Whenever severe epithelial dysplasia or carcinoma in situ is present, surgical excision or carbon dioxide laser excision of the lesions is mandatory. Small lesions may be excised, the margins of the adjacent mucosa undermined and the defect closed by advancing the margins. For larger defects the area should be left to epithelialise spontaneously or alternatively the area can be skin grafted. On the tongue the graft is quilted on to the raw area, whereas on the cheek, floor of mouth or palate the graft can be retained in place by suturing a suitable pack overlying it.

When only mild to moderate epithelial dysplasia is present the patient should be followed up at 4-monthly intervals and the lesions recorded in the notes either photographically or diagrammatically.

**Erythroplakia**

Erythroplakia (Fig. 41.3) is defined as ‘any lesion of the oral mucosa that presents as bright red velvety plaques which cannot be characterised clinically or pathologically as any other recognisable condition’. Such lesions are usually irregular in outline, although clearly demarcated from adjacent normal epithelium. The surface may be nodular. In some cases erythroplakia coexists with areas of leucoplakia. The incidence of malignant change in erythroplakia is 17-fold higher than in leucoplakia. In every case of erythroplakia there are areas of epithelial dysplasia, carcinoma in situ or invasive carcinoma. Clearly, all erythroplastic areas must be completely excised either surgically or with a carbon dioxide laser, and the specimens submitted for careful pathological examination.

**Chronic hyperplastic candidiasis**

In chronic hyperplastic candidiasis (Fig. 41.4), dense chalky plaques of keratin are formed, the plaques being thicker and more opaque than in noncandidal leucoplakia. Such lesions are particularly common at the oral commissures extending on to the adjacent skin of the face.

In 1969 Cawson drew attention to the high incidence of malignant transformation in these candidal leucoplakias, suggesting that the invasive candidal infection is the cause of the leucoplakia and not merely a superimposed infection. It has also been suggested that in such patients there may be an immunological defect which allows the Candida strains to invade the epithelium and may render the patient susceptible to malignant change. It is thought that treatment with nystatin, amphotericin or miconazole to eliminate the candidal infection will reduce the risk of malignant change. However, treatment may be necessary for many months to eliminate the organisms and re-infection is a constant problem. Surgical excision is recommended for persistent lesions.

**Oral submucous fibrosis**

Oral submucous fibrosis (Fig. 41.5) is a progressive disease in which fibrous bands form beneath the oral mucosa. These bands progressively contract so that ultimately opening is severely limited. Tongue movements may also be limited. The condition is almost entirely confined to Asians. Histologically it is characterised by juxta-epithelial fibrosis with atrophy or hyperplasia of the overlying epithelium which also shows areas of epithelial dysplasia. Paymaster in 1956 first discussed the precancerous nature of submucous fibrosis. He noted the onset of a slowly growing squamous cell carcinoma in one-third of such patients. The aetiology is obscure. Hyper-sensitivity to chilli, betel nut, tobacco and vitamin deficiencies have been implicated. Canniff has investigated the various enzymes of the constituents of the ‘betel quid’, and has characterised some alkaloids and collagenases that may be responsible for the connective tissue changes which lead to epithelial atrophy and ultimate malignant degeneration. Tissue culture experiments have shown that alkaloids in the betel nut — particularly arecoline — stimulate collagen synthesis and the proliferation of buccal mucosal fibroblasts. Tannins also present in the betel nut stabilise the collagen fibrils and render them resistant to degradation by collagenase.

The scar bands of submucous fibrosis which result in difficulty in opening can be treated either by intraloesional injection of steroids or by surgical excision and grafting, but this has little effect in preventing the onset of squamous cell carcinoma in the generally atrophic oral mucosa. Any aetiological factors should, of course, be eliminated.

**Syphilitic glossitis**

Prior to the antibiotic era, syphilis was an important predisposing factor in the development of oral leucoplakia and oral cancer. The syphilitic infection produces an interstitial glossitis with an endarteritis which results in atrophy of the overlying epithelium. This atrophic epithelium appears to be more vulnerable to those other irritants which cause oral cancer or oral leucoplakia. As these changes are irreversible there is no specific treatment, although active syphilis must be treated. Regular follow-up is essential. It should be noted that squamous cell carcinomas may arise in syphilitic glossitis even in the absence of leucoplakia.

**Sideropenic dysphagia (Plummer—Vinson syndrome, Paterson—Kelly syndrome)**

In 1936 Ahlbom showed the relation between sideropenic dysphagia and oral cancer. Sideropenic dysphagia (Fig. 41.6) is particularly common in Swedish women, and this accounts for the high incidence of cancer of the upper alimentary tract in this group and the higher incidence of women with oral cancer in Sweden. Of women with oral cancer in Sweden, 25 per cent were sideropenic.

The pathogenesis of oral cancer in such patients may be similar to that of syphilitic glossitis. The sideropenic dysphagia leads to epithelial atrophy, which in itself is excessively vulnerable to carcinogenic irritants. Although the anaemia will respond to treatment with iron supplements, it is not known whether such treatment reduces the risk of subsequent malignant change. There have been some reports that in erosive or atrophic lichen planus (Fig. 41.7) there is a risk of malignant transformation. If there is an association between lichen planus and oral cancer the relation only exists with atrophic or erosive lichen planus. All patients with erosive or atrophic lichen planus should be carefully reviewed. Erosive lichen planus should be treated with topical steroids and, in severe cases, systemic steroids may be necessary.

**Discoid lupus erythematosus**

The oral lesions of discoid lupus erythematosus consist of circumscribed, somewhat elevated, white patches usually surrounded by a telangiectatic halo. Epithelial dysplasia may be seen on histological examination and this may lead to malignant transformation. Malignant change usually occurs in those lesions of the labial mucosa adjacent to the vermilion border, and occurs more often in men than in women. Such patients with discoid lupus erythematosus should be advised to avoid bright sunlight and when in the open air to apply an ultraviolet barrier cream to the lips.

**Dyskeratosis congenita**

This syndrome is characterised by reticular atrophy of the skin with pigmentation, nail dystrophy and oral leucoplakia. Eventually, the oral
mucosa becomes atrophic and the tongue loses its papillae. Finally, the mucosa becomes thickened, fissured and white.
Clinical presentation and diagnosis of oral cancer

Early diagnosis of oral cancer should lead to better treatment results and, ideally, the clinical diagnosis of oral cancer should be easy. Oral lesions, unlike those at many other sites, give rise to early symptoms. In general, patients become aware of and usually complain about minute lesions within the mouth and biopsy may be carried out under local analgesia. Yet, despite all the above, between 27 and 50 per cent of patients present for treatment with late lesions. Many of these patients are elderly and frail and, therefore, delay the effort of visiting their doctor or dentist. Many of this group of patients wear dentures and are accustomed to discomfort and ulceration in the mouth and thus see no urgency in seeking treatment. Furthermore, the practitioner is often not suspicious that a lesion may be malignant and the lesion is often treated initially with antifungal therapy, antibiotics, steroids and mouth-washes, thus contributing to further delay in the ultimate diagnosis and treatment. Another factor is that oral cancer is not usually painful until such rime as either the ulcer becomes secondarily infected or the tumour invades sensory nerve fibres.

The tongue

The majority of tongue cancers occurs on the middle third of the lateral margins, extending early in the course of the disease on to the ventral aspect and floor of the mouth (Fig. 41.8). Approximately 25 per cent occur on the posterior third of the tongue, 20 per cent on the anterior third and rarely (4 per cent) on the dorsum.

Early tongue cancer may manifest in a variety of ways. Often the growth is exophytic with areas of ulceration. It may occur as an ulcer in the depths of a fissure or as an area of superficial ulceration with unsuspected infiltration into the underlying muscle. Leucoplaclie patches may or may not be associated with the primary lesion. A minority of tongue cancers may be asymptomatic, arising in an atrophic depapillated area with an erythroplakic patch with peripheral streaks or areas of leucoplaclie.

Later in the course of the disease a more typical malignant ulcer will usually develop, often several centimetres in diameter. The ulcer is hard in consistency with heaped-up and often everted edges. The floor is granular, indurated and bleeds readily. Often there are areas of necrosis. The growth infiltrates the tongue progressively causing increasing pain and difficulty with speech and swallowing. By this stage pain is often severe and constant, radiating to the neck and ears. Lymph node metastases at this stage are common — indeed 50 per cent may have palpable nodes at presentation. Because of the relatively early lymph node metastasis of tongue cancer, 12 per cent of patients may present with no symptoms other than ‘a lump in the neck’.

The floor of the mouth

The floor of the mouth is the second most common site for oral cancer (Fig. 41.9). It is defined as the U-shaped area between the lower alveolus and the ventral surface of the tongue; carcinomas arising at this site involve adjacent structures very early in their natural history. Most tumours occur in the anterior segment of the floor of the mouth to one side of the midline.

The lesion usually starts as an indurated mass which soon ulcerates. At an early stage the tongue and lingual aspect of the mandible become involved. This early involvement of the tongue leads to the characteristic slurring of the speech often noted in such patients. The infiltration is deceptive but may extend to reach the gingivae, tongue and genioglossus muscle. Subperiosteal spread is rapid once the mandible is reached. Lymphatic metastasis, although early, is less common than with tongue cancer. Spread is usually to the sub-mandibular and jugulodigastric nodes and may be bilateral.

Cancer in the floor of the mouth is associated with a pre-existing leucoplaclie more commonly than at other sites.

The gingiva and alveolar ridge

Carcinoma of the lower alveolar ridge occurs predominantly in the premolar and molar regions (Fig. 41.10).

The patient usually presents with proliferative tissue at the gingival margins or superficial gingival ulceration. Diagnosis is often delayed because there is a wide variety of inflammatory and reactive lesions which occur in this region in association with the teeth or dentures. Indeed, there will often be a history of tooth extraction with subsequent failure of the socket to heal prior to definitive diagnosis. Another common story is that of sudden difficulty in wearing dentures. Regional nodal metastasis is common at presentation, varying from 30 to 84 per cent, although false-positive and false-negative clinical findings are common.

The buccal mucosa

The buccal mucosa extends from the upper alveolar ridge down to the lower alveolar ridge and from the commissure anteriorly to the mandibular ramus and retromolar region posteriorly (Fig. 41.11). Squamous cell carcinomas mostly arise either at the commissure or along the occlusal plane to the retromolar area, the majority being situated posteriorly. Exophytic, ulcero-infiltrative and verrucous types occur. They are subject to occlusal trauma with consequent early ulceration and often become secondarily infected. The onset of the disease may be insidious, the patient sometimes pre-senting with trismus due to deep neoplastic infiltration into the buccinator muscle. Extension posteriorly involves the anterior pillar of the fauces and soft palate with consequent worsening of the prognosis. Ulcero-infiltrative lesions will often involve the overlying skin of the cheek resulting in multiple sinuses. Lymph node spread is to the submental, submandibular, parotid and lateral pharyngeal nodes.

Verrucous carcinoma occurs as a superficial proliferative exophytic lesion with minimal deep invasion and induration. Often the lesion is densely keratinised and presents as a soft white velvety area mimicking benign hyperplasia. Lymph node metastasis is late and the tumour behaves as a low-grade squamous cell carcinoma.

The hard palate, maxillary alveolar ridge and floor of antrum

These three sites are anatomically distinct, but a carcinoma arising from one site soon involves the others (Fig. 41.12). Consequently, it can be difficult to determine the exact site of origin. Except in countries where reverse smoking is practised, cancer of the palate is relatively uncommon. The majority of squamous cancers arises in the antrum and later ulcerates through to involve the hard palate. The majority of malignant tumours arising from the palatal mucosa is of minor salivary gland origin. Palatal cancers usually present as sessile swellings which ulcerate relatively late. A finding in contrast to mandibular alveolar tumours that deep infiltration into the underlying bone is uncommon.

Carcinomas arising in the floor of the maxillary antrum often present as palatal tumours. Although the fully established picture of antral carcinoma is difficult to miss, the early symptoms are nonspecific and may mimic chronic sinusitis. Tumours of the lower half of the antrum below Ongren’s line usually present with ‘dental’ symptoms because of early alveolar invasion. The commonest presenting feature is pain, swelling or numbness of the face. Later symptoms of nasal obstruction, discharge or bleeding, and dental symptoms such as painful or loose teeth, ill-fitting dentures, oroantral fistula or failure of an extraction socket to heal, soon follow. Lymph node metastasis from carcinomas of the
palate and floor of the antrum occurs late but carries a poor prognosis.

**Diagnosis**

The diagnosis of intraoral carcinoma is primarily clinical, and a high index of suspicion is necessary for all those clinicians seeing and treating patients with oral symptoms. A careful and detailed history with particular attention to recording the dates of the onset of particular signs and symptoms precedes the clinical examination. All areas of the oral mucosa are carefully inspected and any suspicious lesion is palpated for texture, tethering to adjacent structures and induration of underlying tissue.
Investigation

Surgical biopsy

A clinical diagnosis of oral cancer should always be confirmed histologically. Within the oral cavity a surgical biopsy can nearly always be obtained using local anaesthesia. An incisional biopsy is recommended in all cases. Whenever possible the patient should be seen at a combined clinic by a surgeon and radiotherapist before even the biopsy is carried out, but provided careful records are made an initial incisional biopsy is acceptable and may save time in the planning and execution of subsequent therapy. The biopsy should include the most suspicious area of the lesion and include some normal adjacent mucosa. Areas of necrosis or gross infection should be avoided as they may confuse the diagnosis.

Fine needle aspiration biopsy

This technique is applicable mainly to lumps in the neck, especially suspicious lymph nodes in a patient with a known primary carcinoma. It consists of the percutaneous puncture of the mass with a fine needle and aspiration of material for cytological examination. The method of aspiration needs no specialised equipment and is fast, almost painless and without complications. The node is fixed between finger and thumb and then punctured by a 21G or 23G needle on a 10-ml syringe, the gauge of the needle depending on the size of the node. Important points to note are that the needle is properly pushed on to the syringe to prevent air leaking in when the plunger is withdrawn and that a small amount of air is already in the syringe (about 2 ml) before the node is punctured in order subsequently to expel the aspirate from the needle onto the slide.

Radiography

Plain radiography is of limited value in the investigation of oral cancer. At least 50 per cent of the calcified component of bone must be lost before any radiographic change is apparent. Furthermore, the facial bones are of such a complexity that confusion from overlying structures makes X-ray diagnosis more difficult. However, rotational pantomography of the jaws can be helpful in assessing alveolar and antral involvement, provided that the above limitations are understood.

Computerised tomography

The increasing availability of computerised tomography (CT) scanning has undoubtedly been of great benefit in the investigation of head and neck tumours. However, for intraoral tumours its value is more limited. For the evaluation of antral tumours, particularly assessment of the pterygoid regions, CT has superseded plain radiography and conventional tomography. CT is also of value in the investigation of metastatic disease in the lungs, liver and skeleton.

Radionuclide studies

Technetium (Tc) pertechnetate bone scans of the facial skeleton are of little value in the diagnosis of primary oral cancers. There will be obvious clinical disease long before bone changes are visible on a Tc scan. Furthermore, such scans are not specific and will show increased uptake wherever there is increased metabolic activity in the bone.

Ultrasound

Abdominal ultrasound to detect liver metastases is probably as accurate as CT scanning. As it is noninvasive, readily available and cost effective, it is probably the most appropriate technique for assessing the liver.
Management of the primary tumour

Choice of treatment

The principal treatments available for primary tumours remain surgery and radiotherapy. The basic decision to be made is between radical radiotherapy and elective surgery. If the former is chosen, surgery is reserved for ‘salvage’, i.e. for biopsy proven recurrent or residual disease. If surgery is chosen, radiotherapy may be used in an adjuvant manner, either preoperatively or postoperatively, but the operation remains fundamentally the definitive curative procedure. Preferences for one or other policy vary considerably between treatment centres.

Many factors must be considered in deciding the optimum management for each individual patient. These include the site, stage and histology of the tumour, and the medical condition and lifestyle of the patient. Ideally, every patient should be seen at a joint consultation clinic by a surgeon and radiotherapist who assess objectively and agree the optimum strategy of management for the particular individual. The following factors should influence the decision on treatment policy.

Site of origin

The choice of treatment depends on the part of the mouth in which the tumour arises. The management of primary tumours at the various anatomical sites is discussed later. In general, surgery is preferred for those tumours arising on or involving the alveolar processes; for other sites surgery and radiotherapy are alternatives.

Stage of disease

A small lesion which can be excised readily without producing any deformity or disability is, in general, best managed surgically. Surgery is also usually more appropriate for a very large mass or where there is invasion of bone, provided the tumour is operable, because of the low cure rates by radiotherapy in these circumstances. The management of lesions of intermediate stage, i.e. larger Ti, most T2 and early exophytic T3 tumours, is more controversial as policies of elective surgery or radical radiotherapy produce generally similar survival rates; hence, discussion centres on the likely functional results and morbidity of either approach.

When there is involvement of cervical lymph nodes the primary and nodes are normally both treated surgically. However, there is no clear evidence that a primary tumour is less likely to be cured by radiotherapy in the presence of lymph node metastases than in their absence.

Previous irradiation

It is not advisable to retreat a tumour arising in previously irradiated tissue. Such a tumour is likely to be relatively radioresistant because of limited blood supply. Re-irradiation of normal tissue is very likely to result in necrosis.

Field change

Where multiple primary tumours are present, or if there is extensive premalignant change, surgery is the preferred treatment. Radiotherapy in these circumstances is unsatisfactory; irradiation of the entire oral cavity causes severe morbidity and may not prevent subsequent new primary tumours arising from areas of premalignant change.

Histology

The histology report on a biopsy specimen has a relatively small influence on choice of treatment. The less common adenocarcinoma and melanoma are relatively radioresistant, and therefore should be treated surgically whenever possible. The grade of malignancy of a squamous carcinoma does not normally influence its management, there being little evidence to suggest that a well-differentiated primary should be treated differently from a poorly differentiated one.

A possible exception is the verrucous carcinoma, which is the subject of much controversy. The observation has been made that where large lesions of this histotype are treated by radiotherapy recurrences appear in some cases which are of a much more anaplastic pattern than the original primary, and it has become widely accepted that radio-therapy induces ‘anaplastic transformation’.

It seems probable that some verrucous carcinomas already contain foci of more malignant cells prior to treatment, and that these cells are the ones most likely to survive after radiotherapy and give rise to recurrence. In practice, most verrucous carcinomas present at an early stage as superficially exophytic lesions and are suitable for local excision. When they cannot be excised locally the weight of evidence suggests that they can be dealt with safely in the same way as squa-mous carcinomas of other types, and either surgery or radio-therapy be chosen as the primary treatment modality according to the site and stage of the lesion and the condition of the patient.

Age

The patient’s age is often quoted as an important factor which must be taken into account when deciding on a course of management. With a young patient there is the fear that if radiotherapy is given it may induce a malignancy in years to come; in fact, this risk is very small compared with the mortality of the disease itself. Elderly patients tend to be poor surgical risks, but they also tend to do badly with radio-therapy, especially external radiotherapy, and often deteriorate and may die as a result of the debility and poor nutritional status induced by the irradiation. Chronological age per se should not necessarily be regarded as a contraindication to surgery.

Carcinoma of the lip

Carcinoma of the lip most commonly arises at the vermilion border of the lower lip away from the line of contact with the upper lip. Only 15 per cent arise from the central third and commissure regions, and 5 per cent from the upper lip.

Initially the tumours spread to the anterior triangle of the neck and invade the mandible. Lymph node metastases occur late. Both surgery and radiotherapy are frequently employed and are highly effective methods of treatment, each giving cure rates of about 90 per cent.

Up to one-third of the lower lip can be removed with aor W-shaped excision with primary closure (Fig. 41.13). This method is suitable for tumours up to 2 cm in diameter. The residual defect is reconstructed by approximating and suturing the borders in three layers; mucosa, muscle and skin. Particular attention should be paid to the correct alignment of the vermilion junction. This simple procedure can readily be performed under local anaesthetic on an out-patient basis. Initially the lip will appear tight, but this improves after about 3 months.

If more than one-third of the lip is removed, primary closure results in microstomia. Therefore, for more extensive lip resections it is necessary
to utilise local flaps for reconstruction. For large central defects of the lower lip, particularly in patients who do not have ageing wrinkled faces, the ‘stepladder’ approach of Johanson gives excellent cosmesis as the reconstruction advances symmetrical bilateral flaps from the lower third of the face (Fig. 41.14). This results in a mini facelift and the scars are concealed in the labiomental groove around the chin point. For defects more laterally, in the lower lip, the upper lip and particularly involving the commissures, Fries’ ‘universal procedure’ gives excellent functional results with acceptable cosmesis especially in the ageing face (Fig. 41.15). With this technique, lateral facial flaps are developed following full-thickness incisions in the cheeks parallel to the branches of the facial nerve. These flaps are then advanced into the lip defect with the sacrifice of Burrows’ triangles to prevent piling up of the facial tissues.

The majority of lower lip cancers is caused by ultraviolet radiation and often the entire vermilion border will show actinic changes. Whenever these changes are seen a total lip shave would be undertaken in addition to resection of the primary tumour. The resection is reconstructed either by advancinglabial or buccal mucosal flaps or, if such tissue is inadequate, by the use of a pedicled anteriorly based tongue flap. After 3 weeks the pedicle is divided and the flap finally set into the lip.

Carcinoma of the tongue

Surgery is the treatment of choice for early lesions suitable for simple intraoral excision, for tumours on the tip of the tongue and for advanced disease when surgery should be combined with postoperative radiotherapy. For intermediate-stage disease surgery and radiotherapy have similar outcomes. When performing surgical excision of less than one-third of the tongue, formal reconstruction is not necessary. Indeed, the best results are obtained by not attempting to close the defect or to apply a split-skin graft. The base of the residual defect should be fulgurated and then allowed to granulate and epithelialise spontaneously. Such treatment is relatively pain free and results in an undistorted tongue.

When available a carbon dioxide laser may be used for the partial glossectomy. The postoperative course is relatively pain free, oedema is minimal and healing occurs with minimal scarring.

Any tongue carcinoma exceeding 2 cm in diameter requires at the very least a hemiglossectomy. Many such tumours will infiltrate deeply between the fibres of the myohyoid muscle. Extensive tongue lesions often involve the floor of the mouth and alveolus. Under any of these circumstances a major resection is indicated. Access is best via a lip split and mandibulotomy (Fig. 41.16). The pull-through procedure is not recommended as it is very difficult to achieve adequate excision in all three dimensions with a limited access. As the resection opens the submandibular space the resection should include a dissection of the neck on the same side and sometimes the other side of the neck. The type of neck dissection will depend upon the node status of the patient. A rim resection of the mandible is indicated if the tumour reaches but does not invade the alveolus. Such extensive defects require recon-struction with flaps. If the volume of the tongue defect does not exceed two thirds of the original tongue a radial forearm free flap with microvascular anastomoses gives a good functional result. For very large volume defects, for total glossectomy or for deeply infiltrating tumours, when the resection extends to the hyoid bone, more bulky flaps are required to fill in the dead space and prevent food pooling.

A pectoralis major muscle flap is the best method. Whenever it is possible, without compromising the resection, at least one of the hypoglossal nerves should be preserved. If this is done, most patients will eventually relearn to swallow and will establish reasonable speech.

Carcinoma of the floor of the mouth

Floor of mouth cancers spread to involve the under surface of the tongue and the lower alveolus at a relatively early stage. Therefore, surgical excision will nearly always include partial glossectomy and marginal resection of the mandible. The resultant defect must always be reconstructed with either a local or a distant flap. It is unacceptable to advance the lateral margin of the residual tongue to the buccal mucosa as this causes very severe difficulties with speech and mastication. Small tumours of the floor of the mouth that do not show deep infiltration can be treated by simple excision.

It is important that a 1-cm margin of normal-appearing mucosa be excised around the tumour. The resulting defect can either be left to granulate if a carbon dioxide laser was used for the excision, or fulgurated if diathermy excision was used. Alternatively, if the defect is large it can be repaired using bilateral nasolabial flaps tunnelled into the mouth and interdigitated anteriorly. The submandibular duct should be identified proximally, well clear of the distal margin of the excision and brought our into the floor of the mouth or lingual gutter posteriorly.

For larger lesions and those involving the ventral tongue and/or the alveolus, surgical access is gained via a midline or lateral (anterior to the mental foramen) mandibulotomy and lip split. As these extensive tumours have a high incidence of nodal involvement, the resection is undertaken in continuity with an ipsilateral neck dissection (Fig. 41.17). Recent work has demonstrated the pattern of bone invasion by carcinoma of the floor of the mouth. Invasion in the edentulous mandible is almost exclusively via deficiencies in the cortical bone of the alveolar crest. In the dentate man-dible invasion is usually via the periodontal ligament and is nearly always above the insertion of the mylohyoid muscle. Once tumour has invaded the mandible it soon enters the inferior dental canal and perineural spread occurs anteriorly and posteriorly. Consequently, in many cases the continuity of the mandible can safely be maintained provided a marginal resection is carried out which includes the inferior dental canal from the lingula to the mental foramen.

When there is evidence of gross tumour invasion of the bone resection of the mandible is mandatory. In order to avoid functional and cosmetic deformity, immediate primary reconstruction is essential. The choice lies between reconstruction with vascularised bone, a free corticocancellous graft or an alloplastic system usually supplemented with cancellous bone mesh.

