to radiotherapy regardless of their state, and osteoradionecrosis is now an unusual complication.

Although not a new technique, brachytherapy using iridium wire implants is regaining popularity. For suitable tumour —Ti and early T2 tumours in mobile soft tissues — this technique delivers very high-dose local irradiation continuously with very little irradiation to adjacent tissues (Fig. 41.1). Local control rates are excellent. Currently, considerable interest is being shown in hyperfractionation techniques, whereby a higher total tumour dose can be achieved by giving more but smaller fractions of radiation.

Chemotherapy

Although many single agents or combinations of drugs can result in a response rate around 60 per cent, there is no evidence that this results in an increase in survival time or cure rate. Some centres advocate the use of induction chemotherapy prior to surgery but, again, there is no evidence based upon prospective studies that this improves survival. Palliative chemotherapy using agents such as cisplatin and 5-fluouracil are sometimes helpful for painful or fungating tumours.

Clinical aspects

Oral cancer has a predilection for certain sites within the mouth, notably the lateral margins and ventral tongue, floor of mouth, retromolar trigone, buccal mucosa and palate. The majority — more than 85 per cent — is mucosal squamous cell carcinomas. Malignant tumours arising in the minor salivary glands are next in frequency with lymphomas, malignant melanomas, sarcomas and metastatic tumours making up the remainder.
Premalignant lesions

The association of oral carcinoma and other oral mucosal lesions has been recognised for many years. Often these lesions are in the form of white plaques (‘leucoplakia’) or bright red velvety plaques (‘erythroplakia’). They may be present for periods of months to years prior to the onset of malignant change and often they will be present together with the carcinoma at presentation. Because of this association the assumption was made that such lesions led directly to invasive carcinoma and hence were themselves premalignant.

Some white plaques do undoubtedly have a potential to undergo malignant transformation, and an examination of established carcinomas will show many to exist in association with white plaques. However, the majority of oral carcinomas is not preceded by or is associated with leucoplakia.

Although historically oral ‘leucoplakia’ has been recognised as premalignant, the risk of malignant transformation is not as great as was previously thought. Early literature suggested a 30 per cent or higher incidence of malignant transformation of these lesions whereas more recent authors quote an incidence of between 3 and 6 per cent.

The following oral lesions are now definitely considered to carry a potential for malignant change:

- leucoplakia;
- erythroplakia;
- chronic hyperplastic candidiasis.

A further group of conditions, although not themselves premalignant, are associated with a higher than normal incidence of oral cancer:

- oral submucous fibrosis;
- syphilitic glossitis;
- sideropenic dysphagia.

There remains a further group of oral conditions about which there is still some doubt as to whether their association with oral cancer is causal or casual:

- oral lichen planus;
- discoid lupus erythematosus;
- dyskeratosis congenita.

Leucoplakia

Using the term leucoplakia (Fig. 41.2) either in a histological or clinical context is a matter of defining what one means by the term. The World Health Organisation (WHO) has defined leucoplakia as ‘any white parch or plaque that cannot be characterised clinically or pathologically as any other disease’. This definition has no histological connotation.

Clinical features

Clinically leucoplakia may vary from a small circumscribed white plaque to an extensive lesion involving wide areas of the oral mucosa. The surface may be smooth or it may be wrinkled, and many lesions are traversed by cracks or fissures. The colour of the lesion may be white, yellowish or grey, with some being homogeneous whilst others are nodular or speckled on an erythematous base. Many lesions are soft whereas other thicker lesions feel crusty. Induration suggests malignant change and is an indication for immediate biopsy. It is important to recognise that it is the speckled or nodular leucoplaikias which are the most likely to undergo malignant change.

Potential for malignant change

It has been shown that the incidence of ultimate malignant change in oral leucoplakia increases with the age of the lesion. One study showed a 2.4 per cent malignant transformation rate at 10 years which increased to 4 per cent at 20 years. It also showed that as the age of the patient increased so did the risk of malignant transformation; for patients younger than 50 years it was 1 per cent whereas for those between 70 and 89 years it was 7.5 per cent during a 5-year observation period. Studies have shown that, in southern England, leucoplakia of the floor of the mouth and ventral surface of the tongue has a particularly high incidence of malignant change. This study suggested that this occurrence was due to pooling of soluble carcinogens in the ‘sump’ of the floor of the mouth.

Aetiology

Tobacco smoking and chewing are undoubtedly important aetiological factors. In Indians who smoke or chew tobacco (often as a component of the betel quid) the incidence of leucoplakia in those of 60 years of age is 20 per cent, whereas in those who neither smoke not chew tobacco the incidence is 1 per cent.

The role of alcohol in the development of oral leucoplakia is difficult to assess. Few studies have been reported, but it has been shown that in patients with leucoplakia the incidence of excessive alcohol consumption is greater than in those free of leucoplakia.

Management

In any patient presenting for the first time with oral leucoplakia a careful history — particularly looking for aetiological factors — and a detailed clinical examination should precede the histological examination of biopsies of any suspicious areas. Suspicion should be aroused by any areas of ulceration or induration or where the underlying tissues are bright red and hyperemic.

If there is a history of tobacco consumption then the patient should be persuaded to stop immediately. It has been shown that if the patient stops smoking entirely for 1 year the leucoplakia will disappear in 60 per cent of the cases.