Carcinoma of the buccal mucosa

Lesions strictly confined to the buccal mucosa should be excised widely including the underlying buccinator muscle, followed by a quited split-skin graft. For more extensive lesions with more complicated three-dimensional shapes, i.e. lesions extending posteriorly to the retromolar area, maxillary tuberosity or tonsillar fossa, reconstruction with a free radial forearm flap is advisable; this adapts very well to such shapes and remains soft and mobile postoperatively (Fig. 41.18).

In situations where a free flap is nor appropriate, alternatives are the buccal fat pad or the forehead flap. The buccal fat pad has proved to be a useful local flap for the reconstruction of small intraoral defects up to 3 x 5 cm. This wellvascularised flap can be left raw to epithelialise spontaneously, and is used to reconstruct maxillary defects, hard and soft palate defects, and cheek and retromolar defects. For large defects at these sites its use can be combined with the temporalis muscle flap.

The use of the forehead flap, an axial flap based on the superficial temporal artery, was first described by McGregor in 1963. It is a very reliable flap able to reach most areas within the mouth including the anterior floor of the mouth. However, it is now rarely used because it results in a very obvious cosmetic defect at the donor site; it is a two-stage procedure requiring division of the pedicle at 3 weeks; and it requires the creation of a tunnel, either deep or superficial, to the zygomatic arch when the flap is needed in the oral cavity.
Carcinoma of the lower alveolus

In general, surgery is the treatment modality of choice for all alveolar carcinomas, except for patients unfit for surgery. Access is achieved via a lip-split approach. Now that the pat-terms of bone invasion are better understood, the continuity of the mandible can often be preserved by performing a marginal resection. If bone invasion is so extensive that the mandible must be resected in continuity, primary reconstruc-tion should always be undertaken as the results are always better than those of delayed reconstruction.

Several techniques are available for immediate reconstruction of the mandible. Historically, free corticocancellous grafts harvested from the iliac crest or rib grafts have been used. Provided there is a good watertight cover to the graft, results can be very satisfactory, although it is difficult to reconstruct the chin prominence with this technique. Boyne and Leake have advocated the use of cancellous bone from the ilium packed into mesh trays preformed to march the resected part of the mandible. The early dacron trays did not prove successful, but the titanium trays currently available have given excellent results (Fig. 41.19).

Microvascular tissue transfer is currently favoured for immediate mandibular reconstruction. The radial forearm flap with a section of the radius, the compound groin flap based on the deep circumflex iliac vessels and free fibula flaps have all been advocated (Fig. 41.20). A problem with the radial flap is that the harvested bone, although restoring mandibular continuity, is barely adequate for prosthetic reconstruction.

Soft-tissue cover for all of these reconstruction techniques is critical. With microvascular free flaps the associated skin is used. For cancellous bone mesh in titanium trays, and for corticocancellous grafts, the pectoralis major muscle-only flap is most useful (Fig. 41.21). The pedicle is brought up through the neck and the flap introduced into the floor of the mouth. The flap is then wrapped around the bone graft and sutured back on to itself on the labial aspect. Thus, the bone graft is totally enveloped in well-vascularised soft tissue. The mucosal resection margins are then sutured to the exposed muscle at their appropriate sites and the bare muscle allowed to epithelialise spontaneously. Such flaps withstand imme-diate postoperative radiotherapy, and the subsequent inser-tion of osteointegrated implants has not proved to be a problem.

Carcinoma of the retromolar trigone

The retromolar trigone is defined as the anterior surface of the ascending ramus of the mandible. It is roughly triangular in shape with the base being superior behind the third upper molar tooth and the apex inferior behind the third lower molar.

Tumours at this site may invade the ascending ramus of the mandible. They may also spread upwards in soft tissue to involve the pterygomandibular space, which can be difficult to detect clinically or radiologically.

A lip split and mandibulotomy are needed to gain access to the retromolar region. Small defects can often be reconstructed with a masseter or temporalis muscle flap. Larger defects are best reconstructed with a free radial forearm flap which can be made to conform very well to the shape of the defect at this site.

Carcinoma of the hard palate and upper alveolus

These sites are considered together because they are closely adjacent and both are rare sites of origin of primary squamous carcinoma. A squamous carcinoma presenting at either of these sites is more likely to have arisen in the maxillary antrum than in the oral cavity. An exception is on the Indian subcontinent where carcinoma of the hard palate is seen in association with reverse smoking. Tumours of minor salivary glands are much more common than squamous carcinomas on the hard palate. The vast majority of squamous carci-nomas which present in the upper gum or hard palate arises from the maxillary antrum.

A tumour confined to the hard palate, upper alveolus and floor of the antrum can be resected by conventional partial maxillectomy. A more extensive tumour confined to the infrastructure of the maxilla requires total maxillectomy. If the preoperative investigations indicate extension of disease into the pterygoid space or infratemporal fossa a more extensive procedure is necessary. The chance of obtaining a cure by surgery alone is small, and postoperative radiotherapy is essen-tial. A combined anteroposterior or lateral facial approach is required. If the tumour extends superiorly to involve the dura then a combined neurosurgical procedure will be required.

Following a maxillary resection the resulting cavity should be skin grafted to ensure rapid healing and to prevent con-traction of the overlying soft tissues.

The defect created by surgery will require either recon-struction or a prosthesis. Various techniques have been described for reconstruction; Obwegeser described a technique using split ribs. More recently, the temporalsis muscle flap has been advocated. The temporalsis muscle flap is a simple tech-nique and has the advantage that it carries with it its own blood supply. It must be remembered that if such a recon-struction is to be undertaken subsequently, it is essential that at the time of the primary maxillectomy the coronoid process of the mandible is not excised, because if it is resected the blood supply to the mobilised temporalsis muscle will have been compromised and the flap will necrose.

Malignant melanoma

Oral melanomas are rare. The peak age incidence is between 40 and 60 years; nearly 50 per cent are on the hard palate and about 25 per cent are on the upper gingivae. About 30 per cent of melanomas are preceded by an area of hyperpigmentation, often by many years. Pigmentation varies from black to brown, while rare nonpigmented melanomas (10per cent of oral melanomas) are red. Oral melanomas may be flat but are usually raised or nodular, and asymptomatic initially, but may later become ulcerated and painful or bleed. Because of their rapid growth, most oral melanomas are at least 1 cm across, and approximately 50 per cent of patients have metastases at presentation (Fig. 41.22).

Clinically, size and rapid growth, particularly if associated with destruction of underlying bone or presence of metastases, are obvious indicators of a poor outcome.

Microscopically, tumour thickness, measured in millimetres from the granular cell layer to the deepest identifiable melanocyte (the Breslow thickness), is the main guide to prognosis. With cutaneous melanomas the 5-year survival rate is inversely proportional to the Breslow thickness. The poor prognosis of oral melanomas is probably due to their later detection than more conspicuous skin tumours.

Other indicators of poor prognosis are malignant melanocytes in blood vessels and multiple, or atypical, mitoses. The morphology of the melanocytes or the amount of the melanin does not appear to affect the outcome.

Once the diagnosis has been confirmed, the only hope of cure is provided by the widest possible excision followed by radical radiotherapy. There is no evidence that chemotherapy is of significant value except for palliation. The over 5-year survival rate appears to be about 5 per
Management of the neck

Patients staged NO. The regional lymph nodes, although clinically impalpable, sometimes contain occult foci of malignant cells. It seems reasonable to expect, therefore, that removal or treatment of regional lymph nodes, even when clinically clear, would improve cure rates. Alternatively, it can be argued that treatment of the regional nodes in all cases is unnecessary, as only a minority has metastases in the nodes.

The arguments expressed in favour of elective block dissection are:

- the incidence of histologically involved nodes in NO necks varies from 25 to 65 per cent;
- survival rates are considerably lower in patients who develop node metastases;
- the recurrence rare following block dissection is higher in advanced disease when there is extracapsular spread or multiple nodes;
- by waiting for clinically detectable disease to develop, many patients will have a worse prognosis;
- some patients fail to attend regular follow-up and may not appear again until nodal metastases are extensive;
- block dissection of the neck carries negligible mortality and an acceptable morbidity;
- retrospective reviews confirm that patients undergoing elective neck dissection have higher survival rates;
- failure to control nodal metastases is a frequent cause of death.

The arguments against elective neck dissection are:

- it is rare for treatment to fail in the neck when the primary is controlled — only 4.5 per cent in one large series;
- the incidence of histologically positive nodes in elective neck dissections exceeds the incidence of subsequent clinical nodal metastases, suggesting that some microscopic foci are destroyed by the body’s defences;
- the primary may recur or a second primary develop and metastasise into the dissected neck, making subsequent management very difficult;
- elective neck dissection gives no guarantee against recurrence of the tumour in the neck;
- block dissection has a considerable morbidity;
- removal of regional lymph nodes may remove a barrier to the further spread of disease;

- there is no prospectively controlled trial to support the argument that elective neck dissection does improve the prognosis.

On balance, the weight of these arguments favours prophylactic neck dissection.

As the submandibular triangle often has to be opened as part of the resection of the primary, a function sparing elective neck dissection for tumours in the floor of the mouth and lower alveolar ridge and tongue is advocated. This dissection, in which structures such as the accessory nerve, internal jugular vein and sternocleido-mastoid muscle are preserved, can be justified. Further, a survey showed that of 501 cancers of the oral cavity, 34 per cent of nodes were found to be positive after elective radical neck dissections. Over 96 per cent of these histologically positive nodes would have been removed by a supra-omohyoid dissection.

The operation should preferably be seen as a staging procedure on which is based the decision to give radical postoperative radiotherapy. All patients with two or more positive nodes or extracapsular spread should be treated with postoperative radiotherapy.

An alternative approach is elective irradiation of the clinically negative neck, and indeed there is good evidence that this is of some benefit in preventing subsequent nodal disease. Certainly, elective irradiation to 40 Gy carries less morbidity than elective neck dissection.

Patients staged N1/N2a/N2b. At present, evidence suggests that the treatment of choice is radical neck dissection, either alone or combined with postoperative radiotherapy if multiple nodal involvement or extracapsular extension is found in the resected specimen (Fig. 41.23). In those patients unfit for radical surgery, radical external beam irradiation is indicated.

Patients staged N2c. It is uncommon for patients with oral cancer to present with bilateral nodes. When they do so, there is often a large inoperable primary tumour which is best treated by external radiation. It therefore seems logical to treat the neck also by irradiation. Occasionally, particularly in young patients, bilateral neck dissection can be justified. A full radical neck dissection is undertaken on the ipsilateral side and the internal jugular vein is spared if possible on the contralateral side. Most often postoperative radiotherapy will be required for multiple nodal involvement or extracapsular spread. In such situations, severe posttreatment oedema or congestion of the face and tongue may be anticipated.

Patients staged N3. N3 indicates massive involvement, usually with fixation. Large fixed nodes are often associated with advanced primary disease with a poor prognosis. Surgery is not normally advisable: removal of the common or internal carotid artery with replacement, or extensive resection of the base of the skull, although technically feasible, is seldom advisable. Treatment is most often by external radiotherapy. In a few younger patients with resectable primaries, it is worth rendering a fixed mass in the neck operable by preoperative radiotherapy.

Nodal metastases appearing after primary treatment

Provided that follow-up at regular intervals is rigorously maintained, it should be possible to detect a lymph node metastasis while it is still relatively small and therefore operable. Fine needle aspiration cytology is particularly useful in this situation to confirm that the palpable node is a carcinoma rather than reactive. Whenever positive, or if there is any doubt, a radical neck dissection is performed, followed by external
irradiation if multiple involved nodes or extracapsular spread are found.

Developmental disorders (Table 42.1)

Aplasia/agenesis

Congenital absence of one or more of the major salivary glands can occur but is very rare. When it does it is usually the parotid gland that is affected.

Duct atresia

Again this disorder is extremely rare. Usually the submandibular duct in the floor of the mouth fails to canulate during embryological development. The newborn infant presents within 2 or 3 days of life with submandibular swelling on the affected side due to a retention cyst in the submandibular salivary gland.

Congenital fistula

Patients with branchial cleft anomalies present usually with unilateral painless swellings in the region of the parotid. Rarely they are bilateral. They form sinus tracts either in the crease behind the pinna or in front of the tragus. They discharge saliva intermittently. Abscess formation due to secondary infection may occur. Complete surgical excision of the sinus tract is essential. The dissection is often very extensive and full dissection of the facial nerve may be required.

Ectopic and aberrant salivary tissue

Ectopic salivary tissue can develop anywhere within the territory of the first and second branchial arches in the lateral neck, pharynx or middle ear. Salivary tissue is regularly found in lymph nodes within the neck and can be mistaken for metastatic disease when found in a neck dissection specimen.

Although rare, the most commonly recognised ectopic salivary tissue is the Stafne bone cyst. This presents as an asymptomatic clearly demarcated radiolucency at the angle of the mandible below the inferior dental canal. It is formed by an invagination into the bone of the lingual aspect of the mandible by an ectopic lobe of the adjacent submandibular salivary gland.

Accessory lobes

An accessory parotid lobe is the most common developmental anomaly. It occurs in as many as 20 per cent of subjects. Its position is constant arising from the horizontal component of the parotid duct as it crosses the masseter muscle. Its importance lies in the fact that any of the diseases that can affect the salivary glands may involve the accessory lobe and lead to diagnostic confusion as the possibility is not considered. This is because the symptoms and signs are not within the normal anatomical territory of the parotid.
Inflammatory disorders (Table 42.2)

**Viral**

**Mumps**

The mumps virus is a paramyxovirus and is the most common cause of acute painful parotid swelling affecting children. The disease starts with a prodromal period of 1 or 2 days during which the child experiences feverishness, chills, nausea, anorexia and headache. This is typically followed by pain and swelling of one or both parotid glands. The parotid pain can be very severe and is exacerbated by eating or drinking. Symptoms resolve spontaneously after 5—10 days.

In a classical case of mumps the diagnosis is based on the history and clinical examination. However, the presentation may be atypical or sporadic or have predominantly unilateral or even submandibular involvement. In this situation, paired blood specimens taken approximately 10 days apart are used to confirm the diagnosis. One episode of infection confers lifelong immunity.

A number of other viral agents —Coxackie A and B, parainfluenza 1 and 3, enteric cytopathogenic human orphan viruses (ECHO) and lymphocytic choriomeningitis —can all cause identical signs and symptoms.

**Bacterial**

Acute ascending bacterial sialadenitis affects mostly the parotid glands. Historically it was described in dehydrated, cachectic patients often following major abdominal surgery when the patient was on a ‘nil by mouth’ regime. The reduced salivary flow and oral sepsis resulted in bacteria colonising the parotid duct and subsequently involving the parotid parenchyma. With current medical practice and improved oral hygiene patients are rarely allowed to become dehydrated and this clinical pattern is uncommon. The typical patient presenting with an acute ascending bacterial parotitis now is an otherwise fit young adult with no obvious predisposing factors (Fig. 42.1). The clinical presentation is of the onset of tender, red, painful parotid swelling over a few hours. There is associated malaise, pyrexia and often regional lymphadenopathy. Pain is exacerbated on attempting to eat or drink. The parotid swelling may be diffuse but often it localised to the lower pole of the gland presumably because the infection tends to localise under the effect of gravity.

If the gland is gently ‘milked’ by massaging the cheek, cloudy turbid saliva can be expressed from the parotid duct and this should be cultured. The infecting organism is usually *Staphylococcus aureus* or *Streptococcus viridans*. Sialography must never be undertaken during the acute phase of infection as the retrograde injection of infected material into the duct system will result in bacteraemia. Ultrasound imaging shows the characteristic dilatation of the acinae (Fig. 42.2).

If the patient presents at an early stage before abscess for-mation, the infection can usually be controlled with antibiotics. In a patient not allergic to penicillin a combination of a broad-spectrum penicillin and a penicillinase-resistant agent is usually effective. If the gland becomes fluctuant indicating abscess formation, the pus must be drained. Occasionally it is possible to drain the abscess by aspirating the pus through a large-bore hypodermic needle but usually it is necessary to undertake formal surgical drainage under general anaesthesia (Table 42.3).

Chronic bacterial sialadenitis is far more common in the submandibular salivary gland and it usually occurs secondary to chronic obstruction. Unfortunately the submandibular gland has a poor capacity for recovery following infection, and in most cases following control of any acute symptoms with antibiotics, the gland itself must be removed. During the operation great care must be taken not to damage the mandibular branch of the facial nerve when making the incision, the lingual nerve when mobilising the gland and clamping the duct and the hypoglossal nerve when separating the gland from the floor of the submandibular triangle.

**Recurrent sialadenitis of childhood**

Recurrent sialadenitis of childhood exists as a distinct clinical entity but little is known regarding its aetiology and prognosis. It is characterised by the rapid swelling of usually one parotid gland accompanied by pain and difficulty in chewing as well as systemic symptoms such as fever and malaise. Although each episode of parotid swelling is normally unilateral the opposite side may be involved in subsequent episodes. Each episode of pain and swelling lasts for 3—7 days and is followed by a quiescent period of a few weeks to several months. Occasionally episodes are so frequent that the child loses a considerable amount of schooling. The onset is usually between 3 and 6 years although it has been reported in infants as young as 4 months. The diagnosis is based on the characteristic history and is confirmed by sialography which shows a very characteristic punctate sialectasis often likened to a snow storm against a dark night sky (Fig. 42.3).

Traditionally the episodes of parotitis have been treated with antibiotic and symptoms settle within 3—5 days on such a regime. Occasionally recurrent episodes are so frequent that prophylactic antibiotics are required for a period of months or years. Spontaneous resolution of symptoms seems to occur at puberty.

**Specific ‘infections’ (granulomatous sialadenitis)**

**Mycobacterial infections**

Tuberculosis and nontuberculous parotitis typically presents as a tumour-like swelling of the gland. Symptoms are usually minimal with little pain and no pyrexia. Often the diagnosis is not suspected and the mass is excised by formal parotidectomy.

**Cat-scratch disease**

Cat-scratch disease is caused by *Bartonella henselae*. It is a common disease in the USA but is not often seen in the UK. Children are usually affected. Symptoms follow a scratch by a cat when a small pustule forms at the site of the scratch. There is an associated lymphadenitis usually affecting the cervical nodes and mild pyrexia and encephalopathy with occasional transient cranial nerve palsies. The parotid glands are swollen in 3 per cent of cases. The condition is self-limiting and resolves without treatment.

**Syphilis**

Syphilitic parotitis is now rare in the UK as the disease itself is uncommon. The glands can be involved in the acute early stages but are more often involved in tertiary syphilis with gumma formation, gland destruction and dense fibrosis.

**Toxoplasmosis**

Toxoplasmosis is due to the protozoan organism *Toxoplasma gondii*. In most cases infection is not recognised and is asymptomatic. When symptoms do occur the patient usually presents with lymphadenopathy and malaise sometimes accompanied by a headache and sore throat.
The enlarged lymph nodes are rubbery and are not tender. On occasion the patient presents with isolated unilateral parotid swelling some weeks before the lymphadenopathy develops. In this situation a parotidectomy is often performed which leads to the diagnosis. Diagnosis is further confirmed by the detection of a positive Sabin—Feldman dye test on the serum. The disease follows a self-limiting course and resolves spontaneously after weeks or months. If symptoms are severe the patient is treated with a 3- or 4-week course of pyrimethamine and sulphadiazine.

**Deep mycoses**

Fungal infections of the salivary glands occur only in immuno-compromised patients and are most commonly seen in human immunodeficiency virus (HIV)-positive patients. Salivary gland involvement is usually just one manifestation of a more generalised infection. The patient presents with a tumour-like swelling of the affected gland. Often there is extensive central necrosis. Fresh material is needed for culture and identification of the organism. Treatment is by appropriate systemic antifungal chemotherapy.

**Sarcoid**

Sarcoidosis has a predilection for salivary tissue, but only rarely is salivary swelling the presenting feature. Parotid gland involvement occurs in 10 per cent of cases classically as part of Heerfordt’s syndrome which comprises parotid swelling, anterior uveitis, facial palsy and fever. Xerostomia may be a prominent feature. A less usual presentation is with bilateral parotid and submandibular swelling which is one of the causes of Mikulicz’ syndrome. In each of these presentations salivary involvement is widespread and representative histology can be obtained from a minor salivary gland biopsy. Rarely the patient will present with a localised tumour-like swelling in one parotid gland — the so-called sarcoid pseudotumour. In the absence of other signs or symptoms the diagnosis is only likely to be made following parotid surgery for a presumed neoplasm.

**Wegener’s granulomatosis**

Although the typical presentation is chronic granulomatous ulceration and destruction in the nasopharynx or sometimes the oral cavity, Wegener’s granulomatosis can involve the major salivary glands. Diagnosis is based on the histological finding of necrotising arteritis often associated with numerous giant cells and granulomas. Pulmonary and renal involvement is very common. Treatment is by cytotoxic chemotherapy such as cyclophosphamide or azathioprine. The prognosis is poor.

**Granulomatous disease of minor salivary glands**

Granulomatous cheilitis, Melkersson—Rosenthal syndrome (recurrent facial palsy/facial swelling/fissured tongue) and Crohn’s disease all affect the minor salivary glands of the lips. Cheilitis glandularis is a rare disorder mainly of adult males in whom the lower lip becomes swollen and hard. The labial salivary glands become nodular and their orifices are inflamed and swollen.

**Allergic sialadenitis**

A variety of potential allergens causing acute parotid swelling has been identified. Some foods, drugs (most frequently chloramphenicol and tetracycline), metals such as nickel and pollens have been incriminated.

**Radiation sialadenitis**

Following the start of therapeutic irradiation when the parotid glands are within the radiation field the patient develops an acute parotitis usually after 24 hours. The glands are swollen and tender and there is a marked rise in salivary amylase and the salivary flow rate is reduced. The reaction is self-limiting and resolves after 2 or 3 days even though the radiotherapy continues. This reaction is quite distinct from the permanent radiation atrophy that occurs with therapeutic doses above 50 Gy, which develops progressively some weeks after the radiation has been completed.

**Human immunodeficiency virus-associated sialadenitis**

Chronic parotitis in children is almost pathognomonic of HIV infection. In adults a sicca syndrome and lymphocytic infiltration of the salivary glands are more usual. The presentation of HIV-associated sialadenitis is very similar to classic-al Sjogren’s syndrome. Dry mouth, dry eyes and swelling of the salivary glands together with lymphadenopathy suggest the diagnosis. Histologically the condition closely resembles Sjogren’s syndrome and differentiation may be difficult. However, autoantibodies including antinuclear, rheumatoid factor, SS-A and SS-B are absent unless the patient coincidentally has a connective tissue disorder. Acquired immunodeficiency syndrome (AIDS)-associated lymphoma presenting as salivary gland swelling has also been described.

Another presentation of salivary gland disease in HIV-positive patients is multiple parotid cysts causing gross parotid swelling and significant facial disfigurement. On imaging with computerised tomography (CT) or magnetic resonance imaging (MRI) the parotids have the appearance of Swiss cheese with multiple large cystic lesions. The glands are not painful and there is no reduction in salivary flow rates. Surgery may be indicated to improve the appearance (Fig. 42.4).

**Sialadenitis of minor salivary glands**

Acute necrotising sialometaplasia is an unusual condition which was first described in 1973. It occurs only on the hard palate in the molar region in the vault of the palate midway between the midline and the gingival margin. It is only seen in heavy smokers. It has a characteristic appearance which resembles a carcinoma with central ulceration and raised erythematous margins. The ulcer may be as much as 3 cm in diameter. As it closely resembles a carcinoma the diagnosis is often made on the basis of a surgical biopsy. The lesions are self-healing but often take 10—12 weeks to resolve (Fig. 42.5).
Obstruction and trauma (Table 42.4)

Papillary obstruction

Occasionally a rough upper molar tooth or an overextended denture flange will irritate the parotid papilla. If this is sufficient to cause ulceration with consequent inflammation and oedema this may obstruct salivary flow, particularly at meal times when the flow rate is increased. In this situation the patient has classical rapid onset pain and swelling at meal times.

If the trauma to the parotid papilla continues there will be progressive scarring and fibrosis in the soft tissues and permanent stenosis of the papilla can occur. A papillotomy will be required. This is a simple procedure performed under local anaesthesia. A probe is inserted into the orifice of the papilla and with a scalpel blade the papilla is split open by incising down on to the probe. This lays open the papilla and divides the stenosis allowing free drainage of saliva.

Stone formation (sialolithiasis)

Eighty per cent of all salivary stones occur in the sub-mandibular gland, 10 per cent occur in the parotid, 7 per cent in the sublingual gland and the remainder occurs in the minor salivary glands. It is believed that the majority of stones occurs in the submandibular glands because their secretions contain mucus and the viscosity is higher. Eighty per cent of submandibular stones are radio-opaque and can be identified using plane radiographs. By contrast the majority of parotid stones are radiolucent and cannot be detected on plane radiography (Fig. 42.6).

The classical presentation is of acute pain and swelling at meal times. Onset is rapid — within a minute of starting the meal — and the swelling resolves over a period of about 1 hour after the meal is completed.

However, this classical picture only occurs when the stone causes almost complete obstruction often when it is impacted at the opening of Wharton’s duct. More often the stone causes only partial obstruction and is lying either within the hilum of the gland or within the duct in the floor of the mouth. In this situation the patient may complain of occasional swelling often with minimal discomfort or of a chronically enlarged mass in the submandibular triangle with episodes of dull aching pain. This results from chronic bacterial infection arising in an obstructed gland with salivary stasis and poor emptying. Often a salivary stone is totally asymptomatic and is discovered coincidentally during radiography for other reasons. If a stone is identified on plane radiographs, no other investigation is necessary. Parotid stones often impact at the parotid papilla or alternatively take on a ‘stag-horn’ shape and form at the junction of the two main collecting ducts and the Stenson’s duct (Fig. 42.7). If the stone is trapped at the duct papilla it can often be released by gently probing and carrying out dilatation of the papilla. It may be necessary to slit the duct in order to release the stone.

If the stone is lying in the submandibular duct in the floor of the mouth anterior to the point at which the duct crosses the lingual nerve (second molar region) the stone can be released by opening the duct longitudinally (Fig. 42.8). It is important to pass a large suture around the duct proximal to the stone so that during the operative procedure the stone cannot be displaced backwards in the duct. Once the stone has been released the wall of the duct should be sutured to the mucosa of the floor of the mouth to maintain an opening for the free drainage of saliva. No attempt should be made to repair the duct wall as this will lead to stricture formation. A parotid stone located at the confluence of the collecting ducts can be released surgically by raising a preauricular flap, exposing the parotid duct and again incising it longitudinally to release the stone.

Obstruction in and around the duct wall

Occasionally a rough upper molar tooth or an overextended denture flange will irritate the parotid papilla. If this is sufficient to cause ulceration with consequent inflammation and oedema this may obstruct salivary flow, particularly at meal times when the flow rate is increased. In this situation the patient has classical rapid onset pain and swelling at meal times.

Papillary obstruction

If the stone is lying in the submandibular duct in the floor of the mouth anterior to the point at which the duct crosses the lingual nerve (second molar region) the stone can be released by opening the duct longitudinally (Fig. 42.8). It is important to pass a large suture around the duct proximal to the stone so that during the operative procedure the stone cannot be displaced backwards in the duct. Once the stone has been released the wall of the duct should be sutured to the mucosa of the floor of the mouth to maintain an opening for the free drainage of saliva. No attempt should be made to repair the duct wall as this will lead to stricture formation. A parotid stone located at the confluence of the collecting ducts can be released surgically by raising a preauricular flap, exposing the parotid duct and again incising it longitudinally to release the stone.

Obstruction in and around the duct wall

Occasionally a rough upper molar tooth or an overextended denture flange will irritate the parotid papilla. If this is sufficient to cause ulceration with consequent inflammation and oedema this may obstruct salivary flow, particularly at meal times when the flow rate is increased. In this situation the patient has classical rapid onset pain and swelling at meal times.

Mucocoeles

Mucus retention cysts and mucus extravasation cysts arise in the minor salivary glands as a result of mechanical damage to the gland or its duct. The common sites are on the mucosal aspect of the lower lip particularly in patients with a deep overbite and in the buccal mucosa posteriorly where an upper wisdom tooth is erupting buccally. Typically the patient presents with a history of recurrent swellings that develop over days or weeks, rupture and then recur after a few weeks. The cysts rarely exceed 1 cm in diameter and are tense bluish sessile swellings.

The classical presentation is of acute pain and swelling at meal times. Onset is rapid — within a minute of starting the meal — and the swelling resolves over a period of about 1 hour after the meal is completed.

However, this classical picture only occurs when the stone causes almost complete obstruction often when it is impacted at the opening of Wharton’s duct. More often the stone causes only partial obstruction and is lying either within the hilum of the gland or within the duct in the floor of the mouth. In this situation the patient may complain of occasional swelling often with minimal discomfort or of a chronically enlarged mass in the submandibular triangle with episodes of dull aching pain. This results from chronic bacterial infection arising in an obstructed gland with salivary stasis and poor emptying. Often a salivary stone is totally asymptomatic and is discovered coincidentally during radiography for other reasons. If a stone is identified on plane radiographs, no other investigation is necessary. Parotid stones often impact at the parotid papilla or alternatively take on a ‘stag-horn’ shape and form at the junction of the two main collecting ducts and the Stenson’s duct (Fig. 42.7). If the stone is trapped at the duct papilla it can often be released by gently probing and carrying out dilatation of the papilla. It may be necessary to slit the duct in order to release the stone.

If the stone is lying in the submandibular duct in the floor of the mouth anterior to the point at which the duct crosses the lingual nerve (second molar region) the stone can be released by opening the duct longitudinally (Fig. 42.8). It is important to pass a large suture around the duct proximal to the stone so that during the operative procedure the stone cannot be displaced backwards in the duct. Once the stone has been released the wall of the duct should be sutured to the mucosa of the floor of the mouth to maintain an opening for the free drainage of saliva. No attempt should be made to repair the duct wall as this will lead to stricture formation. A parotid stone located at the confluence of the collecting ducts can be released surgically by raising a preauricular flap, exposing the parotid duct and again incising it longitudinally to release the stone.

Obstruction in and around the duct wall

Scarring and fibrosis in the duct wall stricture formation will also result in obstruction to salivary flow. It often results as a complication of long-standing sialolithiasis but it may occur as a result of trauma particularly to the floor of the mouth. Subsequent healing and scarring can result in a stenosis of the duct. In patients with masseteric hypertrophy the parotid duct may be stretched around the anterior border of the muscle and this may cause obstruction of salivary flow at meal times.

Mucocoeles

Mucus retention cysts and mucus extravasation cysts arise in the minor salivary glands as a result of mechanical damage to the gland or its duct. The common sites are on the mucosal aspect of the lower lip particularly in patients with a deep overbite and in the buccal mucosa posteriorly where an upper wisdom tooth is erupting buccally. Typically the patient presents with a history of recurrent swellings that develop over days or weeks, rupture and then recur after a few weeks. The cysts rarely exceed 1 cm in diameter and are tense bluish sessile swellings.

The treatment of a ranula is excision of the sublingual gland. Classically the ranula presents as a large tense bluish swelling in the floor of the mouth anteriorly often displacing the tongue (Fig. 42.9). However, the ranula may push its way though the midline mylohyoid dehiscence in the floor of the mouth and enter the submental space presenting as a midline swelling in the upper neck. This is the ‘plunging ranula’. The treatment of a ranula is excision of the sublingual gland.
Salivary neoplasms (Table 42.5)

Salivary neoplasms comprise 1.2 per cent of all neoplastic disease. Nearly all salivary neoplasms present as slowly growing masses which have often been present for several years. Even malignant salivary tumours usually grow slowly. Unfortunately pain is not a reliable indication of malignancy. Certainly if a malignant salivary neoplasm is invading a sensory nerve pain or paraesthesia can occur but frequently at surgery one sees a nerve macroscopically invaded by tumour but which has been functioning normally pre-operatively. Furthermore benign tumours often present with pain and aching in the affected gland presumably due to capsular distension and possibly also due to an element of outflow obstruction. Therefore the only reliable clinical indication of malignancy is facial nerve palsy in the case of the parotid, induration and/or ulceration of the overlying skin or mucosa and regional lymphatic metastasis.

The investigation of salivary neoplasms

For parotid and submandibular tumours CT and MRI scanning are the most helpful imaging techniques (Figs 42.10 and 42.11). They will confirm that the mass being investigated is indeed intrinsic to the gland, they accurately image the borders of the tumour and show whether it is well circumscribed and benign or diffuse, invasive and malignant. In addition they show the relationship of the tumour to other anatomic structures and help with the planning of subsequent surgery.

Open surgical biopsy of intrinsic neoplasms of the major glands is absolutely contraindicated. At least 75 per cent of all parotid tumours and more than 50 per cent of all submandibular gland tumours will prove to be benign pleomorphic adenomas. This tumour which is only poorly encapsulated is very tense and if an incision is made into it the contents of the tumour burst into the surrounding tissue planes and it is impossible to eradicate the microscopic spillage of tumour cells. If this happens the patient will develop multiple local tumour recurrences over many years unless they are subjected to radical postoperative radiotherapy, which is best avoided in the management of benign disease. Clearly if there is skin infiltration or ulceration an open biopsy is essential to establish a preoperative diagnosis upon which to plan surgery. For tumours of the minor salivary glands particularly in the palate there is a much higher chance of the tumour being malignant and as it is not necessary to open up other tissue planes to gain access to the tumour as open incisional biopsy is important.

Fine needle aspiration (FNA) biopsy is a safe alternative to open biopsy of a major gland. Evidence suggests that provided the needle gauge does not exceed 18 G there is no risk of seeding viable tumour cells. Although advocates of this technique claim high accuracy and specificity, there is inevitably a high risk of sampling error.

Epithelial tumours

Seventy-five per cent of all salivary epithelial tumours arise in the parotid glands and, of these, only 15 per cent are malignant. Just over 10 per cent occur in the submandibular glands and, of these, approximately one-third are malignant. About 15 per cent of tumours occur in the minor salivary glands and nearly half of these will be malignant. Tumours arising in the sublingual glands are rare (0.3 per cent) but nearly all of them will be malignant. Both benign tumours — adenomas — and malignant tumours — carcinomas — occur.

Adenomas

Of the variety of benign adenomas that has been described only two — the pleomorphic adenoma and Warthin’s tumour — arise with any frequency. The pleomorphic adenoma occurs at any age (mean 42 years) and has an equal sex incidence. It accounts for at least 75 per cent of parotid tumours and more than 50 per cent of submandibular tumours. It accounts for rather less than 50 per cent of minor gland tumours. Clinically the tumour has the texture of cartilage and has an irregular and bosselated surface. In the palate, the overlying mucosa is rarely ulcerated. Very rarely after a number of years the tumour may undergo malignant change and for this reason all patients presenting with pleomorphic adenomas should be advised to undergo surgical removal of the tumour (Fig. 42.12).

The Warthin’s tumour occurs only in the parotid gland where it accounts for approximately 15 per cent of all neoplasms. It is a disease of the elderly with a mean age of presentation of 60 years. Historically it had a male:female ratio of 4:1 but it is now becoming increasingly common in females. Recent evidence suggests that this tumour is related to cigarette smoking. It is also unusual in that in 10 per cent of cases it arises either bilaterally or is multicentric in the one gland. It does not undergo malignant change.

Carcinomas

The acinic cell carcinoma and the mucoepidermoid carcinoma, although undoubtedly malignant tumours with a potential for local invasion and metastatic spread, are frequently very low grade histologically and do not require the radical treatment needed for more aggressive tumours. Together they account for only 5 per cent of all tumours at any site. The mucoepidermoid tumour is much more common in the USA where it forms 10 per cent of all salivary neoplasms.

The adenoid cystic carcinoma, adenocarcinoma, squamous cell carcinoma and undifferentiated carcinoma are all aggressive malignant tumours that carry a poor prognosis regardless of treatment. The adenoid cystic carcinoma is characterised by relentless perineural spread along the cranial nerves and into the brain. However, it grows extremely slowly and although inevitably fatal the 5- and 10-year survival figures are 70 per cent and 40 per cent, respectively. It is also unusual in having a predilection for distant metastasis to the lungs where it produces often multiple cannon ball tumours which remain symptomless for many years. The other carcinomas mentioned above have 5-year survival figures of around 25—35 per cent.

Management of epithelial tumours

Both benign and malignant tumours arising in the parotid or submandibular glands are treated surgically by excision with surgical clearance. In the parotid gland this is by either superficial or total parotidectomy according to the location of the tumour. Unless the patient presents with facial nerve palsy (indicating a malignant tumour) the facial nerve is always preserved. In the submandibular gland treatment is always by excision of the gland. If a definitive pathological diagnosis is received the tumour is malignant then the patient should receive radical postoperative radiotherapy. In those cases when the tumour involves skin or other adjacent structures or where there is lymphatic metastasis the patient should undergo radical excision, including a neck dissection and sacrificing any structures invaded by tumour, and again treated with postoperative radiotherapy.

Pleomorphic adenomas arising in the minor salivary glands can be treated by local excision with a 5-mm margin. They do not invade periosteum and so in the palate they should be excised subperiosteally. Mucoepidermoid carcinomas and acinic cell carcinomas require rather more radical excision with a 10-mm margin and, when they are situated in the palate, palatal fenestration should be undertaken. Postoperative radiotherapy is only indicated for high-grade tumours or if the margins are not clear. For the remaining carcinomas arising in the minor salivary glands radical surgical excision and postoperative radiotherapy are indicated. In the palate this will be by maxillectomy.

Nonepithelial tumours

A variety of nonepithelial tumours can arise in the salivary glands. Haemangiomas and lymphangiomas (cystic hygromas) occur in childhood. Haemangiomas occur mostly in the parotid and appear shortly after birth and grow progressively for several months. The majority undergoes spontaneous regression by 2 years of age. Females are more frequently affected. Lymphangiomas are less common. They may affect any of the salivary glands. They form sponge-like multicystic lesions. Fifty per cent are manifest by 12 months and 90 per cent will be evident by the
end of the second year. They do not undergo spontaneous involution. They frequently extend into the neck and mediastinum, and can undergo dramatically rapid growth causing respiratory obstruction. Treatment is by complete surgical excision but this may be technically very difficult.

Neurofibromas and neurilemmomas are the commonest nonepithelial tumours arising in adults. Clinically they are nor distinguishable from other salivary tumours and are only diagnosed following surgery for a presumed epithelial tumour. Lipomas occur in the parotids particularly in adult males. They are treated by surgical excision.

**Malignant lymphomas**

True extranodal lymphoma arising in the salivary glands —usually the parotids — is rare. More common is lymphoma arising from the lymph nodes either on the surface of the glands or within the parenchyma of the gland. Lymphoma also arises in the salivary glands, as a complication of HIV disease, and also in benign lymphoepithelial lesion and Sjogren’s syndrome. The peak incidence for non-Hodgkin’s lymphoma is the sixth and seventh decades and females are twice as likely as males to be affected.

Salivary gland lymphomas usually present as firm painless swellings and more than 90 per cent occur in the parotids. If the lymphoma is confined to the parotid, treatment is by parotidectomy with postoperative radiotherapy. If there is evidence of spread beyond the salivary gland, treatment is by polychemotherapy according to the accepted protocols based on histological characterisation.

**Unclassified and allied conditions**

Sialosis is an uncommon noninflammatory cause of salivary swelling usually affecting the parotid glands symmetrically. It is usually associated with metabolic and endocrine conditions such as alcohol abuse, diabetes mellitus, pregnancy, malnutrition and some drugs (usually sympathomimetics). It usually affects middle aged and elderly adults who present with bilateral soft parotid swellings. Biopsy of the glands reveals extensive fatty replacement but otherwise normal tissues. No treatment is known to be effective but sometimes parotidectomy is required to correct the disfigurement.

Necrotising sialometaplasia, benign lymphoepithelial lesion, salivary duct cysts, Kuttner tumour and cystic lymphoid hyperplasia of HIV disease can all mimic salivary gland neoplasia. Similarly, branchial cysts and dermoids can present diagnostic confusion on occasion. As has already been discussed both sarcoid and toxoplasmosis can present as parotid pseudotumours.
Degenerative conditions (Table 42.6)

Sjogren’s syndrome

Sjogren’s syndrome is an autoimmune condition causing progressive destruction of the salivary and lachrymal glands. In 1933 Sjogren first described the association of keratoconjunctivitis sicca (dry eyes) and Xerostomia (dry mouth). Shortly thereafter he noted that these symptoms frequently occurred in patients with rheumatoid arthritis (RA). It has since been realised that Sjogren’s syndrome can occur in association with any connective tissue disorder. Indeed the association is very much commoner in many connective tissue disorders than it is with rheumatoid arthritis. Only 15 per cent of patients with RA develop Sjogren’s syndrome whereas 30 per cent of patients with systemic lupus erythematosus and nearly all patients with primary biliary cirrhosis do so. This combination of dry eyes, dry mouth and a connective tissue disorder — most often RA as this is by far the most frequent connective tissue disorder — is called secondary Sjogren’s syndrome. The same combination of dry eyes and dry mouth but without association with a connective tissue disorder is known as Primary Sjogren’s syndrome. Primary Sjogren’s syndrome also differs from secondary Sjogren’s syndrome by virtue of more severe xerostomia and xerophthalmia, more widespread dysfunction of other exocrine glands, a higher incidence of developing lymphoma and a different antibody profile.

Females are affected more often than males in the ratio of 10:1. Typically they are middle aged. The presenting complaint is usually of the underlying connective tissue disorder and only later does the patient become aware of a gritty feeling in the eyes due to dry eyes or of dry mouth. Occasionally there is enlargement of the parotid glands bilaterally and even more rarely the enlarged parotids are painful (Fig. 42.13). Superinfection of the mouth with Candida albicans is frequent. Less frequently the patient develops bacterial sialadenitis due to ascending infection from the mouth. The condition does not invariably progress to total xerostomia and for any individual patient it is not possible to predict the outcome. The characteristic features of the condition are progressive lymphocytic infiltration, acinar destruction and proliferation of duct epithelium of all salivary and lachrymal tissue.

The diagnosis is often based on the characteristic history. No laboratory investigation is pathognomonic of either primary or secondary Sjogren’s syndrome. However, the following investigations are usually undertaken:

1. Sialography reveals the progressive damage from punctate sialectasis to total parenchymal destruction leaving no more than a grossly dilated duct (Fig. 42.14).
2. Labial salivary gland biopsy can be misleading particularly if only one minor gland is harvested. The characteristic lymphocytic infiltration is focal and a single gland may not show the changes. A minimum of three glands should be submitted to the pathologist.
3. Estimation of salivary flow may be unhelpful as the normal variation in flow rates makes the interpretation of the results difficult.
4. Viral staining of the cornea with rose Bengal and examination of the cornea with a slit-lamp is a very sensitive assessment of a dry eye.
5. Autoantibody screen. See Table 42.7.
6. Blood tests usually show a moderately raised erythrocyte sedimentation rate (ESR) and a mild microcytic anaemia (the anaemia of chronic disease).

The management of Sjogren’s syndrome must be symptomatic. No known treatment modifies or reverses the xerostomia and keratoconjunctivitis sicca. Artificial tears are essential to protect the cornea. For the dry mouth various artificial saliva preparations are available but often the patient prefers to use frequent drinks and learns to carry a bottle of water with them at all times. If patients are to use saliva substitutes it is important that, if they are dentate, the product should not have a low pH and should contain fluoride as rampant dental caries are a frequent complication. There is also increased incidence of developing lymphoma in patients with Sjogren’s syndrome. The risk is highest in those with primary Sjogren’s syndrome. Monocytoid B-cell lymphoma is the usual complication. Its onset is often heralded by immunological changes (falling immunoglobulin levels, falling titre of rheumatoid factor, rising B2-microglobulin titre, rising serum macroglobulin titre and the appearance of monoclonal light chains in the serum and urine), lymphadenopathy and weight loss.

‘Benign’ lymphoepithelial lesion

The term ‘benign lymphoepithelial lesion’ was coined by Godwin in 1952. Use of the word ‘benign’ to describe the lesion is misleading as approximately 20 per cent of patients with benign lymphoepithelial lesion or Sjogren’s syndrome ultimately develop lymphoma. Histologically it is not possible to distinguish benign epithelial lesions from Sjogren’s syndrome. Both are characterised by lymphocytic infiltration, acinar atrophy and ductal epithelial proliferation. Indeed they may well be manifestations of the same condition.

Clinically benign lymphoepithelial lesion presents as diffuse swelling of the parotid. The swelling is firm and often painful. In 20 per cent of cases the parotid swelling is bilateral. Eighty per cent of patients are female and most are over 50 years old at presentation. Often there is an associated connective tissue disorder and the risk of developing lymphoma is particularly high in those with rheumatoid arthritis. Most patients will be treated by parotidectomy in order to establish the diagnosis but if any parotid remnants are left, the swelling may recur again with the risk of lymphomatous change. Prolonged follow-up is essential.

Mikulicz’ syndrome

In 1888 Mikulicz described benign, asymptomatic, symmetrical enlargement of the lacrimal and salivary glands. His original publication described a series of patients who clearly had a variety of different conditions. Benign lymphoepithelial lesion, Sjogren’s syndrome, lymphoma, lymphocytic leukemia, sarcoid and Sialosis can all present in this way. The term Mikulicz’ syndrome is now helpful and should not be used (Fig. 42.19).

Xerostomia

A complaint of dry mouth is common. It seems to be particularly frequent in postmenopausal women who also complain of a burning tongue or mouth. Normal salivary flow decreases with age in both men and women. The situation is further confused as patients with Sjogren’s syndrome are frequently unaware of having a dry mouth and patients who complain of dry mouth frequently have normal salivary flow rates.

The most common causes of xerostomia in order of frequency are:

- chronic anxiety states and depression;
• dehydration;
• drugs — many drugs have been implicated in causing xerostomia as an undesirable side effect (Table 42.8);
• salivary gland diseases as described earlier.

Xerostomia can be difficult to treat. Treatment is aimed at the relief of symptoms and the avoidance or control of complications. Frequent sips of water help most patients. Artificial salivas are nor well accepted but their lubricant properties may be particularly useful at meal times. Cholinergic drugs such as pilocarpine can be tried but their side effects — diarrhoea and pupillary dilatation often outweigh any benefit.

Rampant caries and destructive periodontal disease are major complications due to oral infection. Meticulous oral hygiene and the weekly use of topical fluoride are essential. There is a high incidence of oral candidiasis and antifungal drugs are necessary.

Sialorrhoea (Table 42.9)

Some drugs and painful lesions in the mouth increase salivary flow rates. In normal health this is rarely noticed as the excess saliva is swallowed spontaneously. ‘False ptylism’ is more common and is a well-recognised delusional symptom or occurs due to faulty neuromuscular control leading to drooling despite normal saliva production. Uncontrollable drooling is usually treated surgically. As the submandibular gland contributes most resting saliva, attention is directed at these glands bilaterally. The submandibular ducts can be mobilised and repositioned in the base of the anterior pillars of the fauces. Alternatively the two glands may be excised.
Surgery of salivary gland disease

The most common indication for removal of the sublingual salivary gland is in the management of a ranula, which is a mucous extravasation/retention cyst of the gland. Neoplasms of the sublingual gland occur only rarely but nearly all tumours at this site will be malignant. In this situation sur-gery is the same as that for any other malignancy in the floor of the mouth — resection with a clear margin often involving the mandible and when necessary en bloc with a neck dissection. Before an incision is made it is helpful to infiltrate the floor of the mouth with a local anaesthetic containing vasopressors intravenously or as a subcutaneous injection. A linear incision is made in the floor of the mouth parallel to and just lateral to the submandibular duct, with care taken not to extend the incision more posteriorly than the first molar tooth so as to avoid damage to the lingual nerve (Fig. 42.16). The incision should open the cavity of the ranula and allow the mucinous contents to be aspirated. The submandibular duct is now carefully identified and retracted medially. Stay sutures passed through the margins of the mucosa are helpful to aid retraction. Using blunt dissection with scissors the lingual nerve is identified. The sublingual gland which lies adjacent to the inner cortex of the mandible is then mobilised and its multiple ducts which drain into the submandibular duct are divided carefully to prevent damage. The anterior mandibular branch of the facial nerve may be attached to the perimandibular region of the gland by fibrous tissue and this must be divided carefully. Following removal of the gland, the mucosa of the floor of the mouth is loosely closed with two or three plain gut sutures. When sublingual gland excision is necessary for a tumour, it should be removed with a wide margin including a rim resection of the mandible (Fig. 42.17).

Complications

Damage to the lingual nerve posteriorly or the submandibular duct medially is avoided by careful surgical technique. Meticulous haemostasis is required to avoid a postoperative haematoma in the floor of the mouth.

Submandibular gland excision

The patient is positioned supine on the operating table with moderate neck extension and the chin rotated to the opposite side. It is helpful to have head-up tilt on the operating table as this reduces venous engorgement. Following routine skin preparation and draping the incision is mapped out. The line should run within a skin crease in the neck at least 3 cm below the lower border of the mandible in order to avoid risk of damaging the mandibular branch of the facial nerve as it loops down below the lower border of the mandible. The incision should be approximately 7 cm long. The incision line is infiltrated with conventional dental local anaesthetic solution containing 2 per cent lignocaine and 1:80,000 adrenaline. This results in some vasoconstriction which limits capillary ooze and helps to define tissue planes. The incision edge is either a fine cutting diathermy or a fine surgical blade or a fine cutting diathermy whilst the assistant holds down the tip of the blade or a fine cutting diathermy whilst the assistant holds down the tip of the incision line. The incision is made directly down to platysma. The subcutaneous fat is stripped with firm pressure and a swab from the underlying muscle for approximately 1 cm on each side of the incision as this facilitates a layered closure later. The underlying platysma is then incised to the full extent of the skin incision again with either a blade or cutting diathermy. The assistant can now retract the wound margins using ‘cat paws’ or Allis forceps applied to the cur edge of the platysma muscle (never the skin edges!). The underlying investing layer of the deep cervical fascia is next divided, preferably with scissors, after the fascia is first tented outwards with toothed forceps. Often the fascia consists of a series of separate laminae like an onion skin but occasionally it is composed of a single thicker sheet. Again the fascia should be divided along the full length of the incision to avoid the operative field becoming ever smaller.

Posteriorly, the fascial incision approaches the angular tract where the deep cervical fascia splits to form the investing layer that has just been incised and the deeper layer that forms the floor of the submandibular triangle containing the submandibular gland.

The mandibular branch of the facial nerve normally runs on the deep aspect of the investing layer of fascia although occasionally it lies between the platysma and the fascia. Great care must be taken to protect the mandibular branch.

The anterior facial vein which lies in the connective tissue overlying the submandibular gland is clamped, divided and tied. The loose connective tissue is separated with scissors to expose the submandibular gland. The dissection from now on continues on the capsular surface of the gland. For chronically infected glands there is frequently extensive fibrosis, and care and patience are required to maintain this plane. For all tumours contained within the submandibular gland capsule, this plane is safe as it forms an effective barrier. For malignant tumours that have infiltrated beyond the capsule, a full submandibular clearance, usually as part of a neck dissection, and often including the perimandibular region of the lower and inner aspect of the mandible, is needed.

The anterior pole of the superficial lobe of the submandibular gland is first mobilised and retracted upwards with Allis forceps (Fig. 42.18). This reveals the posterior belly of the digastric muscle which is then gently retracted downwards with a small Langenbeck retractor. This exposes the facial artery which emerges from behind the stylohyoid muscle and passes upwards and forwards to enter the deep surface of the submandibular gland. The artery is then clamped, divided and tied. Great care must be taken to secure the proximal ligature. As the vessel is divided it is often lifted off the mandible and as a result the vessel can be very difficult to identify.

The course of the facial artery is variable. Often it deeply penetrates the substance of the gland to emerge again at its upper border. Sometimes the artery lies in a groove in the deep aspect of the gland. The dissection in the plane of the submandibular gland capsule continues to mobilise the anterior pole of the superficial lobe of the gland, which is then gently retracted posteriorly. During this dissection a number of small arteries and veins will be identified entering the gland. These should be carefully clamped, divided and tied or diathermised according to size. As the dissection continues posteriorly along the lower border of the mandible, the facial artery and anterior facial vein are encountered as they hook around the mandible. The vessels are again clamped, divided and ligated at this point. At this stage in the operation, the anterior pole of the superficial lobe of the gland can be retracted posteriorly to reveal the groove between the superficial and deep lobes of the submandibular gland. The posterior border of the mylohyoid muscle lies within this groove. It is gently freed with scissors and then retracted forwards with a Langenbeck retractor. The deep lobe of the submandibular gland can now be mobilised either with a finger or by opening the blades of the scissors applied to the surface of the gland. On the deep aspect of the deep lobe, one or two small veins may be encountered running from the gland through the underlying hypoglossus into the lingual veins. If these veins are not tied or adequately diathermised, troublesome bleeding may be encountered.

The submandibular salivary gland can now be pulled downwards revealing the V-shaped lingual nerve. The apex of the V is the point at which parasympathetic secreto-motor fibres tether the lingual nerve to the salivary gland. It is very important to identify carefully the V of the lingual nerve and its parasympathetic fibres as the latter must be transected to free the gland (Fig. 42.19). As these fibres are cut, the lingual nerve springs forwards. Finally the submandibular duct is clamped, divided and tied as far forward as possible with just enough left to drain the major sublingual gland which empties into the duct. A thin layer of loose connective tissue remains in the gland bed overlying the hypoglossal nerve. The wound is inspected for any bleeding points, a vacuum drain inserted and the wound closed in layers using a subcuticular suture to close the skin. The wound edges are reinforced with skin closure tapes.

Complications

Three cranial nerves are at risk during removal of the sub-mandibular salivary gland — the mandibular branch of the facial nerve, the lingual nerve (a branch of the third division of the trigeminal nerve) and the hypoglossal nerve.

When chronic infection and subsequent fibrosis have occurred, it is sometimes difficult to identify the lingual nerve and the deep aspect of the deep lobe may be attached to the hypoglossal nerve. At these stages of the operation, the surgeon must be convinced that these structures have been identified before using any sharp dissection.

Meticulous haemostasis is required throughout the opera-tion as many of the vessels entering and leaving the sub-mandibular gland are only apparent when the gland is under traction and as soon as they are divided the vessels retract into the adjacent muscle planes.

Parotidectomy

Treatment of parotid tumours is by superficial parotidectomy for all benign tumours in the superficial lobe and total parotidectomy for all benign
deep lobe and dumb-bell tumours. Such tumours including deep lobe tumours should never be approached from the pharyngeal aspect. The facial nerve is preserved in all cases.

The prognosis for malignant parotid tumours is poor. There is little evidence that radical parotidectomy, which includes sacrificing the entire facial nerve, adds significantly to the patient’s survival. It does, however, considerably increase the morbidity. For this reason, superficial or total parotidectomy for malignant tumours is undertaken with preservation of those branches of the facial nerve not macroscopically invaded by tumour. This is followed in all cases of malignant parotid tumours by radical radiotherapy.

For any malignant parotid tumour with or without involvement, facial nerve weakness, mandibular invasion, extension into the infratemporal fossa or lymph node metastasis, radical resection often in continuity with radical neck dissection must be undertaken with reconstruction with the use of appropriate flaps and followed by radical postoperative radiotherapy.

**Surgical technique**

Whenever the facility is available and the patient fit, hypotensive anaesthesia is used, as this considerably reduces oozing and thus makes it easier to trace the facial nerve fibres. The incision line is infiltrated with lignocaine hydrochloride and 1:80 000 adrenaline and the incision made with a knife or fine cutting diathermy. Following a preauricular incision extending downwards to continue in a suitable skin crease in the neck, the skin flap is raised in the plane of the pre parotid fascia and then held forward by suturing the margins for the flap to the adjacent towels. The blood-free plane anterior to the external auditory meatus is opened up by blunt dissection and this leads the surgeon down to the base of skull just superficial to the stylomastoid process and the stylomastoid foramen. This plane is then gently opened up in an inferior direction by blunt dissection until the trunk of the facial nerve is seen. With large posterior tumours this plane may be difficult to open up. In this situation it is helpful to identify the posterior belly of the digastric muscle in the cervical extension of the incision. The anterior border of the sternocleidomastoid muscle is mobilised and retracted inferiorly to display the digastic muscle beneath it (Fig. 42.20). This manoeuvre may necessitate sectioning the great auricular nerve. The posterior belly of the digastric is traced upwards and backwards to its insertion on to the mastoid, which lies immediately below the stylomastoid foramen, thus leading the operator to the facial nerve from below.

There are four anatomical landmarks leading to the identification of the trunk of the facial nerve as it leaves the stylomastoid foramen (Fig. 42.21).

1. The cartilaginous external auditory meatus forms a pointer at its anterior, inferior border indicating the direction of the nerve trunk.
2. Just deep to the cartilaginous pointer is a reliable bony landmark formed by the curve of the bony external meatus and its abutment with the mastoid process. This forms a palpable groove leading directly to the stylomastoid foramen. Unfortunately this groove is filled with fibrofatty lobules that often mimic the trunk of the facial nerve which can lie as much as 1 cm deep to this landmark.
3. The anterior, superior aspect of the posterior belly of the digastric muscle is inserted just behind the stylomastoid foramen.
4. The styloglossus process itself can be palpated superficial to the stylomastoid foramen and just superior to it. The nerve is always lateral to this plane and passes obliquely across the stylodermal process. A branch of the postauricular artery is usually encountered just lateral to the nerve.

Once the facial nerve trunk has been identified the superficial lobe of the parotid can be exteriorised by opening up the plane in which the branches of the facial nerve run between the two lobes by blunt dissection. Initially, as it leaves the stylomastoid foramen, the trunk of the facial nerve turns abruptly to become more superficial and also divides into the larger zygomaticofacial trunk and smaller cervicofacial trunk. The main branches of the nerve are then followed peripherally through the parotid until the superficial lobe is completely freed. This part of the operation is performed using fine scissors, opened up in the plane of the facial nerve branches, with care always taken to identify the nerve fibres before dividing parotid tissue (Fig. 42.22).

During the lower part of the dissection, branches of the posterior facial vein will be encountered immediately deep to the marginal mandibular branch. Great care must be taken when vascular clamps are applied to these branches to avoid damaging the facial nerve.

If the superficial parotidectomy is being performed for chronic infection, the dura should be tied off as far forward as possible to prevent recurrent ascending infection from the oral cavity.

If the tumour lies in the deep lobe of the gland a conventional superficial parotidectomy is performed as described. Next, the branches of the facial nerve are mobilised and lifted on nylon tapes to enable the deep lobe to be freed around its margins and removed when the mass is dropped downwards (Fig. 42.23). As this space is wedge shaped with its apex superior, it is almost invariably possible to do this. The deep lobe is covered by a capsule (the deep layer of the deep cervical fascia which splits to envelope the parotid) and is surrounded by the parotid fat. Thus, it is relatively easy to mobilise the deep lobe by blunt dissection with either scissors or a finger. Only very rarely is it necessary to perform a mandibulotomy to gain access to the deep lobe.

Very rarely most often after recurrent infection with fibrosis or previous radiotherapy — the trunk of the facial nerve cannot be confidently identified. In this situation the peripheral branches of the nerve are identified at the anterior border of the parotid and traced centrally towards the stylomastoid process. Following removal of the parotid gland the blood pressure is returned to normal, all bleeding points are controlled, a vacuum drain is placed and the wound closed in layers. A pressure dressing is then applied for 48 hours.

**Complications**

Permanent facial nerve paralysis following superficial or total parotidectomy is rare except when branches of the facial nerve have been deliberately sacrificed. When the facial nerve or its branches are sacrificed as a result of macroscopic tumour involvement, an immediate nerve graft may be undertaken using conventional microneural techniques.

Temporary weakness due to neuropaxia occurs in approximately 30 per cent of operations but recovers rapidly, usually within 6 weeks. Anaesthesia of the skin flap slowly resolves as the sensory nerves regenerate from the periphery.

Anaesthesia of the ear lobe due to sectioning of the great auricular nerve can be troublesome, particularly in females who find it difficult to wear earrings. Recovery can take up to 18 months and sometimes is never complete.

Gustatory sweating (Frey's syndrome) is a regular sequel to parotidectomy occurring in up to 54 per cent of cases. Surgical manoeuvres to treat it once established are not successful and most patients either learn to live with it or alternatively use an antiperspirant containing aluminium chloride.

Spillage of a benign pleomorphic adenoma should not occur if a formal superficial parotidectomy is undertaken. However, there are four circumstances where even with meticulous surgical technique this can happen:

- extremely large pleomorphic adenomas occupying the entire superficial lobe making mobilisation of the gland difficult;
- tumours that are intimately associated with branches of the facial nerve requiring very delicate dissection along the capsule of the tumour to release the nerve;
- tumours with lobular extensions extending beneath the mastoid, zygomatic arch or mandible;
- some tumours that are abnormally friable with even routine retraction of the superficial lobe resulting in rupture. If rupture occurs an extremely
careful inspection of the wound must be undertaken and the area thoroughly irrigated. In all such cases postoperative radiotherapy should be undertaken in order to avoid multiple recurrences due to tumour seeding.

Other rare complications such as sialocele or salivary fistula occasionally follow parotidectomy. Both complications are managed conservatively and resolve spontaneously after days or weeks. Very rarely a parotid fistula persists despite attempts at surgical closure. In this situation postoperative radiotherapy will destroy the residual functioning acinar tissue and allow the fistula to close.

Radiotherapy

Parotid tumours are often considered to be ‘radioresistant’. This is not true: regression after radiotherapy is usually slow, but this reflects the slow cell turnover time of the majority of these tumours, rather than the inability of radiation to effect a cure. There are many reports of long-term local control of large inoperable tumours by radiotherapy. Nevertheless, the chance of successful radiotherapy does seem lower than in the case of squamous cell carcinoma, and therefore the primary treatment should be surgical wherever possible.

Radiotherapy is of value for the inoperable tumour, and also should be used postoperatively whenever there is a risk of incomplete excision such as rupture of a pleomorphic adenoma. It should also be used prophylactically to radical dosage following excision of any malignant parotid tumour. In cases where reoperation is required for recurrence or where there is gross residual tumour, radiation in high doses increases survival significantly.

Adenoid cystic carcinoma has been reported to be the most, consistently radio responsive tumour type. In view of the propensity of this tumour for later recurrence, it is doubtful whether high local control rates at 3 or 5 years really indicate radio curability.

A wide volume around the tumour should be irradiated, especially in the case of adenoid cystic carcinoma. A dose close to the limits of normal tissue tolerance is necessary.

Clinical anatomy and physiology

The pharynx

The pharynx is a fibro muscular tube forming the upper part of the respiratory and digestive passages. It extends from the base of the skull to the level of the sixth cervical vertebra at the lower border of the cricoid cartilage where it becomes continuous with the oesophagus. It opens anteriorly into the nose, mouth and larynx from above downwards, and is therefore divided into three parts, the nasopharynx, oropharynx and hypopharynx (Fig. 43.1).

Nasopharynx

The nasopharynx lies anterior to the first cervical vertebra and has the openings of the eustachian tubes in its lateral wall, behind which lie the pharyngeal recesses, the fossae of Rosen Muller. The adenoids are situated submucosally at the junction of the roof and posterior wall of the nasopharynx. The nasopharynx is closed off from the oropharynx during swallowing by the raising of the soft palate and contraction of the palatopharyngeal sphincter.

Oropharynx

This is bounded above by the soft palate, below by the upper surface of the epiglottis and anteriorly by the anterior faucial pillar which contains the palatoglossus muscle. The oropharynx therefore contains the palatine tonsils situated in the latero-al wall between the anterior and posterior pillars of the fauces and the posterior third of the tongue. These palatine tonsils are part of the complete ring of lymphoid tissue (Waldeyer’s ring) which additionally comprises the adenoids and the lingual tonsils on the posterior third of the tongue. This ring of lymphoid tissue occupying the entry of the air and food passages is constantly exposed to new antigenic stimuli. It is an important part of the mucosal-associated lymphoid tissue (MALT) which processes antigen and presents it to T-helper cells and B-cells. The tonsillar tissue produces immunoglobulin G (IgG), IgA and a small amount of IgD. These immunoglobulins are secreted into the pharynx and their output is increased in response to a wide variety of inflammatory processes (Fig. 43.2).

Swallowing

Swallowing is a complex neuromuscular act. Trauma and disease may result in dysphagia and at times aspiration of food and fluid into the airway. In considering the diseases which involve the pharynx and larynx, it is important to have a basic understanding of swallowing and the functions of the larynx. Swallowing consists of three stages: oral, pharyngeal and oesophageal (Fig. 43.3). Knowledge of the physiology of normal swallowing and the problems as a consequence of disease has been enhanced in the last two decades by use of video fluoroscopic techniques. This is the radio graphical evaluation of the passage of a bolus of radio-opaque liquid or solid from the point at which it enters the oral cavity down to its passage within the stomach. This investigation is considerably more accurate than the older-fashioned radiological techniques. This is the radiographic evaluation of the passage of a bolus of radio-opaque liquid or solid from the point at which it enters the oral cavity down to its passage within the stomach. This investigation is considerably more accurate than the older-fashioned radiological examination of barium swallow, where the object was to con-centrate on the plain X-ray examination of the oesophagus, rather than the new technique which shows a complete video of all stages of swallowing. This can be reviewed on many occasions, if necessary, and gives far more detail than plain radiograph films.

Swallowing is mediated via efferent fibres passing to the medulla oblongata through the second division of the trigeminal nerve (V), glossopharyngeal (IX) and vagus nerves (X). The afferent pathway is from the nucleus ambiguous, and is mediated via the glossopharyngeal (IX), vagus (X) and hypoglossal (XII) nerves.

Damage to these major cranial nerves at any point along their pathway, by trauma or disease, may cause dysphagia with or without aspiration.

In the oral voluntary phase of swallowing the lips, cheeks, tongue, floor of mouth, teeth and palate participate in preparing the food. The food is held in the oral cavity, lateralised for mastication and then formed into a bolus. The tongue propels the formed bolus posteriorly into the oropharynx in the second involuntary pharyngeal phase. The soft palate is elevated to prevent nasopharyngeal escape, and the lateral and posterior walls contract to propel the food downwards. The larynx moves upwards and forwards as the posterior tongue moves backwards and downwards.

The main function of the larynx is in fact not the production of voice but the protection of the tracheobronchial airway and lungs. It is basically a three-tiered sphincter mechanism: the first tier consisting of the epiglottis, aryepiglottic folds and arytenoids; the second the false cords; and the third level the true vocal folds. The whole larynx not only moves upwards and forwards but the three-tier sphincter mechanism closes on every occasion that swallowing occurs.

As the food enters the piriform fossa there is an anticipatory relaxation of the upper oesophageal sphincter and the food enters the oesophagus. Oesophageal peristaltic waves then convey the food down into the stomach. Gravity aids both the involuntary pharyngeal and oesophageal phases of swallowing.

Relations of the pharynx (Fig. 43.4)

The parapharyngeal space — this potential space lies lateral to the pharynx and is of importance when understanding disease of the pharynx and neck. It is a potential space which extends from the base of the skull above to the superior mediastinum below, and it is occupied by the carotid vessels, internal jugular vein, deep cervical lymph nodes, the last four cranial nerves and the cervical sympathetic trunk. Infection and
suppuration of the cervical lymph node in the parapharyngeal space most commonly occurs from infections of the tonsils or teeth (particularly the third lower molar tooth). It may then spread throughout the parapharyngeal space up to the skull base or down to the paraoesophageal region and superior mediastinum. Retropharyngeal space — this potential space lies posterior to the pharynx bounded anteriorly by the posterior pharyngeal wall and its covering buccopharyngeal fascia and posteriorly by the cervical vertebrae and their covering muscles and fascia. It contains the retropharyngeal lymph nodes, which are usually paired lateral nodes, but which are separated by a tough median partition which connects the prevertebral with the buccopharyngeal fascia. These nodes are more developed in infancy and young children, and it is at this age that they are most likely to be involved in inflammatory processes which, if severe, may affect swallowing and respiration as a consequence of gross swelling and suppuration of the retropharyngeal space.

Larynx

The larynx is the protective sphincter which closes off the airway during swallowing. In humans and some other mam-mals it is also responsible for the generation of sound, which in humans is modified by the pharynx, oral cavity, nasal passages, sinuses, tongue, lips and teeth to produce speech. The larynx has a mainly cartilaginous framework which may ossify in later life and which consists of the hyoid bone above, the thyroid and cricoid cartilages, and the intricate arytenoid cartilages posteriorly.

The cricoid cartilage is the only complete ring in the entire airway and bounds the sub glottis which is the narrowest point of the airway. This is the commonest site for damage from endotracheal tubes, occasionally causing laryngotracheal stenosis.

An anatomical description of the larynx divides it into the supraglottis, glottis and subglottis (Fig. 43.5). The true vocal folds (often incorrectly called the vocal cords) are normally white in contrast to the pink mucosa of the rest of the larynx and airway. The true vocal folds meet anteriorly at the mid-level of the thyroid cartilage, whereas posteriorly they are separate and attached to an arytenoid cartilage. This arrangement produces the ‘V’ shape of the glottis (Fig. 43.6).

Nerve supply

The sensory nerve supply to the larynx above the vocal folds is from the superior laryngeal nerve and below the vocal folds from the recurrent laryngeal nerve. Both of these nerves are branches of the vagus (X). The motor nerves supply to the larynx is from the recurrent laryngeal nerve, which is a branch of the vagus and which supplies all intrinsic muscles. Only one of these intrinsic muscles, the posterior cricoarytenoid, abducts the vocal folds during respiration. All other intrinsic muscles adduct the cords.

Lymphatics

The lymphatic drainage of the supraglottis above the vocal folds is to the upper deep cervical nodes, whilst in contrast that of the subglottis is to inferior deep cervical nodes and to the paratracheal and mediastinal nodes.

• The vocal folds themselves have a very sparse lymphatic drainage. The commonest form of malignant disease affecting the true vocal folds is squamous cell carcinoma, and tumours confined to the true vocal folds do not metastasise to lymph nodes unless they spread into supraglottic or subglottic tissue.

All of the intrinsic muscles of the larynx are supplied by the recurrent laryngeal nerve, and therefore damage to this nerve or to the vagus nerve will cause paralysis of the vocal fold on the side of the damage.

Phonation/speech

During expiration air from the lungs passes out through the larynx under pressure and the vocal folds channel this into a column of high-speed vibrating air, thus producing sound. This sound is converted into intelligible speech by the remainder of the vocal tract, i.e. the pharynx, tongue, lips, teeth and the resonating chambers of the nose and sinuses. The larynx functions by closing the vocal fold against the air being exhaled from the lungs but the rise in subglottic pressure forces the vocal folds apart slightly for an instant with accompanying vibration of the vocal fold epithelium. The opening and closing occurs in rapid sequence to produce a vibrating column of air which is the source of sound. The pitch of the sound is controlled by the frequency of the vocal fold epithelial vibration, which in turn is determined by the thickness, length and tension of the vocal folds controlled by the intrinsic musculature. The loudness or intensity of the sound is governed by the expiratory air pressure and the amplitude of the vocal fold vibrations.

Paralysis or overt disease of the vocal folds or closely associated laryngeal structures will give rise to disturbance of the sound and creation of the symptom of hoarseness (Table 43.1).

The neck

The neck is divided into anterior and posterior triangles by the sternocleidomastoid muscle. The anterior triangle extends from the inferior border of the mandible to the sternal notch, and is bounded by the midline and the sternocleidomastoid muscle. The posterior triangle extends backwards to the anterior border of trapezius and inferiorly to the clavicle. The upper part of the anterior triangle is commonly subdivided into the submandibular triangle above the digastic muscle and the submental triangle below. The lymphatic drainage of the head and neck is of considerable clinical importance (Fig. 43.7). The most important chain of nodes is the deep cervical nodes which run adjacent to the internal jugular vein. The other main groups are the submental, submandibular, preauricular and postauricular, occipital and posterior triangle nodes.

The upper deep cervical nodes, which contain the large jugulo-digastric node, drain the oropharynx, including the tonsils, postero-lateral aspects of the oral cavity, superior aspects of the larynx and piriform fossae, and are the commonest site of enlargement due to disease in these areas.

The upper deep cervical nodes may be palpated along the anterior border of the sternocleidomastoid muscle but when the muscle is well developed or the neck is obese it may be difficult to evaluate their true size and under these circumstances clinical examination may be unreliable.

Metastatic spread of squamous cell carcinoma, which accounts for 80 per cent of malignant disease of the head and neck, most commonly occurs with tumours of the nasopharynx, tongue base, tonsil, piriform fossae and supraglottic larynx. When an enlarged neck node is detected and the possibility of malignant disease suspected, it is these five primary sites which must receive careful investigation.

Metastatic spread to regional lymph nodes in the neck is managed surgically in many cases by resection of the neck nodes, and a detailed knowledge of their anatomy is thus required. The parotid and submandibular salivary glands, and the thyroid and parathyroid glands, are
additional important neck structures which will be covered separately in their respective chapters.
Clinical examination

Pharynx and larynx

Prior to examination of the pharynx, the oral cavity should be examined with the aid of a good light and tongue depressors (Fig. 43.8).

The ear, nose and throat (ENT) surgeon customarily uses a reflecting mirror on the head or a headband-mounted fibreoptic light source which permits use of both hands to hold instruments. Inspection should include the buccal mucosa and lips, the palate, the tongue and floor of the mouth, all surfaces of the teeth and gums, opening and closing of the mouth, and dental occlusion. Patients should be asked to elevate the tongue to the roof of the mouth and protrude the tongue to both the right and the left. Palpation may be required using one or two fingers gently intraorally to feel any swellings, and this may be combined with extra oral palpation of the submental and submandibular lymph nodes and salivary glands. Simple percussion of the teeth may reveal tenderness indicating adjacent pathology in the maxilla or mandible. Examination of the mouth without adequate illumination, the use of a tongue depressor, and gentle palpation may fail to reveal common and important pathology. Following examination of the oral cavity, the oropharynx is inspected with the light and with the tongue depressor placed firmly on to the tongue base to depress it inferiorly. The anterior and posterior faucial pillars, the tonsil, retromolar trigone and posterior pharyngeal wall should all be inspected for colour changes, ulceration, pus, foreign bodies and swellings. Even with an experienced examiner, approximately one-third of patients cannot tolerate the depression of the posterior base of tongue without gagging. Pain and trismus as a consequence of pharyngolaryngeal or neck pathology may add to the difficulty of the examination. However, if the patient is co-operative the nasopharynx may be further examined by posterior rhinoscopy using a postnasal mirror introduced along the tongue depressor and moved so that a mirror image is seen of the nasopharynx. Likewise, further examination of the infe-rior oropharynx, larynx and piriform fossae can be obtained by indirect laryngoscopy using laryngeal mirrors. Both of these mirror examination techniques require the use of a headlight and both of the examiner’s hands. Indirect laryngoscopy allows visualisation of the larynx to the level of the vocal folds, and sometimes additional views of the subglottic and tracheal airway. Vocal fold mobility may be assessed.

Fibre-optic pharyngolaryngoscopy

The fibre-optic nasendoscope is passed through the nose under topical anaesthesia, and the entire nasopharynx, oropharynx and larynx can be seen and demonstrated to others. This technique allows high-quality visualisation in over 90 per cent of patients (Fig. 43.9). Modern fibre-optic nasendoscope have produced tremendous improve-ments in examination Of the nasal cavities, pharynx and larynx. They are now widely available and should he used whenever possible.

The neck

With the patient sitting, expose the whole neck so that both clavicles are clearly seen. Inspect the neck from in front and ask the patient to swallow, preferably with the aid of a sip of water. Note the movements of the larynx and any swelling in the neck. Ask the patient to protrude the tongue if there is a midline neck swelling. A thyroglossal cyst will move upwards with the tongue protrusion. Then stand behind the seated patient who should sit with the chin flexed slightly downwards to remove any undue tension in the strap muscles, platysma and sternocleidomastoid. Palpate the neck bilaterally using the pulps of the fingers, not the tips. It is important to palpate the groups of lymph nodes in a definite manner comparing the two sides of the neck. Begin with the superficial chain around the upper neck and carefully palpate the entire length of the deep cervical nodes around the internal jugular vein. On examining for a lump in the neck it is often helpful to ask the patient to point to the lump first. Ask them whether the lump is tender. A swelling beneath the sternomastoid muscle may be considerably larger than your evaluation on palpation. If you are suspicous that a neck node is enlarged as a result of malignancy (it may be hard, irregular or fixed to overlying skin or to deep structures) then it is mandatory to inspect the nasopharynx, tonsils, tongue base, piriform fossa and supraglottic larynx (Table 43.2).
Investigation of diseases in the pharynx, larynx and neck

Plain lateral X-rays

Plain lateral radiographs of the neck and cervical spine may show soft-tissue abnormalities; of particular importance is the depth and outline of the prevertebral soft-tissue shadow. The outline of the laryngotracheal airway may be a useful guide to the presence of disease in the pharynx and larynx (Fig. 43.10). Radio-opaque foreign bodies may be visible, impacted in the pharynx, larynx or upper oesophagus. There should be no air within the upper oesophagus, if this is seen it is indicative of pathology.

Barium swallow

This X-ray has traditionally been used to assess the pharynx and oesophagus using simple barium liquid and plain X-rays. However, it has now been superseded in many places by the use of video fluoroscopic studies which record the moving images of a small quantity of radio-opaque liquid, enabling evaluation of the oral and pharyngeal phases of swallowing in much more detail (Fig. 43.11).

Manometric analysis and pH recordings within the pharynx and oesophagus are used in specialised units and may be coupled with simultaneous video fluoroscopy to assess changes in luminal pressure and pH to define muscular inco-ordination and the role of reflux of low-pH gastric contents.

Computerised tomography (CT) scanning

CT scanning is widely used to assess head and neck disorders, and the increasing quality of the images provides much improved demonstration of disease in the pharynx, larynx and neck. Intravenous contrast given at the same time as the CT scan (dynamic scanning) further improves the demonstration of disease in these areas (Fig. 43.12).

Other techniques

Magnetic resonance imaging (MRI) is being increasingly used and may give better soft-tissue definition of some diseases but poorer definition of bony and cartilaginous structures. Ultra-sound scanning can be useful in differentiating solid lesions, e.g. malignant lymph nodes from cystic lesions such as a branchial cyst.

Fine needle aspiration cytology

This technique can be performed under local anaesthesia either in the out-patient department or in a cytology clinic. Fine needle aspiration cytology is useful particularly if a neck lump is thought to be malignant. Increasingly high rates of accurate histological diagnosis are reported and there is no evidence of spread of tumour through the skin track caused by the fine hypodermic needle used with this technique. Fine needle aspiration may be further aided by ultrasound or CT guidance.

Angiography or digital subtraction vascular imaging

These may be indicated if a vascular lesion such as a carotid body tumour is suspected. Angiography may have a therapeutical role to play by facilitating embolisation of the lesion.

Voice analysis

An increasing variety of techniques is now available for the measurement of vocal function including videostroboscopy. This technique utilises a flexible or rigid endoscope coupled to a video-camera and a stroboscopic light. This allows identification of the fine epithelial movements of the vocal folds and demonstrates this on a monitor to the patient, doctor and speech therapist. This technique allows very sensitive assessment of laryngeal vocal fold pathology.

Direct pharyngoscopy and laryngoscopy

An examination of the pharynx, larynx and neck under general anaesthesia may be required as a result of problems with the routine examination of patients. This may be due to an inadequate view as a consequence of trismus from pain, poor patient compliance, or large obstructive pharyngeal or laryngeal pathology. These examinations may be further aided by the use of an operating microscope, or rigid telescopes (Hopkin’s rods) which improve the visualisation of the pharynx and larynx (Fig. 43.13).
Diseases of the pharynx

Nasopharynx

Enlarged adenoid

The most common cause of an enlarged adenoid (there is only one nasopharyngeal adenoid, despite the common use of the term ‘adenoids’) is physiological hypertrophy (Fig. 43.14). The size of the adenoid alone is not an indication for removal. It is often associated with hypertrophy of the other lymphoid tissues of Waldeyer’s ring. If excessive hypertrophy causes blockage of the nasopharynx in association with tonsil hypertrophy, the upper airway may become compromised during sleep causing obstructive sleep apnoea. This condition is becoming increasingly diagnosed, and is important because it can cause sleep deprivation and secondary cardiac complications. It has been implicated in some cases of a sudden infant death syndrome. The most common symptom is snoring, which is typically irregular, with the child actually ceasing respiration (apnoea) and then restarting with a loud inspiratory snort. The child is often restless and may take up strange sleeping positions as he or she tries to improve the pharyngeal airway. Surgical removal of the tonsils and adenoid is curative, but it is important to avoid sedative premedications and opiates analgesics postoperatively because they may further depress the child’s respiratory drive. Obstructive sleep apnoea may also occur in adults, where the obstruction may result from nasal deformity, a hypertrophic soft palate associated with an altered nasopharyngeal isthmus, obesity and general narrowing of the pharyngeal airway, or supraglottic laryngeal pathology. Surgery may be indicated following investigation by means of a sleep study, during which measurement of the patient’s sleep pattern and arterial oxygenation is undertaken.

Hypertrophy of adenoid tissue most commonly occurs between the ages of 4 and 10 years, but the adenoid tissue usually undergoes spontaneous atrophy during puberty, although some remnants may persist into adulthood. The relationship of adenoid enlargement to recurrent secretory otitis media or recurrent acute otitis media is not entirely clear. It has long been thought that eustachian tube dysfunction results from either inflammatory oedema or interference with palatal elevation which opens the eustachian tube. However, the exact relationship has not been determined and many children who have secretory otitis media do not always benefit from adenoid removal.

Adenoidectomy

Adenoid tissue can be removed alone or in conjunction with a tonsillectomy.

Indications are:

- obstructive sleep apnoea associated with postnasal obstruction;
- postnasal discharge;
- recurrent acute otitis media or prolonged serous otitis media usually longer than 3 months’ duration;
- recurrent rhinosinusitis.

Operative technique. The adenoid tissue is removed with a guarded curette (Fig. 43.15) pressed against the roof of the nasopharynx and then carried downwards in a moderately firm sweeping movement bringing the excised adenoid into the oropharynx (Fig. 43.16). The guard on the curette secures the adenoid and prevents it from dropping inferiorly into the airway. A postnasal swab is placed into the nasopharynx until all haemorrhage has ceased. Reactionary or secondary haemorrhage during the recovery period may require the placement of a nasopharyngeal pack under a further anaesthetic. This can occasionally cause respiratory depression in children and adults, and they require strict observation while the pack is in place.

Tumours of the nasopharynx

Benign. There are two main types of benign tumour of the nasopharynx: the angiofibroma and the antrochoanal polyp.

Angio fibroma. This is often termed ‘nasopharyngeal angio-fibroma’, but this is incorrect as the tumour arises in the area of the sphenopalatine foramen in the posterior part of the nasal cavity. However, it readily expands into the nasopharynx and, although the tumour is not malignant in that it never metastasises, it does spread relentlessly over the skull base expanding anteriorly into the nasal cavities displacing the nasal septum, compressing the posterior wall of the maxillary antrum and often entering it by bone erosion. Likewise, it may enter and expand the sphenoid sinus and spread laterally through the pterygopalatine fissure and onwards into the infratemporal fossa occasionally to reach the soft tissues of the cheek and orbit via the inferior orbital fissure. Inferiorly it may fill the nasopharynx, depress the soft palate and eventually appear within the oropharynx (Fig. 43.17).

Macroscopically there is a firm reddish-blue tumour covered with normal mucous membrane, but ulceration may occur if the tumour hangs into the oropharynx or becomes exposed anteriorly at the nostril. Microscopically it is composed of immature fibroblasts and blood vessels, and it remains benign even in its advanced stages. It should probably be regarded as a hamartoma. Clinically the tumour is confined to male patients commonly between the ages of 8 and 20 years, i.e. around puberty. It occasionally occurs in the 20s and 30s.

It rarely regresses and usually causes progressive nasal obstruction, recurrent severe epistaxis, purulent rhinorrhea and occasionally loss of vision due to compression of the optic nerve. Although the tumour is rare, these symptoms in a young boy should always arouse suspicion. The tumour occurs in many countries around the world but is most common in northern India. The reasons for this are unknown.

Standard clinical examination may easily reveal the tumour in the nasal cavity or nasopharynx, but CT scanning best demonstrates the extent of the tumour and its accompanying bony erosion. MRI scanning will further define the soft-tissue extent and with these two modern investigations angio-graphic evaluation is rarely indicated.

Biopsy should be avoided unless clinical and radiological examination is not clear. There should be definite reasons for undertaking biopsy, and matched blood must be in readiness and the surgeon prepared to deal with the haemorrhage.

Whilst radiotherapy has occasionally been advocated, sur-gical resection is by far the commonest management worldwide and requires an adequate exposure of the entire region either through a midfacial degloving approach or a lateral rhinotomy (Figs 43.18 and 43.19). Both of these approaches allow ligature of the feeding maxillary artery. A transpalatal approach may be used for the smaller tumours but this does not give full control of any potential bleeding.
Antrochoanal polyp. This relatively uncommon lesion is not a tumour but a simple mucosal polyp. It does not arise in the nasopharynx, but from the maxillary antrum, from which it prolapses into the nasal cavity and thence expands back-wards into the nasopharynx and occasionally down into the oropharynx (Figs 43.20 and 43.21). It also commonly occurs in young males, and therefore may mimic a tumour of the nasal cavity or nasopharynx. It is distinguished clinically from an angiofibroma by its avascularity, pale colour, its site of origin on endoscopic examination and imaging, as it is a simple mucosal polyp. Whilst it may be removed intra nasally by an avulsion snare, a portion often remains in the antrum producing recurrent symptoms and it requires complete removal via an endoscopic approach through the middle meatus or, occasionally, a Caldwell—Luc procedure to prevent recurrence.

Malignant. Nasopharyngeal carcinoma is an interesting squamous cell carcinoma with a very variable incidence. In most parts of the world the tumour is rare with an incidence of less than one person in 100 000 per year. However, it is a common tumour amongst southern Chinese, and this high-risk population has rates of 30—50 people per 100 000 per year. In the rest of China there are substantial variations in the incidence but, in general, the incidence decreases from south to north. Higher frequencies of nasopharyngeal carcinoma are also observed in emigrant southern Chinese populations in south-east Asia and elsewhere around the world, and it is also more common amongst Eskimo, the Kadazans in East Malaysia and parts of northern Africa. It is now well accepted that mechanisms leading to development of a cancer often involve a multi step process, and the aetiology of nasopharyngeal carcinoma is most likely to be multifactorial with no single cause adequately explaining the epidemiology of the disease. However, it is also clear that three well-defined major aetiologial factors are involved in its development (Table 43.3). The exact mechanism as to how these factors act is not yet fully understood. The majority of squamous carcinomas of the nasopharynx is undifferentiated and the morphology of this tumour is characteristic. Only a few are well-differentiated squamous carcinomas, and these two lesions make up over 90 per cent of nasopharyngeal malignancy in endemic areas. Other rare epithelial tumours are adenocarcinoma and adenoid cystic carcinoma. B- and T-cell lymphomas also occur in this region and should not be confused with the more common undifferentiated carcinoma.

Nasopharyngeal carcinoma affects a younger age group of the population than almost any other head and neck neoplasm. In endemic regions at least 60 per cent of patients are under 50 years of age and this applies to both sexes.

Clinical features. Symptoms are closely related to the position of the tumour in the nasopharynx and the degree of distant spread which may be present. Early symptoms are often minimal in nature and thus liable to be ignored by both patient and doctor.

• Approximately half the patients will present with a mass in the neck. This percentage is even higher in patients under 21 years of age. It indicates that the tumour has already reached an advanced stage. Fine needle aspirate or a biopsy of a neck node showing undifferentiated carcinoma requires immediate thorough examination of the nasopharynx.

• The nasopharynx may look normal or only minimally asymmetric but contain submucosal nasopharyngeal carci-noma. Nasal complaints occur in one-third of patients and aural symptoms of unilateral deafness, as a consequence of eustachian tube obstruction and secretory otitis media, occur in approximately 20 per cent. Neurological com-plications with cranial nerve palsies due to disease on the skull base occur relatively late in the disease but are a poor prognostic factor.

A biopsy of the nasopharynx is mandatory if there is suspicion of nasopharyngeal malignancy. The traditional method of indirect examination with a mir-ro, although adequate in some patients, has been superseded by direct inspection carried out by a flexible or rigid nasendoscope. If topical anaesthesia is used, a biopsy may be taken. Serological investigation for Epstein—Barr virus-associated anti-genic markers, in combination with the clinical and histological examination, is valuable for the early detection of disease. Highly sensitive assays for antiviral antibodies, together with the newly discovered virus-associated serological markers, are assisting not only in the early detection but in the treatment and control of this disease. IgA antiviral capsid antigen (VCA) antibody has recently been evaluated in mass surveys in southern China and has been found to be an excellent screening method for the early detection of nasopharyngeal carcinoma in high-risk groups.

Imaging. Imaging is essential to determine the extent of the disease and to enable correct staging. In areas where CT and MRI are available plain film radiography of the naso-pa-rynX and other ancillary methods, such as xerography and tomography, have now been superseded. A chest X-ray, how-ever, should still be performed. CT has a major role in determining the size and position of the tumour essential for radiotherapy planning and assessing the response to treatment, diagnosing recurrence and detecting complications.

Treatment. Primary treatment of nasopharyngeal carcinoma is radiotherapy. The majority of the tumours belongs to the radiosensitive undifferentiated squamous cell group. With the advent of CT, precise radiotherapy treatment plan-nig is now possible and brachytherapy (intracavitary and interstitial radiotherapy) and chemotherapy are increasingly added in the management plan. Elective external radio-therapy is given to the neck in all cases, even when no neck nodes are apparent. For early disease, 3-year disease-free survival rates of more than 75 per cent are now common. However, late disease has figures of only 30—50 per cent for 3-year disease-free survival. Although the benefit of modern radiotherapy is beyond doubt, the value of additional chemo-therapy remains debated, but it is likely that a combination of chemotherapy and radiotherapy will produce better loco regional control of the tumour. Surgery is reserved for recurr-ent disease in neck nodes and the occasional removal of recurrent skull base disease which has not responded to additional radiotherapy or chemotherapy.

Oropharynx

Acute tonsillitis

This common condition is characterised by a sore throat, fever, general malaise, dysphagia, enlarged upper cervical nodes and sometimes referred otalgia. Approximately half the cases are bacterial, the most common cause being a pyogenic group A streptococcus. The remainder is viral and a wide variety of viruses has been implicated; in particular, infectious mononucleosis may frequently be mistaken for bacterial tonsillitis. On examination the tonsils are swollen and erythematous, and yellow or white pustules may be seen on the palatine tonsils, hence the name ‘folicular tonsillitis’. A throat swab should be taken at the time of examination and blood for Paul—Bunnell testing (Fig. 43.22).

Treatment. Paracetamol or similar analgesia may be admin-istered to relieve pain and gargles of glycerol—thymol are soothing. The condition is frequently sensitive to benzyl or phenoxymethylpenicillin (penicillin V) and these are given until antibiotic sensitivities are known. Ampicillin is avoided as it may exacerbate the situation and precipitate a rash in patients with infectious mononucleosis. Most cases resolve in a few days.

Quinsy

This is the formation of an abscess in the peritonsillar region causing severe pain and trismus, and most usually associated with streptococcal infection (see Fig. 43.23). Trismus caused by spasm induced in the pterygoid muscles from the spreading infection may make examination difficult. This may be overcome by the instillation of local anaesthesia into the posterior nasal cavity (thereby anaesthetising the pheno-palatine ganglion) and directly into the oropharynx. This simple manoeuvre aids subsequent examination which should be carried out with good illumination and suction. A diffuse swelling of the soft palate just superior to the involved tonsil is seen displacing the uvula medi ally. 
and, in more advanced cases, there may be an area of pus pointing underneath the thin mucosa.

Treatment. In the early stages where no distinct abscess is pointing, intravenous broad-spectrum antibiotics are indi-cated and may produce resolution. However, if there is frank abscess formation, incision and drainage of the pus can be carried out under local anaesthesia (Fig. 43.24). A small scalpel is best modified by winding a strip of adhesive tape around the blade so that only 1 cm of the blade projects. In teenagers and young adults the patient sits upright and an incision is made in the position shown in Fig. 43.24. This is approximately mid-way between the base of the uvula and the third upper molar tooth. This may produce immediate release of pus but, if not, dressing forces are now pushed firmly through the incision directly backwards and, on opening, pus may then be encountered. In small children general anaesthesia may be required.

**Chronic tonsillitis**

Chronic tonsillitis usually results from repeat attacks of acute tonsillitis in which the tonsils become progressively damaged and provide a reservoir for infective organisms.

Tonsillectomy. Indications for tonsillectomy may be divided into absolute or relative (Table 43.5). When the size of the tonsils is contributing to airway obstruction or a malignancy of the tonsils is suspected, the decision to perform tonsillectomy is relatively straightforward. Complete tonsillectomy is preferable to wedge biopsies when squamous cell carcinoma is suspected, and bilateral tonsillectomy is performed in the case of suspected lymphoma as part of the staging process.

Considerable interest now focuses on the area of sleep apnoea and related problems. Patients should be admitted for formal sleep studies to establish the exact extent and site of the problem following which a variety of medical and surgical treatments may be deemed appropriate, one of which is tonsillectomy.

Recurrence acute tonsillitis is the commonest relative indication for tonsillectomy in children and adolescents, although it is important that these attacks are well documented and do not simply constitute a minor sore throat usually of viral origin and of short duration. Chronic tonsillitis more frequently affects young adults in whom it is important to establish that chronic mouth breathing secondary to nasal obstruction is not the main problem rather than the tonsils themselves.

Ideally, the procedure should be undertaken when the tonsils are not acutely infected, and it is important to discuss factors which may increase the tendency to bleed. Blood transfusion is rarely required but it is normal practice to perform a ‘group and save’ in children under 15 kg in weight.

Dissection tonsillectomy is carried out under general anaesthesia during which the patient lies supine with the head extended and with the surgeon sitting at the end of the operating table. The mucosa of the anterior faucial pillar is incised and the tonsil capsule identified. Using blunt dissection the surgeon separates the tonsil from its bed until only a small inferior pedicle is left (Fig. 43.25). Usually a snare is used to separate it from the lingual tonsil. Ribbon gauze is placed in the tonsillar bed and pressure applied for some minutes following which bleeding points may be controlled by ligature or by bipolar diathermy. Following surgery, the patient is kept under close observation for any systemic or local evidence of bleeding with regular monitoring of pulse and blood pressure, and observation to see whether the patient is swallowing excessively (Fig. 43.26). The patient is kept nil by mouth for the first few hours in case an immediate (or reactionary) haemorrhage should necessitate a return to theatre. After this period the patient is encouraged to use the mouth and a normal diet rapidly instituted. Paracetamol is preferred to aspirin-containing analgesics. Patients are generally allowed home on the following day and are warned that they may experience otalgia due to referred pain from the glossopharyngeal nerve and that late (or secondary) haemorrhage may occur up to 10 days following the surgery, which would necessitate their immediate return to hospital.

Haemorrhage is obviously the most common complication, occurring in the immediate postoperative period (Table 43.6). Local pressure, hydrogen peroxide, gurgles and general supportive measures may help in mild cases, but it is generally worst to return to theatre for definitive treatment particularly in younger patients. Blood loss is replaced with crystalloid whilst a cross-match is performed, and frequent observations of blood pressure, pulse and respiratory rate are made. Adequate analgesia is given without causing respiratory depression. With the patient sitting upright in bed the mouth is examined under reasonable illumination to determine the site of bleeding and if possible to suction away clots from the tonsillar fossa. A swab soaked in 1 in 1000 adrenaline may be held against the bleeding area in a co-operative patient, but if this is not possible and/or the bleeding persists theatre should be alerted. Under general anaesthesia it may be possible to identify a bleeding spot, but often a more generalised ooze is observed and suturing of the tonsil bed combined with the application of Surgicel and bipolar diathermy is often more successful than attempted placement of ligatures.

Late haemorrhage is generally secondary to infection and patients should be immediately commenced on intravenous antibiotics with aerobic and anaerobic cover. Significant or persistent bleeding may require a further general anaesthetic and under sewing of the surgical bed, which by this time will often be covered with slough and granulation tissue. Post-operative tonsillar haemorrhage must still be regarded as a serious and life-threatening complication and should not be underestimated, particularly in the younger patient.

**Parapharyngeal and retropharyngeal abscess**

Parapharyngeal abscess. The parapharyngeal abscess may be confused with a peritonsillar abscess but the maximal swelling is behind the posterior faucial pillar and there may be little oedema of the soft palate. The patient is usually a young child and there may be a severe degree of general malaise. With an obvious abscess pointing into the oropharynx, drain-age may be carried out with a blunt instrument or the gloved finger but general anaesthesia is frequently required and the expertise of a senior anaesthetist, good illumination and good suction are absolutely essential. A large parapharyngeal abscess may compromise both the airway and swallowing. In the earlier cases admission to hospital and the institution of fluid replacements coupled with intravenous antibiotics may produce resolution. The advanced cases also require intravenous antibiotics.

Acute retropharyngeal abscess

This is the result of suppuration of the prevertebral lymph nodes and, again, is most commonly seen in children with most of the cases occurring in those under 1 year of age. It is associated with infection of the tonsils, nasopharynx or oropharynx, and is frequently accompanied by severe general malaise, neck rigidity, dysphagia, drooling, a croupy cough, an altered cry and marked dyspnoea. Indeed, dyspnoea may be the prominent symptom, and may also be accompanied by febrile convulsions and vomiting.

These children should always be carefully examined, and an inspection of the posterior wall of pharynx may show gross swelling and an abscess pointing beneath the thinned mucosa. In countries where diphtheria still occurs, an acute retropharyngeal abscess may be confused with this but the presence of the greyish-green membrane aids differentiation. Occasional-ly, a foreign body, most commonly a fish bone which has perforated the posterior pharyngeal mucosa, will give rise to an abscess in this situation in older children and young adults.
These patients should be admitted to hospital and intravenous antibiotics instituted immediately. Surgical drainage of the abscess may not be necessary but, if so, requires experienced anaesthesia as on induction care must be taken to avoid rupturing the abscess. The airway is protected by placing the child in a head-down position whilst a pair of dressing forceps guided by the finger may be thrust into an obvious abscess in the posterior wall with the contents being evacuated. On other occasions an approach anterior and medial to the carotid sheath via a cervical incision may be required.

**Chronic retropharyngeal abscess**

This condition is now rare and most commonly the result of an extension of tuberculosis of the cervical spine which has spread through the anterior longitudinal ligament to reach the retropharyngeal space. In contrast to the acute retropharyngeal abscess, this condition occurs almost solely in adults and radiology usually shows evidence of bone destruction and loss of the normal curvature of the cervical spine. The spine may be quite unstable and undue manipulation may precipitate a neurological event. In addition to the retropharyngeal swelling seen intraorally, there may be fullness behind the sternocleidomastoid muscle on one side. A chronic retropharyngeal abscess must not be opened into the mouth, as such a procedure may lead to secondary infection. Drainage of the abscess may not be necessary if suitable treatment of the underlying tuberculosis disease is instituted. If it is necessary then it should be carried out through a cervical incision anterior to the sternocleidomastoid muscle with an approach anterior and medial to the carotid sheath to the retropharyngeal space. The cavity is opened and suctioned dry after taking biopsy material. Occasionally surgery is required to decompress the spinal cord if there is a progressive neurological deficit.

**Glandular fever (infectious mononucleosis)**

This systemic condition is usually caused by Epstein—Barr virus but similar features can be due to cytomegalovirus or toxoplasmosis.

**Clinical features.** The tonsils are typically erythematous with a creamy-grey exudate, and they appear almost confluent and usually symmetrical in contradistinction to a quinsy. In addition to the discomfort and dysphagia, the patient may drool saliva and have respiratory difficulty, particularly on inspiration. They commonly have a high temperature and gross general malaise with other notable cervical or generalized lymphadenopathy. Occasionally an enlarged spleen or liver may be detected. These features most commonly occur in teenagers and young adults, and diagnosis can be confirmed by serological testing showing a positive Paul—Bunnell test, an absolute and relative lymphocytosis, and the presence of atypical monocyttes in the peripheral blood.

**Treatment.** Analgesia and maintenance of fluid intake are important. A small number of patients requires admission to hospital if the airway is compromised and a short course of steroids may be helpful. If this is necessary it should only be carried out as an in-patient where the airway can be constantly monitored. Antibiotics are of little value and, indeed, ampicillin is contraindicated because of the frequent appearance of a widespread skin rash.

**Human immunodeficiency virus**

The human immunodeficiency virus (HIV) is the causative agent of acquired immunodeficiency syndrome (AIDS) which, although it was initially associated with intravenous drug users and homosexual males, is now spreading in many parts of the world to affect the heterosexual community. It can affect almost all of the head and neck structures at any point during the disease. The initial seroconversion may pre-date the symptoms of glandular fever which is followed by an asymptomatic period of variable length. In the pre-AIDS period, prior to the full-blown symptoms of the AIDS-related complex, many patients have minor upper respiratory tract symptoms which are often overlooked such as otitis externa, rhinosinusitis and a nonspecific pharyngitis. As the patient moves into the full-blown AIDS-related complex a persistent generalised lymphadenopathy is frequently found affecting the cervical nodes which is usually due to follicular hyperplasia. However, patients may also develop tumours such as Kaposi’s sarcoma, sometimes seen in the oral cavity, and high-grade malignant B-cell lymphoma affecting the cervical lymph nodes and nasopharynx. In addition, multiple ulcers may be found in the oral cavity or pharynx associated with herpes infection. Severe candidia may affect the oral cavity pharynx or even larynx, and a hairy leucoplakia may affect the tongue (Fig. 43.27). There is also an increased incidence of squamous cell carcinoma of the oral cavity.

**The globus syndrome**

A wide variety of patients has a predominant symptom of a feeling of a lump in the throat (Latin: globus lump). The symptom most commonly affects adults between 30 and 60 years of age. This feeling is not true dysphagia as there is no difficulty in swallowing. Most patients notice the symptom more if they swallow their own saliva, i.e. a forced dry swallow, rather than when they eat or drink. The aetiology of this common symptom is unknown but some patients may have gastro-oesophageal reflux or spasm of their cricopharyngeus muscle. The symptom may be symptomatic if they swallow their own saliva, i.e. a forced dry swallow, rather than when they eat or drink. The aetiology of this common symptom is unknown but some patients may have gastro-oesophageal reflux or spasm of their cricopharyngeus muscle. The symptom may be associated with the presence of a pharyngeal pouch, or tumours in the oropharynx, hypopharynx or upper oesophagus.

The original name of globus hystericus is unhelpful and although these patients may be anxious and at times introverted, they none the less require full examination to exclude local disease. Radiological and endoscopic investigation may be necessary to exclude an underlying cause.

**Pharyngeal pouch**

The pouch is a protrusion of mucosa through Killian’s dehis-cence, a weak area of the posterior pharyngeal wall between the oblique fibres of thyro-arytenoids and the transverse fibres of cricopharyngeus at the lower end of the inferior constrictor muscle. These fibres, along with the circular fibres of the upper oesophagus, form the physiological upper oesophageal sphincter mechanism. Quite why the pouch forms is not yet clear even with modern video fluoroscopic and manometric studies. Many patients with pharyngeal pouches have been demonstrated to have normal relaxation of the upper oesophageal sphincter mechanism in relation to swallowing, but others have been shown to have incomplete pharyngeal relaxation, early cricopharyngeal contraction and abnormalities of the pharyngeal contraction wave. As the pouch enlarges the resistance of the vertebral column behind usually causes it to turn laterally to the left (Fig. 43.28).

**Clinical features.** Patients suffering from this condition are commonly more than 60 years of age and it is twice as common in women as in men.

In the initial phases when there is a small diverticulum the patients may present with globus-type symptoms of a feeling of something in the throat or minor difficulties and slight regurgitation on swallowing. A videofluoroscopic or barium swallow study may show abnormalities of the upper oesophageal sphincter in association with the small pouch. As the diverticulum enlarges patients may experience regurgita-tion of undigested food sometimes hours after a meal, partic-ularly if they are bending down or turning over in bed at night. They are sometimes awoken at night with a feeling of tightness in the throat and a fit of coughing. Occasionally they may present with recurrent unexplained chest infections as a result of small amounts of liquid and food being aspirat-ed from the pouch. As the pouch increases in size the patients may notice gurgling noises from the neck on swallowing and the pouch may become large enough to form a visible swelling in the neck. This swelling may increase when the patient drinks and, indeed, there may be increasing difficulty with swallowing associated with weight loss and...
Radiological examination. If a pharyngeal pouch is suspected, this is an extremely useful examination. A thin emulsion of barium is given to the patient as a barium swallow (Fig. 43.29) or, better still, as part of a videofluoroscopic swallowing study. Care should be exercised in patients who cough on swallowing indicating they may have aspiration. Just a few millilitres of barium is sufficient to outline the pharynx pouch and upper oesophagus. The videofluoroscopic study gives additional information about the pharyngeal contraction waves and the performance of the upper oesophageal sphincter. Occasionally there is an associated hiatus hernia at the lower end of the oesophagus and this should be excluded. A chest X-ray is important to exclude aspiration pneumonitis. Rigid oesophagoscopy or pharyngoscopy under general anaesthesia is unnecessary for diagnosis and may be dangerous. When the diagnosis is unsuspected, oesophagoscopy performed without realising the pathology may be associated with the tip of the oesophagoscope entering the pouch and perforating the fundus. Subsequent mediastinitis is associated with a high mortality.

Treatment. Surgery is indicated when the pouch is associated with progressive symptoms, and particularly when a prominent cricopharyngeal bar of muscle associated with abnormality of the upper oesophageal sphincter mechanism causes considerable dysphagia. In very elderly patients a decision to operate may be offset by the general condition of the patient. Preoperative physiotherapy and attention to the respiratory, cardiovascular and nutritional aspects of the patient are important. Preoperative chest physiotherapy and perioperative antibiotics are recommended. In the classical operation the opening to the pouch is first identified using a pharyngoscope and a nasogastric tube placed into the oesophageal lumen to allow postoperative nutrition. This initial endoscopy is often difficult because the normal oesophageal opening is small compared with the lumen of the pouch but it may be facilitated by using a Dohlmann’s rigid endoscope which allows better visualisation. The naso-gastric tube allows identification of the oesophagus sub-sequently by palpation and facilitates the myotomy, in addition to allowing postoperative feeding. The pouch may be packed with ribbon gauze soaked in proflavine solution to aid identification of the neck of the pouch.

A lower neck incision along the anterior border of the left sternocleidomastoid muscle, or a transverse crease incision, is then used and the sternocleidomastoid muscle and carotid sheath are retracted laterally and the trachea and larynx medially. The middle thyroid vein is divided and, if necessary, the inferior thyroid artery is found and ligated well laterally. The retropharyngeal space is entered above the inferior corner of the thyroid cartilage, thereby avoiding risk of damage to the recurrent laryngeal nerve. The pouch is found medially behind the lower pharynx and is carefully isolated and dissected back to its origin at Killian’s dehiscence. It may then be excised and the pharynx closed in two layers or, if it is small, it may be invaginated into the pharyngeal lumen before closing the muscle layers. In all cases a myotomy dividing the fibres of the cricopharyngeus muscle and the upper oesophageal circular muscle fibres must be performed. The wound is usually closed with drainage and the patient fed through the nasogastric tube for 3—7 days.

Complications. This classic operation has been associated with wound infection, mediastinitis, pharyngeal fistulaformation and stenosis of the upper oesophagus. Variations have been tried which include simply hitching up the pouch into a superior position without excising it, thus allowing the fundus and body to empty continuously into the oesophagus. This is unsatisfactory with the larger pouches. Endoscopic division of the bar of muscle forming the anterior wall of the pouch and the posterior aspect of the lumen of the oesophagus has been advocated for many years using Dohlmann’s instruments and, more recently, a laser applied via a special pharyngoscope. There is increasing evidence that both the open operative intervention and previous endoscopic tech-niques can be improved by using an endoscopic stapling technique, whereby a specialised staple gun is passed down a modified pharyngoscope which safely divides the anterior wall of the pouch and the posterior wall of the oesophagus. This completes a full myotomy and allows any food and fluid to drain from the pouch directly down the oesophagus. The staples provide an instant two-layer closure at the site of division, and this endoscopic technique is associated with very low morbidity and a high success rate for the relief of the patient’s symptoms. Low morbidity is particularly important in this elderly group of patients.

Sideropenic dysphagia

Prolonged iron deficiency anaemia may lead to dysphagia, particularly in middle-aged females. In addition, they may have koilonychia, cheilosis and angular stomatitis, together with lassitude and poor exercise tolerance. The dysphagia is caused by a postcricoid web, and these patients have a higher incidence of postcricoid malignancy. Prognosis of these post-cricoid tumours is very poor, requiring radical treatment with radiotherapy and major surgery, and it is therefore important to prevent this problem by recognition and treatment of the anaemia. The syndrome is associated with the names of Plummet and Vinson, and Patterson and Brown Kelly.
Tumours of the oropharynx

Benign

Benign tumours of the oropharynx are rare, papillomas being the most common. These are usually incidental findings and are rarely of any importance.

Malignant

The most important epithelial tumour is squamous cell carcinoma, which constitutes roughly 90 per cent of all epithelial tumours in the upper aerodigestive tract (Figs 43.30 and 43.31). In the oropharynx the proportion is less (70 per cent) because of the higher incidence of lymphoma (25 per cent) and salivary gland tumours (5 per cent).

Aetiology

Squamous carcinomas of the oropharynx have strong associations with cigarette smoking and the consumption of alcohol, and these two factors cause varying incidence throughout the world. In countries where the consumption of tobacco and alcohol is associated with poor oral hygiene these malignancies assume major importance. Due to the rich lymphatic drainage of the oropharynx, cervical node metastases are common. They may be the only presenting feature with an apparent occult primary often being unsuspected and missed in the tonsil or tongue base. The majority of lymph node metastases from oropharyngeal squamous carcinomas is to the jugulodigastric node. This is the commonest site for the so-called 'branchial cyst carcinoma', but several studies in recent times have shown that this is probably an extremely rare pathology and that usually the diagnosis represents cystic degeneration in a jugulodigastric node from a small undetected primary squamous carcinoma in the tonsil or tongue base. Squamous cell carcinomas are most common in the sixth and seventh decades and more frequent in men.

Treatment

Treatment patterns vary with facilities, but early tumours may be cured by radiotherapy, laser excision or more conventional excision. Recurrent disease following radiotherapy is managed surgically, and repair of the oropharynx may require regionally based myocutaneous flaps or free flaps with microvascular anastomosis. Neck dissection is required in a large proportion of cases of advanced disease. Postoperative dysphagia with aspiration, as a result of interference in the complex neuromuscular control of the second phase of swallowing, is a particular problem in these patients. More advanced tumours may also require additional resection of the mandible or an associated total laryngectomy, so this type of surgery is best carried out in a centre undertaking this work on a regular basis.

Lymphoma of the head and neck

Lymphomas of the head and neck may arise in nodal or extranodal sites, and both Hodgkin’s disease and non-Hodgkin’s lymphoma commonly present as lymph node enlargement in the neck. Hodgkin’s disease is rare in the oropharynx, but non-Hodgkin’s lymphoma accounts for 15—20 per cent of tumours at this site in some countries. Most are of the B-cell type and have features in common with other tumours of MALT sites. Many of the lymphomas of the oropharynx have no demonstrable deposit elsewhere in the body when a full lymphoma investigation is carried out. On occasions, however, they may be secondary or coincident with deposits at other sites in the neck, the gastrointestinal tract, lung and the testes. Further evaluation with CT scanning of the thorax and abdomen, and bone marrow evaluation are essential. Radiotherapy is undoubtedly the treatment of choice for localised non-Hodgkin’s lymphoma and may give control rates as high as 75 per cent at 5 years. For disseminated non-Hodgkin’s lymphoma the treatment of choice is systemic chemotherapy. Combination chemotherapy is used in patients with an unfavourable histological type.
Tumours of the hypopharynx

Benign

Benign tumours of the hypopharynx are very rare, the most common being the fibroma and the leiomyoma. These are polypoid tumours which usually present with dysphagia and are seen on videofluoroscopy or barium swallow. They show a smooth constant mass lying in the lumen of the hypo-pharynx or oesophagus.

Malignant

Malignant tumours of the hypopharynx are almost exclusively squamous cell carcinoma with a predominance of moderate and poor differentiation. The tumours are usually classified according to their anatomical site of origin from the piriform fossa, postcricoid region or posterior pharyngeal wall but, as mentioned in the section on pharyngeal anatomy, it can be difficult to determine the site of origin when a tumour has spread to involve one or more of these areas. Even differentiation between laryngeal and hypopharyngeal tumours can be difficult in the advanced disease when the aryepiglottic fold has been replaced or covered by tumours. Marked differences in the incidence of these tumours occur throughout the world in association with factors such as iron deficiency anaemia (see subsection on Sideropenic dysphagia) and they may be associated with marked submucosal spread of 10 mm or more which further complicates their evaluation. Tumours arising from the piriform fossa and posterior pharyngeal wall may spread to upper or lower cervical nodes. Tumours arising in the postcricoid area typically metastasise to paratracheal and para-oesophageal nodes which may not be palpable. As with oropharyngeal tumours, alcohol and tobacco are two principal carcinogens implicated in these tumours. Postcricoid carcinoma, although essentially a rare disease, is more common in women than men. The diagnosis of hypopharyngeal carcinoma should be considered in all patients presenting with dysphagia or hoarseness, particularly if they have a history of iron deficiency and anaemia, smoking or significant alcohol consumption.

On examination indirect laryngoscopy may show only subtle signs of disease such as oedema or pooling of saliva unilaterally in a piriform fossa, or diminution of vocal fold mobility. All regions of the neck must be assessed in a systematic manner. Fine needle aspirate is advocated for suspicious nodes. A suspected primary may require videofluoroscopy or barium swallow study, endoscopy and biopsy, and CT or MRI scanning if available. A chest X-ray should be taken to detect a second primary or metastasis.

Treatment

Squamous carcinoma of the hypopharynx commonly presents late and carries a poor prognosis. Early lesions may be treated with radiotherapy alone, and surgery is generally used for recurrence after radiotherapy or as primary excision in advanced disease. Total pharyngolaryngectomy is commonly required and, for lesions extending into the upper oesophagus, oesophagectomy and total thyroidectomy may additionally be needed.

Reconstruction of the excised pharynx and/or oesophagus may be undertaken by the use of a myocutaneous flap, free jejunal transfer or gastric transposition. These major surgical techniques require excellent preoperative preparation of the patient and surgical teams with a high standard of expertise as they have a potential mortality and a wide variety of complications. Swallowing and voice rehabilitation are necessary to support patients after this major surgery if they are to adjust themselves and maintain some quality of life.

Cytotoxic drugs have not been found to have significant value as an adjunct to surgery or radiotherapy in the treatment of patients with hypopharyngeal squamous carcinoma. It is to be hoped in the future that they will produce better results so that the major surgery and its associated debility can be avoided. Before deciding to give chemotheraphy in any form of squamous carcinoma of the head and neck one has to balance the prognosis of the disease against the expected relief and possible toxic side effects. The most commonly used agents are cisplatin, 5-fluorouracil (5FU) and methotrexate. These drugs are best administered by doctors expert in their use and as part of controlled trials until we can evaluate the most suitable method of administration and the best combination of agents.
Diseases of the larynx

Emergencies

Stridor

Stridor means noisy breathing. It may be inspiratory or expiratory or occurring in both phases of respiration. Inspiratory stridor is usually due to an obstruction at or above the vocal folds and most commonly is a result of an inhaled foreign body or acute infection such as epiglottitis. Expiratory stridor is usually from the lower respiratory tract and gives rise to a prolonged expiratory wheeze. It is most commonly associated with acute asthma or acute infective tracheobronchitis. Biphasic stridor is usually due to obstruction or disease of the tracheobronchial airway and distal lungs.

Stridor in children (Table 43.7)

Infants and children presenting with stridor need assessment with a full history and careful examination if appropriate. If on presentation a child is cyanosed and severely unwell the airway must be secured as soon as possible but it is often possible to obtain a brief history from the parents, with important pointers. A nurse or colleague may be derailed to do this whilst the resuscitation is taking place.

History. In infants in the first year of life it is important to establish whether the stridor is associated with particular activities such as swallowing, crying or movement. These may suggest congenital laryngomalacia or subglottic stenosis. If the stridor is exacerbated by feeding, particularly in the first 4 weeks of life, this suggests a vascular ring or tracheo-oesophageal fistula. If the cry is weak or abnormal this -suggests a vocal fold palsy. If the problem only occurs in association with an upper respiratory tract infection and, in particular, is biphasic this would suggest congenital subglottic stenosis. In a young child inspiratory stridor and drooling suggest acute epiglottitis, whereas biphasic stridor without drooling suggests laryngotracheobronchitis or croup.

Examination.

Observe the child carefully at rest; do not attempt to move or handle the child, particularly if the stridulous child is being held by its mother or other family member. Once a baby starts to cry it may be impossible to study its resting respiratory pattern for some time. Ask the mother, nor a nurse or a colleague, to move a baby or young child into different positions such as face down and supine, and watch for changes in its respiratory pattern and level of distress. Observe any drooling and with neonates and infants always try to watch the child being fed, listening to the trachea and chest with a stethoscope if possible. Always examine the whole child, looking for any evidence of congenital abnormalities before attempting any examination of the throat.

If a child is stridulous and drooling and sitting upright in its mother's arms or chair do not attempt to lie it down and do not attempt to look inside the mouth. These are potentially life-threatening circumstances as the child may aspirate a large quantity of thick saliva contained within its oral cavity. The child does nor wish to attempt swallowing in the case of a retropharyngeal abscess, parapharyngeal abscess or acute epiglottitis as these conditions are so painful. It is particularly important in acute epiglottitis as the aspiration of thick saliva may be associated with further laryngeal spasm and a respiratory arrest. Restlessness, increasing tachycardia and cyanosis are important signs of hypoxia. If the child is not distressed and drooling, and nor markedly stridulous it may be co-operative enough for it to be possible to look inside the mouth and check the palate, tongue and oropharynx. In stridulous children, particularly neonates and infants, a trans-cutaneous oximeter is invaluable if available. It may be placed on the child before any examination and during any subsequent manage-ment. A resuscitation trolley with the necessary equipment for emerg-ency intubation or tracheostomy should be close at hand, if at all possible, before commencing examination and investigation of these children.

Investigation. In addition to the oximeter, plain lateral X-rays of the neck and a chest X-ray can be obtained but only if the child’s condition permits. If the child is severely stridulous they should not be sent to an X-ray department without access to medical staff or resuscitation equipment. The X-rays may confirm the presence of a foreign body or show soft-tissue shadowing consistent with a retropharyngeal or parapharyngeal abscess, acute epiglottitis or chest disease.

Examination under anaesthesia.

Examination under anaesthesia is essential in all children whose diagnosis remains in doubt. Cytotoxic drugs have nor been found to have significant value as an adjunct to surgery or radiotherapy in the treat-ment of patients with hypopharyngeal squamous carcinoma. It is to be hoped in the future that they will produce better results so that the major surgery and its associated debility can be avoided. Before deciding to give chemotherapy in any form of squamous carcinoma of the head and neck one has to balance the prognosis of the disease against the expected relief and possible toxic side effects. The most commonly used agents are cisplatin, 5-fluorouracil (5FU) and methotrexate. These drugs are best administered by doctors expert in their use and as part of controlled trials until we can evaluate the most suitable method of administration and the best combination of agents. This requires a high level of skill and close co-operation between surgeon and anaesthetist, and appropriate rigid laryngoscopes, bronchoscopes, endoscopic Hopkin's rods and an operating microscope should be made available.

Equipment should be available at all times to undertake an urgent tracheostomy to establish or maintain an airway.

Acute epiglottitis (Table 43.7)

This illness may occur in adults, although fortunately the stridor rarely progresses as rapidly as in children. In children it is of rapid onset and tends to occur in children of 2 years of age or over. Stridor is usually associated with drooling of saliva. The condition is caused by Haemophilus influenzae infection which initially causes a severe pharyngitis at the junction of the oropharynx and hypopharynx before pro-gressing to produce inflammation and oedema of the laryng-geal inlet. As it progresses it actually involves the whole of the supraglottic larynx, with severe oedema of the aryepiglottic folds and epiglottis being the most notable component; hence the commonly used term ‘acute epiglottitis’. Exam-ination and investigation are outlined above, but these children frequently require intensive management with emergency intubation or tracheostomy followed by oxygenation, humidification, continuous oximetry and antibiotics such as ampicillin or chloramphenicol to combat the haemophilus infection. This may be associated with septicaemia and blood cultures should be obtained. Children with acute epiglottitis may develop airway obstruction rapidly. Insertion of a spatula into the mouth may precipitate a respiratory arrest and is best avoided. Infants and children have small airways and high oxygen demand. It is extremely important to pre-empt any respiratory arrest.

Laryngotracheobronchitis (croup)

This is usually of slower onset in contrast to acute epiglottitis and occurs most commonly in children under 2 years of age. It is usually viral in origin and the cases often occur in clusters. The children have a biphasic stridor and often hoarseness, and a typical barking cough. Airway
intervention is required less often but admission to hospital with oxygenation and humidification coupled with antibiotics may be necessary if there are signs of secondary infection.

**Foreign bodies**

Both children and adults may inhale foreign bodies. Young children will attempt to swallow a wide variety of objects, but coins, beads and parts of toys are particularly common. In adults the aspiration is usually of food, particularly inade-quate chewed bones and meat. This is more common in elderly edentulous adults and occasionally portions of dentures may be inhaled, particularly in association with road traffic accidents.

**Clinical features.** The history is often paramount and it is important to always believe the patient, particularly a parent who gives a history of foreign body ingestion or inhalation in a child, even though the pain, dysphagia, coughing, etc., may have settled. Adult patients will, on the whole, have a clear recall and the diagnosis is more easy, but this may not always be the case particularly if the patient is suffering from mental illness. Fish bones may lodge in the tonsils or base of tongue with minimal symptoms but in certain areas of the world, notably Asia, small fish bones may impact in the tonsils, oropharynx or hypopharynx and give rise to parapharyngeal and retropharyngeal abscess formation.

**Examination.** Examination may be prevented by trismus, pain and anxiety, but the presence of a foreign body may be suspected by a salivary pool within the piriform fossa or adjacent oedema and erythema of the pharyngolaryngeal mu cosa.

**Radiology.**

Radiology may be helpful but is not critical. Fish bones are often not visible on plain X-rays, and a normal plain X-ray does not exclude a foreign body within the pharynx, larynx, oesophagus or lungs. Specialised studies may help in cases of doubt using tomo-graphy of the neck, CT scan or a .gastrograffin swallowing study in the case of a suspected oesophageal foreign body.

**Treatment.** In the case of an inhaled foreign body causing severe stridor in a neonate or infant it may be removed either by hooking it from the pharynx with a finger or by inverting the child carefully by its ankles and slapping its back. In a larger child it may be more appropriate to bend them over your knee with their head hanging down and again strike them firmly between the shoulders. In the case of adults an impacted laryngeal foreign body may be coughed out in association with a Heimlich manoeuvre. This involves stand-ing behind the patient, clasping the arms around the lower thorax such that the knuckles of the clasped hands come into contact with the patient’s xiphisternum, and then a brief firm compression of the lower thorax may aid instant expiration of the foreign body.

If none of these immediate emergency measures removes the foreign body and the patient is cyanosed and severely stridulous, an immediate cricothyroidotomy or tracheostomy may be necessary.

If less urgent cases, if the radiography is not useful but a foreign body is strongly suspected, then detailed endoscopy under general anaesthesia may be indicated. It is important to remember that the symptoms of foreign body ingestion are more reliable than the results of specialist radiology investigations. Angioneurotic oedema, radiotherapy, laryngeal trauma associated with road traffic accidents, corrosives, scalds and smoke ingestion may all cause significant pharyngolaryngeal oedema, in addition to the acute infective conditions mentioned elsewhere. Hoarseness is the predominate symptom along with dysphagia prior to the increase in dyspnoea. If laryngoscopic examination is possible marked oedema of the supraglottis and pharynx can be seen. Humidified oxygen, adrenaline nebulisers, systemic antihistamines and steroids may be valuable in these cases. Morphine should not be given to these patients to combat their distress as it may cause respiratory depression and respiratory arrest. If the dyspnoea progresses intubation or tracheostomy will be necessary. This procedure is to relieve airway obstruction or to protect the airway by fashioning a direct entrance into the trachea through the skin of the neck. Tracheostomy may be done as an emergency when the patient is in extremis and the larynx cannot be intubated but it is not always an easy procedure, particularly in the obese patient, and should not be embarked upon unless absolutely necessary. An easier alternative for the inexperienced doctor is the insertion of a large intravenous cannula or, alternatively, a small tube into the cricothyroid membrane which lies in the midline immediately below the thyroid cartilage. Emergency intubation is a further option when the laryngotracheal airway is not obstructed, and tracheostomy may be performed following initial endotracheal intubation.

**Choice of operation**

- The degree of urgency in establishing tracheostomy will determine the method used, but preference should always be for the elective procedure. One of the most appropriate pieces of advice in surgery is ‘the time to do a tracheostomy is when you first think it may be necessary’. All of the potential complications of tracheostomy are markedly decreased if a meticulous elective procedure is performed under controlled circumstances by an experienced team

If time allows the following should be undertaken:

- inspection and palpation of the neck to assess the laryngo-tracheal anatomy in the individual patient;
- indirect or direct laryngoscopy;
- tomography of the larynx and upper trachea;
- assessment of pulmonary function.

- Whenever possible the procedure should be adequately explained to the patient beforehand, with particular emphasis on the inability to speak immediately following the operation and possible difficulties with swallowing.

Emergency tracheostomy. If a skilled anaesthetist is unavailable local anaesthesia is employed, but in desperate cases where the patient is unconscious none is required. The only word of warning would be in those patients who have suffered severe head and neck trauma, and may have an unstable cervical spine fracture. Cricothyroidotomy may be more suitable under these circumstances.

If it is possible the patient should be laid supine with padding placed under the shoulders and the extended neck kept as steady as possible in the midline. This aids palpation of the thyroid and cricoid cartilage between the thumb and index finger of the free hand. The movements of the fingers of the free hand are important in this technique. The operation is more difficult in small children and thick-necked adults as the landmarks are difficult to palpate.

A vertical midline incision should be made from the inferior aspect of the thyroid cartilage to the suprasternal notch and continued down between the infrahyoid muscles (Fig. 43.32). There may be heavy bleeding from the wound at this point, particularly if the neck is congested as a result of the patient’s effort to breathe around an acute upper airway obstruction. No steps should be taken to control this haemorrhage.
although an assistant and suction apparatus are valuable if available. The operator should feel carefully, and without undue haste, for the cricoid cartilage using the index finger of the free hand whilst retracting the skin edges by pressure applied by the thumb and middle finger. If the situation is one of extreme urgency a further vertical incision straight into the trachea at the level of the second, third and fourth ring should be made immediately without regard to the presence of the thyroid isthmus (Fig. 43.33). The knife blade is rotated through 90° thus opening the trachea. At this point the patient may cough violently as blood enters the airway. The operator should be aware of this possibility and avoid losing the position of the scapel in the open trachea. Any form of available tube should be inserted into the trachea as soon as possible and blood and secretion sucked out. Once an airway has been established haemostasis is then secured. With the emergency under control the tracheostomy should be refashioned as soon as possible.

Should additional equipment and more time be available once the cricoid cartilage has been identified, blunt finger dissection inferiorly can be used to mobilise the thyroid isthmus which should be divided between haemostats, clear-ing the trachea before making a vertical incision through the second—fourth rings. A tracheal dilator should be inserted through the tracheal incision and the edges of the tracheal wound separated gently. In cases of suspected HIV infection or diphtheria the surgeon should place a swab over the wound so that the violent expiratory efforts which may follow do not contaminate the operator(s) with infected mucus and blood. When respiratory efforts have become less violent a tracheostomy tube should be inserted into the trachea and the dilator removed. It is important that the surgeon keeps a finger on the tube while the assistant ties the attached tapes round the patient’s neck.

Elective tracheostomy.

The advantage of an elective procedure is that there is complete airway control at all times, unhurried dissection and careful placement of an appropriate tube.

Close co-operation between the surgeon, anaesthetist and scrub nurse is essential, and attention to the details will markedly reduce possible complications and morbidity from the procedure. Following induction of general anaesthesia and endotracheal intubation, the patient is positioned with a combination of head extension and placement of an appro-priate sandbag under the shoulders (Fig. 43.34). There should be no rotation of the head. Children’s heads should nor be over-extended as it is possible to enter the trachea in the fifth or sixth rings under these circumstances. The inexperienced surgeon may find the insertion of a bronchoscope in the trachea of great help when performing tracheostomy in young children. A transverse incision may be used in the elective situation. The thyroid isthmus is divided carefully and oversown, and tension sutures are placed either side of the tracheal fenestration in children (Figs 43.34-43.38). A Björk flap may be used in adults. The advantages of the Björk method far outweigh the potential disadvantages, and the method is particularly useful for those surgeons who under-take occasional tracheostomy or where the level of skill and experience of the nursing staff are limited. Performed correctly it is safe and allows reintroduction of a displaced tube with the minimum of difficulty. The inferiorly based flap is begun at its apex with an incision on the superior aspects of the second ring and extended down either side through the second and third rings. The tip of the flap should be stitched to the inferior edge of the transverse skin incision using horizontal mattress sutures through the structure of the second ring. These sutures should be generous enough so that they will not cut out. The first tracheal ring should not be violated under any circumstances.

Tracheostomy tubes. These are basically made of two materials, silver or plastic (Fig. 43.39). Both materials have been used to make tubes of various sizes with varying curves, angles, cuffs, inner tubes and speaking valves. A cuffed tube is used initially, which may be changed after 3—4 days to a noncuffed plastic or silver tube. The pressure within the tube cuff should be carefully monitored and should be low enough not to occlude circulation in the mucosal capillaries. When in position the tube should be retained by double tapes passed around the patient’s neck with a reef knot on either side. It is important that the patient’s head is flexed when the tapes are tied otherwise they may become slack when the patient is moved from the position of extension, thereby resulting in a possible displacement of the tube if the patient coughs. Alternatively, the flanges of the plastic tube may be stitched directly to the underlying neck skin.

Knowledge of the physiological changes induced by tracheostomy is an essential requirement for the understanding of postoperative management. All forms of tracheostomy and cricothyroidotomy bypass the upper airway and have the following advantages:

- the anatomical dead space is reduced by approximately 50 per cent;
- the work of breathing is reduced;
- alveolar ventilation is increased;
- the level of sedation needed for patient comfort is decreased and, unlike endotraacheal intubation, the patient may be able talk and eat with a tube in place. However, there are several disadvantages:
  - loss of heat and moisture exchange performed in the upper respiratory tract;
  - desiccation of tracheal epithelium, loss of ciliated cells and metaplasia;
  - the presence of a foreign body in the trachea stimulates mucus production. Where no cilia are present this mucociliary stream is arrested;
- the increased mucus is more viscid, and thick crusts may form and block the tube, particularly in children;
- whilst many patients with a tracheostomy can feed satisfactorily, there is some splinting of the larynx which may prevent normal swallowing and lead to aspiration. This aspiration may be `silent', i.e. not apparent.

Postoperative treatment is designed to counteract these effects, and frequent suction and humidification are most important (Table 43.9). A trolley must be placed by the bed containing a tracheal dilator, duplicate robes and introducers, retractors and dressings. Oxygen should be at hand and, in the initial period, a nurse must be in constant attendance. Humidification will render the secretions less viscid; a sucker with a catheter attached should be on hand to keep the tracheobronchial tree free from secretions. The catheter must be kept in a sterile holder and introduced with aseptic precautions by all concerned. When mucus is very tenacious and consequently difficult to aspirate, isotonic saline or a mucolytic agent may be administered through the tracheostomy tube by a fine nebuliser. If there is an inner tube it should be removed and washed in sodium bicarbonate solution every 4 hours or more if necessary. A number of complications is associated with tracheostomy but all can be avoided with care and attention to operative and postoperative detail (Table 43.10).

Other emergency airway procedures.

Fibre-optic endotraacheal intubation. In most emergency situations endotracheal intubation is the most direct and satisfactory method of securing the airway. Nasotracheal intubation in expert hands is also a well-established technique and is particularly useful if the patient has trismus, severe mandibular injuries, cervical spine rigidity or an obstructing mass within the oral cavity. Both of these forms of intubation can be aided in difficult patients by passing a modern fibre-optic endoscope through the centre of an endotracheal tube, hence guiding it into the larynx.
and trachea under direct vision (Fig. 43.40).

**Transtracheal ventilation.** This technique has been increasingly advocated in the last decade and, although some specialist equipment is required, the actual technique is simple and effective. It will allow ventilation of the patient for periods in excess of 1 hour and will often give ample time to

The cricothyroid membrane is located by palpation of the neck with the index finger, and a 14G or 16G plastic-sheathed intravascular needle and a 10-ml syringe containing a few millilitres of lignocaine are introduced in the midline and directed downwards and backwards into the tracheal lumen (Fig. 43.41). The needle is advanced steadily and negative pressure is placed on the syringe until bubbles of air are clearly seen. The tissues of the neck may be infiltrated with the anaesthetic if desired and the tracheal mucosa likewise partly anaesthetised by the introduction of 1—2 ml after gaining the lumen. The needle is removed and the plastic-sheath cannula remains in the trachea. It is attached by means of a Luer connection to the high-pressure oxygen supply. Ventilation may be undertaken in a controlled man-ner with a jetting device with the chest being observed for appropriate movements. If there is severe obstruction of the laryngopharynx by the foreign body or tumour, the exhaled outflow of gases can be aided by placement of one or two further cannulae as exhalation ports. This procedure gains extremely rapid control of ventilation and requires a minimum of technical expertise.

**Cricothyroidotomy.** Cricothyroidotomy has gained increas-ing support in some centres and is advocated when endotracheal intubation is not possible. It has the advantages of speed and ease requiring little equipment and surgical expertise. However, its use for all but the briefest access to the airway remains controversial, and there are conflicting reports with regard to the subsequent incidence of complications, partic-ularly those of subglottic stenosis and long-term voice changes.

The patient’s neck is extended and the area between the prominence of the thyroid cartilage and the cricoid cartilage below is palpated with the index finger of the free hand. In the emergency situation a vertical skin incision is recom-mended with dissection rapidly carried down to thecricothyroid membrane. A 1cm transverse incision is made through the membrane immediately above the cricoid cartilage and the scalpel twisted through a right angle to gain access to the airway (Figs 43.42). If available artery forceps, dilator or tracheal hook will aid improving the aperture and the insertion of an available tube (Fig43.43).

Depending on the degree of emergency it may be necessary for the surgeon to assess the results of the procedure by direct laryngoscopy, and the authors recommend that careful consideration should be given to conversion of the cricothyroidotomy to a tracheostomy. Although there is debate about the frequency of subglottic stenosis following this procedure, there is general agreement that it is much increased if any long-term ventilation is undertaken via even a modest size tracheostomy tube through the cricothyroid membrane.
Laryngeal disease causing voice disorders

Vocal nodules

These are known as singers' nodules in adults and screammers nodules in children (Fig. 43.44). They are fibrous thickenings of the vocal folds at the junction of the middle and anterior third, and are the result of vocal abuse. Speech therapy is therefore the preferred treatment and the lesions will resolve spontaneously in most cases. Occasionally the nodules will need to be surgically removed using modern microlaryngoscopic dissection or laser techniques. Follow-up by the speech therapist is necessary until all of the underlying errors in voice production are overcome.

Vocal fold polyps

These are usually unilateral and may be associated with an acute infective episode, cigarette smoking and vocal abuse.

Laryngeal papillomata

These occur mainly in children but can also present in adults. They are most commonly found on the vocal folds but may spread throughout the larynx and tracheobronchial airway (Fig. 43.46). They are caused by papilloma viruses and need removal by laser surgery in order to maintain a rea-sonable voice and airway. Antiviral treatment by such drugs as interferon remains of doubtful value at present. Endo-sopic laser surgery is the least traumatic way of removing these lesions and should not produce scarring or cause implantation of the papillomata elsewhere in the airway.

Acute laryngitis

This often occurs in association with upper respiratory tract infections in association with a cough and pharyngitis. It may, however, be localised to the larynx, is usually viral and settles quickly if the patient rests the voice during the active inflam-mation. Steam inhalations are soothing along with mild analgesics but antibiotics are unnecessary. The condition should resolve in 2—3 weeks with voice care. Hoarseness lasting for 3—4 weeks should always be referred for an ENT opinion, particularly in smokers.

Chronic laryngitis

Chronic laryngitis may be specific and can be caused by mycobacteria, syphilis and fungi. Treatment is directed towards the causative organism. Nonspecific laryngitis is common, and the main predisposing factors are smoking, chronic upper and lower respiratory sepsis and voice abuse. In some cases the laryngeal mucosa may become dysplastic, particularly over the true vocal folds, and is a premalignant condition. It may require microlaryngoscopic examination and biopsy. Treatment is by the elimination of any predis-posing factors, particularly smoking, and attention to any vocal abuse under the guidance of a speech therapist. Diagnosis of chronic laryngitis should not be made unless the larynx has been fully evaluated by a laryngologist.

Vocal fold palsy

This may be unilateral or bilateral, but a unilateral left vocal fold palsy is the commonest as a consequence of the long intrathoracic course of the left recurrent laryngeal nerve which arches around the aorta and may be commonly involved in inflammatory and neoplastic conditions involving the left hilum (Fig. 43.47). Lung cancer is the commonest single cancer in many parts of the world and a left vocal fold palsy should be considered to be due to a carcinoma of the lung until proved otherwise. Other malignant lesions can cause a similar effect and may arise in the nasopharynx, thyroid gland or oesophagus. Bilateral vocal fold paralysis is uncommon and tends to occur after thyroid surgery or head injuries (Table 43.12).

Clinical features

Unilateral recurrent laryngeal nerve palsy of sudden onset produces hoarseness which is most notable for lack of volume to the voice and occasionally may be associated with difficulty in swallowing liquids and weakening of the cough. These symptoms may be short lived and the voice may return to normal within a few weeks as the muscles in the opposite vocal fold compensate and move it across the midline to meet the paralysed vocal fold which usually lies in the paramedian position. Owing to this efficient compensation, in slowly progressive lesions the patient may only experience slight weakness of the voice with prolonged use.

Bilateral recurrent laryngeal nerve palsy is an occasional and very serious complication of thyroidectomy. Acute dyspnoea occurs as a result of the paramedian position of both vocal folds which reduce the airway to 2—3 mm and which tend to get sucked together on inspi-ration. In severe cases tracheostomy or intubation is necessary immediately otherwise death occurs from asphyxia.

Investigation of vocal fold paralysis is most easily encompassed nowadays by a CT scan from skull base to diaphragm. This technique has replaced the multiple previous investiga-tions which were necessary and reveals most of the pathology which may give rise to an undiagnosed vocal fold palsy. Approximately 20—25 per cent of cases of vocal fold paralysis occurs without known pathology and spontaneous recovery may occur. In unilateral vocal fold paralysis, where compensation does not occur, the paralysed fold may be medialised by injecting Teflon paste lateral to the vocal fold and displacing it medially. Alternatively, a small external operation on the thyroid cartilage may be undertaken in order to enter the paraglotric space and displace the fold medially (thyroplasty). These surgical procedures should be performed early if the cause is carcinoma of the bronchus and the outlook of the patient is poor. When the pathology is unknown it may be better to wait for a period of 1 year to see whether spontaneous improvement occurs and to allow further recovery with the help of speech therapy.

In bilateral vocal fold paralysis the patients frequently require tracheostomy, but surgery may be carried out to remove a small portion of the posterior aspect of one vocal fold or a portion of one arytenoid cartilage. These proce-dures are most easily performed endoscopically with a car-bon dioxide laser. They increase the size of the posterior glottic airway allowing the patient to be decannulated or even to avoid a tracheostomy in the first place. Some laryngologists have advocated reinnervation procedures for the paralysed larynx by rotating a nerve muscle combination into the larynx from the neck. However, these techniques have not yet found widespread acceptance.

Tumours of the larynx

Benign tumours of the larynx are extremely rare and squamous carcinoma of the larynx predominates over all others, being responsible for more than 90 per cent of tumours within the larynx. It is the commonest head and neck cancer and almost always occurs in elderly male smokers. However, over the past two decades the sex incidence has changed as a consequence of increasing smoking amongst women, and in some areas they now make up more than 20 per cent of the patients. The squamous epithelium of the vocal folds and the respiratory epithelium of the supraglottis undergo dysplastic change stimulated by cigarette smoking and other factors. The incidence of laryngeal cancer in the three compartments supraglottis, glottis and subglottis varies around the world; the glottis is generally the commonest site followed by
the supraglottis (Fig. 43.48). True carcinomas of the subglottis are very rare and most are a consequence of inferior spread from the glottis.

**Clinical features**

The frequent glottic origin means that patients almost always present with hoarseness. This is of great importance because if a diagnosis can be made while the tumour is in the first stage, i.e. confined only to one vocal fold, these cancers have more than a 90 per cent 5-year disease-free cure rate when treated with radiotherapy alone. The cure rate drops dramatically once the lymphatically rich supraglottis or subglottis is involved, owing to spread to neck nodes. The appearance of more than one neck gland halves the overall prognosis of the patient.

**Investigations**

Direct laryngoscopy, preferably a microlaryngoscopy, together with Hopkin’s rod examination allows precise determination of the extent of the tumour and biopsy con-firms an exact histology (Table 43.13). CT and MRI scanning give further details of the extent of larger tumours demonstrating escape of the tumour outside the larynx and suspicious nodal involvement within the neck which may not be determined on clinical examination.

**Treatment**

Early supraglottic and glottic tumours stages I and II are optimally treated with megavoltage radiotherapy where these facilities exist. Five-year cure rates for stages I and II are approximately 90 and 70 per cent, respectively, and the patient has an excellent voice following this type of treatment. If modern megavoltage radiotherapy is not available then early tumours may be excised by means of endoscopic laser surgery or open partial laryngectomy surgery. This latter may be in the form of a laryngofissure when the thyroid cartilage is opened anteriorly in the midline and the squamous carcinoma excised under direct vision from the vocal fold or supraglottis or, in the case of more extensive unilateral glottic and supraglottic growths, a vertical hemilaryngectomy may be undertaken. This leaves a defect on one side of the larynx which is usually reconstructed with adjacent strap muscles. With early bilateral supraglottic tumours a horizontal laryngectomy may be undertaken excising the supraglottic growth and the remainder of the glottis. The subglottic part of the larynx is then stitched to the tongue base to provide continuity. In most patients undergoing partial laryngeal surgery of this type the voice result is not as satisfactory as that with radiotherapy, although the cure rates are often comparable.

**Advanced laryngeal disease**

Once the squamous carcinoma has caused fixation of the vocal fold or has infiltrated outside the larynx into adjacent structures such as the thyroid gland and strap muscles, some form of subtotal or total laryngectomy is required to attempt to cure the disease. Total laryngectomy is frequently required when radiotherapy fails (Figs 43.49-43.51). After the larynx has been removed, the remaining trachea is brought out on to the lower part of the neck as a permanent tracheal stoma and the hypopharynx, which is opened at the rime of the operation, is closed to restore the continuity for swallowing. Thus, the upper aerodigestive and digestive tracts are permanently disconnected. Part or all of the thyroid gland and associated parathyroid glands may also need to be removed depending on the extent of the disease, so patients after this type of radical surgery may require oral thyroxine and calcium supplements for the remainder of their lives. Laryngectomy patients must obviously avoid immersion in water as this would flow straight into their tracheal stoma. However, a rather complex form of snorkle device has been developed to allow laryngectomy patients to go swimming and simple protection of the stoma with a towel may allow them to take a careful shower.

**Vocal rehabilitation**

The loss of the larynx as a generator of sound does not prevent patients speaking as long as an alternative source of vibrating can be created in the pharynx. There are basically three ways of achieving this.

- An artificial device which produces sound when applied to the soft tissues of the neck which is turned into speech by the vocal tract comprising the tongue, the pharynx, oral cavity, lips, teeth and nasal sinuses. These devices are usually battery powered.

- Voice production may be restored in some patients by learning to swallow air into the pharynx and upper oesophagus. On regurgitating the air, a segment of the pharyngo-oesophageal mucosa vibrates to produce sound which is once again modified by the vocal tract into speech (Fig. 43.52).

- The most modern method is to gain use of the expired air from the lungs to power speech which is achieved by plac-ing a small valve through the back wall of the tracheal stoma into the pharynx. This is a one-way valve allowing air from the trachea to pass into the pharynx but it does not allow food and liquid to pass into the airway (Fig. 43.53).

There is a variety of these type of valves, the best known being the Blom—Singer valve which was developed in the USA. With the restoration of expired air passing into the pharynx, the segment of vibrating pharyngeal mucosa has a much greater quantity of air than when it is simply swallow-ed into the pharynx and oesophagus, and this gives an improved flow and quality to the speech of total laryngectomy patients. These valves are common nowadays in laryngectomy patients in many countries and they must not be confused with tracheostomy tubes. Like all foreign bodies, the speaking valves are associated with minor complications such as the formation of granulations, bleeding or leakage of pharyngeal contents.
The neck

Lump in the neck

The correct diagnosis of a lump in the neck can often be made with a careful history and examination. The clinical signs of size, site, shape, consistency, fixation to skin or deep structures, pulsatility, compressibility, transillumination or the presence of a bruit still remain as important as ever.

Branchial cyst

In the fifth week of foetal development four grooves can be seen on each side of the neck. These are the branchial clefts and the intervening bars are the branchial arches. Each arch contains a central cartilage and each cleft is composed of a groove on the outside and a pouch on the inside. The first cleft persists as the external auditory meatus, but the second, third and fourth normally disappear. A branchial cyst develops from the vestigial remnants of the second branchial cleft, is usually lined by squamous epithelium and contains thick turbid fluid full of cholesterol crystals (Fig. 43.54).

The branchial cyst usually presents in the upper neck in early or middle adulthood and is found at the junction of the upper third and middle third of the sternomastoid muscle at its anterior border. It is a fluctuant swelling which may transilluminate and is often soft in its early stages so that it may be difficult to palpate. If infection occurs it may become markedly erythematous and tender, and on occasions it may be difficult to differentiate from a tuberculous abscess. Ultrasound and fine needle aspiration both aid with diagnosis, and treatment is by complete excision. This is best undertaken when the lesion is quiescent as attempted excision of an acutely inflamed cyst may convert it into a branchial sinus which may be more troublesome. Although the anterior aspect of the cyst is easy to dissect, it may pass backwards and upwards through the foramen of the common carotid artery as far as the pharyngeal constrictors. It passes superficial to the hypoglossal and glossopharyngeal nerves but deep to the posterior belly of the diaphragm. The hypoglossal and spinal accessory nerve are encountered in the operative field and must be positively identified to avoid damage. Microscopic examination of these cysts commonly shows a layer of lymphoid tissue suggesting that these cysts may arise as a result of branchial epithelium entrapped within a lymph node.

Branchial fistula

A branchial fistula (Fig. 43.55) may be unilateral or bilateral and are thought to represent a persistent second branchial cleft. Their external orifice is nearly always situated in the lower third of the neck near the anterior border of the sternocleidomastoid, whilst the internal orifice is located on the anterior aspect of the posterior faucial pillar just behind the tonsil. However, the internal aspect of the tract may well end blindly at or close to the lateral pharyngeal wall, constituting a sinus rather than a fistula. The tract is lined by ciliated columnar epithelium and as such there may be a small amount of recurrent mucous or mucopurulent discharge on to the neck. The tract follows the same path as a branchial cyst and requires complete excision often by more than one transverse incision in the neck.

Branchogenic carcinoma

It is doubtful whether a primary carcinoma occurs in association with a branchial cyst and it is almost certainly due to cystic degeneration in a lymph node containing a deposit of squamous carcinoma. The primary focus giving rise to the squamous carcinoma may not be apparent, but is usually in the nasopharynx, tonsil, tongue base, piriform fossa or supra-glottic larynx. Full examination, scanning and biopsy of these areas is necessary to exclude the occult primary.

Cystic hygroma (cavernous lymphangioma)

Around the sixth week of embryonic life, the primitive lymph sacs develop in the mesoblast, the principal pair being situated in the neck between the jugular and subclavian veins; these, which correspond to the lymph parts of lower animals, are known as the jugular lymph sacs. Sequestration of a portion of the jugular lymph sac from the lymphatic system accounts for the appearance of these swellings (Fig. 43.56). Cystic hygroma usually manifests itself in the neonate or in early infancy, and occasionally may be present at birth and be so large as to obstruct labour. Swelling usually occurs in the lower third of the neck and as it enlarges it passes upwards towards the ear. Often the posterior triangle of the neck is mainly involved. As a result of the intercommunication of its many compartments, the swelling is soft and partially compressible; it visibly increases in size when the child coughs or cries, but the characteristic that distinguishes it from all other neck swellings is that it is brilliantly translucent. The cheek, axilla, groin and mediastinum are other, although less frequent, sites for a cystic hygroma. Cystic hygromas of the neck can on rare occasions be associated with lymphangiomatous lesions of the tongue. The behaviour of cystic hygromas during infancy is so uncertain that it is impossible at that age to predict what will happen. They sometimes expand rapidly and occasionally respiratory difficulty ensues demanding immediate aspiration of much of the cyst’s contents and even, on occasion, a tracheostomy. The lesion may become infected when it becomes inflamed and painful. Spontaneous regression may occur. The cysts are filled with clear lymph and lined by a single layer of epithelium with a mosaic appearance.

Definitive treatment is excision of all of the cyst at an early stage. This requires a meticulous conservative neck dissection with excision of all lymphatic-bearing tissues whilst preserving the normal neurovascular structures if possible. A pre-liminary injection of sclerosing agents is not advisable as itdestroys normal tissue planes making the curative surgery more difficult.

Thyroglossal duct cysts

Embryology. The thyroid gland descends early in foetal life from the base of the tongue towards its position in the lower neck with the isthmus lying over the second and third tra-cheal ring. At the time of its descent the hyoid bone has not been formed and the track of the descent of the thyroid gland is variable passing in front, through or behind the eventual position of the hyoid body. Thyroglossal duct cysts represent a persistence of this track and may therefore be found any-where in or adjacent to the midline from the tongue base to the thyroid isthmus. Rarely, a thyroglossal cyst may be the only functioning thyroid tissue in the body.

Clinical features. The cysts almost always arise in the midline but when they are adjacent to the thyroid cartilage they may lie slightly to one side of the midline (Fig. 43.57).Classically, the cyst moves upwards on swallowing and notably with tongue protrusion but this may occur with other midline cysts, such as dermoid cysts, as it merely indicates attachment to the hyoid bone. Thyroglossal cysts may become infected and rupture on to the skin of the neck presenting as a discharging sinus. Whilst they often occur in children they may also present in adults even as late as the sixth or seventh decade of life.

Treatment. Treatment must include excision of the whole thyroglossal tract which involves removal of the body of the hyoid bone and the suprahypoid tract through the tongue base to the vallecula at the site of the primitive foramen caecum together with a core of tissue on either side. This operation is known as Sistrunk’s operation and prevents recurrence, most notably from small side branches of the thyroglossal tract.
Approximately 0.5 per cent of people have a seventh cervical rib, of which approximately half are unilateral and more commonly found on the right side. The cervical rib may give rise to nerve pressure symptoms and Fig. 43.58 shows the four main varieties of cervical rib. At their exit from the neck, the brachial plexus and subclavian artery pass through a narrow triangle and, if the base of the triangle is raised by the height of one vertebra due to the interposition of a cervical rib, the subclavian artery and the fourth first dorsal nerve are bound to be angulated or compressed. The artery may become constricted with a fusiform dilation of the first 2—4 cm distal to the constriction. Clotting may occur and portions of a mural thrombus may become detached and give rise to an embolus or emboli (Fig. 43.59). Three clinical situations are encountered with cervical ribs, the simplest being the patient presenting with a lump in the lower part of the neck which may be visible, bony hard and fixed. It may cause tenderness in the supraclavicular fossa. A cervical rib with vascular symptoms occurs only when the rib is complete, and pain in the forearm, but in some instances radiating to the upper arm, is the prevailing symptom. The pain is brought on by use of the arm and the pain is accelerated if the arm is in a raised position at the time of exercise. The pain is relieved by rest and is due to ischaemic changes in the muscles of the arm. The hand on the affected side may be colder than the opposite side, may become unduly pale when it is held aloft and may become blue when it is dependent for a time. The radial pulse may be less than on the normal side and sometimes absent. This will depend on the level of collateral circulation. The distal part of the subclavian artery should be auscultated and the systolic bruit will be significant. Numbness of the fingers may occur, followed by ulceration and very occasionally gangrene.

Treatment is by prompt extraperiosteal excision of the cervical rib together with any bony prominence from the first rib. It may be advisable to perform sympathetic denervation of the upper limb. True cervical rib with nerve pressure symptoms is probably a rare occurrence as most cases have been found to be related to cervical spondylosis with pressure on the cervical roots in the region of the intervertebral foramina or by carpal tunnel syndrome which may cause wasting of the thenar eminence. Other conditions such as motor neuron disease and syringomyelia may cause similar symptoms. If a cervical rib needs excision it is essential to remove it with its periosteum or it will regenerate. Care must be exercised to avoid damage to the brachial plexus and phrenic nerves.
Trauma to the neck

Cut throat

In the majority of cases admitted to accident and emergency centres the wound does not involve important neurovascular structures but only skin, platysma and sternocleidomastoid or strap muscles. It is, however, prudent to explore all of these wounds formally.

Wounds above the hyoid bone

The cavity of the mouth or pharynx may have been entered and the epiglottis may be divided via the pre-epiglottic space. These wounds require repair with absorbable sutures on a formal basis under a general anaesthetic. If there is any degree of associated oedema or bleeding, particularly in relation to the tongue base or laryngeal inlet, it is advisable to perform a tracheostomy to avoid any subsequent respiratory distress.

Wounds of the thyroid and cricoid cartilage

Blunt crushing injuries or severe laceration injuries to the laryngeal skeleton can cause marked haematoma formation and rapid loss of the airway. There may be significant disruption of the laryngeal skeleton. These patients should not have an endotracheal intubation for any length of time, even if this is the initial emergency way of protecting the airway. The larynx is a delicate three-tiered sphincter and the presence of a foreign body in its lumen after severe disruption gives rise to major fibrosis and loss of laryngeal function. These injuries are frequently an absolute indication for a low tracheostomy, following which the larynx can be carefully explored and damaged cartilages repositioned and sutured, and the paraglottic space drained. An indwelling stent of soft sponge shaped to fit the laryngeal lumen and held by a nylon retaining suture through the neck may be left in place for approximately 5 days. This stent can be removed endoscopically after cutting the retaining suture and as the laryngeal damage heals the patient may then be decannulated.

Division of the trachea

Wounds of the trachea are fortunately rare but they should all be formally explored, and in order to obtain adequate exposure it is usually necessary to divide and ligate the thyroid isthmus. A small tracheostomy below the wound and then repair of the trachea with a limited number of submucosal sutures is appropriate. In self-inflicted wounds the recurrent laryngeal nerves, which lie protected in the tracheo-oesophageal grooves, are rarely injured. However, in stab wounds to the neck any nerve may be involved including the vagus, recurrent laryngeal nerve or cervical sympathetic chain. Primary repair is rarely possible but may be undertaken at the time of formal exploration of a major neck wound. Vascular complications of cut throat

In contrast to nerve damage, vascular damage can be severe. Major haemorrhagic shock may occur as a consequence of injury to the common carotid, external or internal carotid, or a venous air embolism as a result of damage to one of the major veins, most commonly the internal jugular. Infection of large neck wounds is not uncommon, and cellulitis may supervene and spread inferiorly to the mediastinum. Surgical emphysema may result if damage to the trachea is not recognised and air escapes into the neck. Oesophageal and pharyngeal fistula may occur but usually heal spontaneously. Aphonía or dysphonia may follow injury to the vocal folds or division of the recurrent laryngeal nerves. Stenosis of the trachea or larynx may be caused by scarring from major injuries due to road traffic accident or attempted hanging.

Wounds of the cervical portion of the thoracic duct

Wounds to the thoracic duct are fortunately rare and most often occur in association with dissection of lympha nodes in the left supraclavicular fossa. When damage to the duct is not recognised at the time of operation, chyle may subsequently leak from wound in amounts up to 2 litres/day and, as a result, the patient may waste rapidly.

Treatment

Should the damage be recognised during an operation, the proximal end of the duct must be ligated. Ligation of the duct is not harmful because there is a number of anastomotic channels between the lymphatic and venous system in the lower neck. If undetected, chyle usually starts to discharge from the neck wound within 24 hours of the operation. On occasions firm pressure by a pad and bandage to the lower neck may stop the leakage but frequently this is unsuccessful and it is best to re-explore the wound and locate and ligate the damaged duct. If the patient is given some cream to drink 2 hours before the operation the cut end of the duct is more easily found just lateral to the lower 4 cm of the left internal jugular vein. If it proves impossible to find the duct, particularly in an area of oedematous and fragile tissue, the wound can be packed firmly with a Whitehead’s varnish pack and allowed to heal by granulation.
Inflammatory conditions of the neck

Parapharyngeal and retropharyngeal abscess formation has been covered earlier in this chapter.

Ludwig angina

Ludwig described a clinical entity characterised by a brawny swelling of the submandibular region combined with inflammatory oedema of the mouth. It is these combined cervical and intraoral signs that constitute the characteristic feature of the lesion, as well as the putrid halitosis that is always present. The infection is often caused by a virulent streptococcal infection associated with anaerobic organisms and sometimes with other lesions of the floor of the mouth such as carcinoma. The infection encompasses both sides of the mylohyoid muscle causing oedema and inflammation such that the tongue may be displaced upwards and backwards giving rise initially to dysphagia and subsequently to potential obstruction of the airway.

Clinical cause

Unless the infection is controlled cellulitis may extend down the neck beneath the deep fascial layers to involve the larynx causing glottic oedema.

Treatment

Antibiotic therapy should be instituted as soon as possible using intravenous broad-spectrum antibiotics such as amoxycillin or cefuroxime combined with metronidazole to combat the anaerobes. In advanced cases where the swelling does not subside rapidly with such treatment, a curved submental incision may be used to drain both submandibular triangles. The mylohyoid muscle may be incised to decompress the floor of the mouth. Simple but generous corrugated drains may be placed in the wound which is then lightly sutured. This operation may be conducted under local anaesthesia and on rare occasions an additional tracheostomy may be necessary.

Cervical lymphadenitis (Table 43.14)

There are approximately 800 lymph nodes in the body; no fewer than 300 of them lie in the neck. Inflammation of the lymph nodes of the neck is exceedingly common. Infection occurs from the oral and nasal cavities, the pharynx, larynx, ear, scalp and face. The source of the infection must be sought systematically.

Acute lymphadenitis

The affected lymph nodes are enlarged and tender, and there may be varying degrees of general constitutional disturbance of the patient with pyrexia, anorexia and general malaise. The treatment in the first instance is directed to the primary focus of infection, for example tonsillitis or a dental abscess. If, despite antibiotic therapy, the pain continues or abscess formation occurs in the lymph nodes, parapharyngeal or retropharyngeal space then surgical drainage may be required.

Chronic lymphadenitis

Chronic painless lymphadenopathy may be either tuberculous, in children or young adults, or due to secondary malignant metastases most commonly from a squamous carcinoma in older people. Lymphoma also commonly presents in cervical nodes in young adults. Careful inspection of the upper airways and food passages is essential to exclude primary malignancy of the nasopharynx, tonsil, tongue base, piriform fossa or larynx. Fine needle aspiration of enlarged cervical lymph nodes is preferable to any form of open biopsy.

Tuberculous adenitis

Tuberculosis (TB) remains a problem throughout the world and is still a common cause of cervical lymphadenopathy. The condition most commonly affects children or young adults, but can occur at any age. The deep upper cervical nodes are most commonly affected, but there may be a widespread cervical lymphadenitis and the matching together of a substantial number of lymph nodes may be evident.

In most instances the tubercular bacilli gain entrance through the tonsil of the corresponding side of the lymphadenopathy. Both bovine and human TB may be responsible. In approximately 80 per cent of cases the tuberculous process is limited to the clinically affected group of lymph nodes but a primary focus in the lungs must always be suspected and investigated. As renal and pulmonary TB occasionally coexist, the urine should be examined carefully. Rarely, the patient may develop a natural resistance to the infection and the nodes may be detected at a later date as evidenced by calcification on an X-ray. This can also be seen after appropriate general treatment of tuberculous adenitis. If treatment is not instituted, the caseated node may liquefy and break down with the formation of a cold abscess in the neck (Fig. 43.60). The pus is first confined by the deep cervical fascia but after weeks or months this may become eroded at one point and the pus flows through the small opening into the space beneath the superficial fascia. The process has now reached the well-known stage of a ‘collar stud’ abscess. The superficial abscess enlarges steadily and, unless suitable treatment is adopted, the skin will soon become reddened over the centre of the fluctuating swelling and before long a discharging sinus occurs in the neck.

Treatment. The patient should be treated by appropriate chemotherapy, as confirmed by assessment of abscess contents for sensitivities to the antituberculous drugs. If an abscess fails to resolve despite appropriate chemotherapy and general measures, occasionally excision of the abscess and its surrounding fibrous capsule is necessary together with the relevant lymph nodes. If there is active TB of another system, for example pulmonary, then removal of tuberculosis lymph nodes in the neck is inappropriate. The nodes are commonly related to the internal jugular vein, common carotid and vagus nerve, and they may be associated with a great deal of surrounding fibrosis. Surgery can be difficult and a portion of the internal jugular vein may require excision with considerable care to avoid damage to the vagus or the cervical sympathetic trunk. A good view and access should be obtained at all times during this surgery and the sternocleidomastoid muscle divided to facilitate access, particularly if the disease is adjacent to the spinal accessory nerve or the hypoglossal nerve. The resected nodes should be sent for both pathological and micro-biological analysis.

Primary tumours of the neck

Neurogenous tumours

Chemodectoma (carotid body tumour). This is a rare tumour but there is a higher incidence in areas where people live at high altitudes, for example in Peru and Mexico where increased numbers have been reported as a consequence of chronic hypoxia leading to carotid body hyperplasia. The tumours most commonly present in the fifth decade and approximately 10 per cent of patients have a family history. There is an association with phaeochromocytoma. The tumours arise from the chemoreceptor cells on the medial side of the carotid bulb and at this point the tumour is adherent to the carotid wall (Fig. 43.61). The cells of the chemodectoma are not hormonally active and the tumours are...
usually benign with only a few proven metastases in a small number of cases.

**Clinical features.**

The patients often present with a long history of several years of a slowly enlarging painless lump at the carotid bifurcation. About one-third of patients present with a pharyngeal mass pushing the tonsil medially and anteriorly. The mass is firm, rubbery, pulsatile and is mobile from side to side but not up and down, and can sometimes be emptied by firm pressure, after which it will slowly refill in a pulsatile manner. A bruit may also be present. Swellings in the parapharyngeal space which often displace the tonsil medially should not be biopsied from within the mouth.

**Investigations.** When a chemodectoma is suspected a duplex study and, if indicated, a carotid angiogram should be carried out to demonstrate the carotid bifurcation which is usually splayed and a blush which outlines the normal tumour vessels. This tumour must not be biopsied and fine needle aspiration is also contraindicated.

**Treatment.** Because these tumours rarely metastasise and their overall rate of growth is slow, the need for surgical removal must be considered carefully as complications of surgery are potentially serious. The operation is best avoided in elderly patients. Radiotherapy has no effect. In some cases it may be possible to dissect the tumour away from the carotid bifurcation, but at times when the tumour is large it may not be separable from the vessels and resection will be necessary such that all appropriate facilities should be available to establish a bypass whilst a vein autograft is inserted to restore arterial continuity in the carotid system.

Vagal body tumours. Vagal paragangliomas arise from nests of paraganglionic tissue of the vagus nerve just below the base of the skull near the jugular foramen. They may also be found at various sites along the nerve down to the level of the carotid artery bifurcation.

**Clinical features.**

They also present as slowly growing and painless masses in the anterolateral aspect of the neck, and may also have a long history commonly of 2—3 years before diagnosis. Diagnosis is confirmed by CT and MRI scanning and additional arteriography if necessary. They may spread into the cranial cavity and surgery may be required. Peripheral nerve tumours. Schwannomas are solitary and encapsulated tumours attached to or surrounded by a nerve. Paralysis of the associated nerve is unusual. The vagus nerve is the commonest site for these tumours within the neck. Neurofibromas also arise from the Schwann cell and may be part of von Recklinghausen syndrome of multiple neuro-fibromatosis. Multiple neurofibromatosis is an autosomal dominant hereditary disease and the neurofibromata may be present at birth and often multiple. These lesions may occur in the neck and in about 10 per cent of these tumours malignant change occurs, although they usually enlarge slowly over a period of many years and the painless neck mass is the only sign. As with the lesions above, diagnosis requires angiography and scanning to differentiate them from other parapharyngeal tumours, but on occasions the diagnosis must wait until excision.

**Secondary carcinoma of the neck**

Secondary carcinomatous infiltration of the cervical lymph nodes is a common occurrence from important primary sites in the head and neck. These are nasopharynx, tonsil, tongue, piriform fossa and supraglottic larynx. All of these areas must be carefully assessed to search for the primary growth before considering biopsy or any surgery on the neck. Investigation is further assisted by fine needle aspirate of the neck node.

**Management**

The management of the involved cervical lymph nodes depends on the overall treatment regime to be given to the patient.

- If surgery is being used to treat the primary disease and the cervical nodes are palpable, and in excess of 3 cm, they may be excised *en bloc* with the primary lesion.

- If radiotherapy is used initially, as is always the case in carcinoma of the nasopharynx, then radiotherapy may also be given to the neck nodes whatever their stage. In the case of tongue, pharynx or larynx, however, if the node exceeds 3 cm in diameter then surgery may be necessary for the neck nodes even if the primary is treated by radiotherapy.

- If radiotherapy is used initially, as is always the case in carcinoma of the nasopharynx, then radiotherapy may also be given to the neck nodes, whatever their stage. In the case of the tongues, pharynx or larynx however, if the node exceeds 3 cm in diameter then surgery may be necessary for the neck nodes, even if the primary is treated by radiotherapy. If radiotherapy is used initially with resolution of the primary but there is subsequent residual or recurrent nodal disease then this situation will require cervical lymph node dissection.

**Types of neck dissection**

- Classical radical neck dissection (Crile) — the classic operation involves resection of the cervical lymphatics, the lymph nodes and those structures closely associated such as the internal jugular vein, the accessory nerve, the submandibular gland and the sternomastoid muscle. These structures are all removed *en bloc* and in continuity with the primary disease if possible. The main disability that follows the operation is the drooping of the shoulder due to paralysis of the trapezius muscle as a consequence of excision of the accessory nerve.

- Modified radical neck dissection — in selected cases one or more of the three following structures are preserved, the accessory nerve, the sternocleidomastoid muscle or the internal jugular vein, but otherwise all major lymph node groups and lymphatics are excised. Whichever structures are preserved at this dissection should be clearly noted.

- Selective neck dissection — in this type of dissection one or more of the major lymph node groups is preserved along with sternomastoid muscle, accessory nerve and internal jugular vein. Under these circumstances the exact groups of nodes excised must be documented.
Further reading

Embryology

The thyroid gland develops from the median bud of the pharynx (the thyroglossal duct) which passes from the foramen caecum at the base of the tongue to the isthmus of the thyroid. The ultimobranchial body which arises from a diverticulum of the fourth pharyngeal pouch of each side amalgamates with the corresponding lateral lobe. Parafollicular cells (C-cells) are derived from the neural crest and reach the thyroid via the ultimobranchial body. Recently, consideration has been given to the possibility that some C-cells are of endodermal rather than neural crest origin. It is doubtful whether the branchial apparatus itself contributes to the thyroid follicular cells.

Surgical anatomy (Figs 44.1 and 44.2)

The normal gland weighs 20—25 g. The functioning unit is the lobule supplied by a single arteriole and consisting of 24—40 follicles which are lined by cuboidal epithelium. The resting follicle contains colloid in which thyroglobulin is stored. The arterial supply is rich, and extensive anastomoses occur between the main thyroid arteries and branches of tracheal and esophageal arteries. There is an extensive lymphatic network within the gland. Although some lymph channels pass directly to the deep cervical nodes, the subcapsular plexus drains principally to the juxta-thyroid nodes, i.e., pretracheal ('Delphic') and paratracheal nodes, and nodes on the superior and inferior thyroid veins, and thence to the deep cervical and mediastinal group of nodes.

Ectopic thyroid and anomalies of the thyroglossal tract

Some residual thyroid tissue along the course of the thyroglossal tract is not uncommon, and may be lingual, cervical or intrathoracic. Very rarely the whole gland is ectopic.

Lingual thyroid

This forms a rounded swelling at the back of the tongue at the foramen caecum (Figs 44.3 and 44.4) and it may represent the only thyroid tissue present. It may cause dysphagia, impairment of speech, respiratory obstruction or hemorrhage. It is best treated by full replacement with thyroxine when it should get smaller, but excision or ablation with radioiodine is sometimes necessary.

Median (thyroglossal) ectopic thyroid

This forms a swelling in the upper part of the neck (Fig. 44.4) and is usually mistaken for a thyroglossal cyst. Again, this may be the only normal thyroid tissue present.

Lateral aberrant thyroid

There is no evidence that aberrant thyroid tissue ever occurs in a lateral position (Willis). "Normal thyroid tissue" found laterally, separate from the thyroid gland, must be considered and treated as a metastasis in a cervical lymph node from an occult thyroid carcinoma, almost invariably of papillary type. Struma ovarii is not ectopic thyroid tissue, but part of an ovarian teratoma. Very rarely, neoplastic change occurs or hyperthyroidism develops.

Thyroglossalcyst

This may be present in any part of the thyroglossal tract (Fig. 44.5). The common situations, in order of frequency, are beneath the hyoid, in the region of the thyroid cartilage, and above the hyoid bone. Such a cyst occupies the midline, except in the region of the thyroid cartilage, where the thyroglossal tract is pushed to one side, usually to the left. It is to be remembered that the swelling moves upwards on protrusion of the tongue as well as on swallowing because of the attachment of the tract to the foramen caecum.

A thyroglossal cyst should be excised because infection is inevitable, owing to the fact that the wall contains nodules of lymphatic tissue which communicate by lymphatics with the lymph nodes of the neck. An infected cyst is often mistaken for an abscess and incised, which is one way in which a thyroglossal fistula arises.

Thyroglossal fistula

Thyroglossal fistula (Fig. 44.6a, b) is never congenital; it follows infection or inadequate removal of a thyroglossal cyst. Characteristically the cutaneous opening of such a fistula is drawn upwards on protrusion of the tongue. A thyroglossal fistula is lined by columnar epithelium, discharges mucus, and is the seat of recurrent attacks of inflammation.

Treatment. Because the thyroglossal tract is so closely related to the body of the hyoid bone, this central part must be excised, together with the cyst or fistula, or recurrence is certain. When the thyroglossal tract can be traced upwards towards the foramen caecum, it must be excised with the central section of the body of the hyoid bone, and a central core of lingual muscle (Sistrunk’s operation).

Physiology. The hormones tri-iodothyronine (T3) and thyroxine (T4) (extracted by E.G. Kendall in 1916) are bound to thyroglobulin within the colloid. Synthesis within the thyroglobulin complex is controlled by several enzymes, in distinct steps:

• trapping of inorganic iodide from the blood;
• oxidation of iodide to iodic acid;
• binding of iodic acid to tyrosine to form mono-iodotyrosines;
• coupling of mono-iodotyrosines and di-iodotyrosines to form T3 and T4

when hormones are required the complex is resorbed into the cell and thyroglobulin broken down; T3 and T4 are liberated and enter the blood where they are bound to serum proteins: albumin and thyroxine binding globulin (TBG) and prealbumin (TBPA). A small amount of hormone remains free in the serum in equilibrium with the protein-bound hormone and is biologically active. The metabolic effects of the thyroid hormones are due to unbound free 14 and 13 (0.03 per cent and 0.3 per cent of the total circulating hormones, respectively). 13 is quick acting (within a few hours) whereas 14 acts more slowly (4—14 days). 13 is the more important physiological hormone and is also produced in the periphery by conversion from 14.

Therapeutic notes: L-thyroxine (T4) is the official name; trade name Eltroxin; tablet size 0.1 mg and 0.05 mg. Tri-iodothyronine (T3), official
name liothyronine; trade names Cynomel, Tertroxin; tablet size 20 µg.

**Thyrocalcitonin**

See calcitonin, Chapter 45.

**The pituitary thyroid axis**

Synthesis and liberation of thyroid hormones from the thyroid is controlled by thyroid-stimulating hormone (TSH) from the anterior pituitary. Secretion of TSH depends upon the level of circulating thyroid hormones and is modified in a classic negative feedback manner. In hyperthyroidism, where hormone levels in the blood are high, TSH production is suppressed whereas in hypothyroidism it is stimulated. Regulation of TSH secretion also results from the action of thyrotrophin-releasing hormone (TRH) produced in the hypothalamus.

**Thyroid-stimulating antibodies**

A family of IgG immunoglobulins binds with TSH receptor sites (TRAbs) and activate TSH receptors on the follicular cell membrane. They have a more protracted action than TSH (16—24 hours versus 1.5—3 hours) and are responsible for virtually all cases of thyrotoxicosis not due to autonomous toxic nodules. Serum concentrations are very low and not routinely measured.
Tests of thyroid function

There is a variety of tests of thyroid function available, some of which are now only of historic interest and others in the province of the endocrinologist rather than the endocrine surgeon. The number of investigations requested should be the minimum necessary to reach a diagnosis and formulate a management plan. Only a small number of parameters needs to be measured as a routine although this may require supplementation or repeat when inconclusive.

Serum thyroid hormones

Serum TSH. TSH levels can be measured accurately down to very low serum concentrations and if the serum TSH level is in the normal range it is redundant to measure the T3 and T4 levels. Interpretation of deranged TSH levels however depends on knowledge of the T3 and T4 values (Table 44.1). In the euthyroid state, T3, T4 and TSH levels will all be within the normal range. Florid thyroid failure results in depressed T3 and T4 levels with gross elevation of the TSH. Incipient or developing thyroid failure is characterised by low normal values of T3 and T4 and elevation of the TSH. In toxic states the TSH level is suppressed and undetectable. Thyroxine (T4) and tri-iodothyronine (T3) are transported in plasma bound to specific proteins (thyroxine-binding globulin, TBG). Only a small fraction of the total (0.03 per cent of T4 and 0.3 per cent of T3) is free and physiologically active. Assays of both total and free hormone are available but the total values depend on the level of circulating proteins which are affected by the level of circulating oestrogen. Thus, pregnant women and those on the oral contraceptive pill have elevated total T4 and T3 levels without evidence of toxicity. The free hormone levels are unaffected. Similarly some patients have low levels of TBG either as a primary phenomenon or secondary to a reduction in serum protein levels as a result of systemic or liver disease and the total level of circulating hormone may be low. For these reasons the free levels are more meaningful. Highly accurate radioimmunoassays of free T3 and free T4 are now routine. T3 toxicity (with a normal T4) is a distinct entity and may only be diagnosed by measuring the serum T3, although a suppressed TSH level with a normal T4 is suggestive.

Various combinations of these tests are used in different laboratories. An appropriate combination is to establish the functional thyroid status at initial assessment, with TSH supplemented by free T4, and T3 evaluation when TSH is abnormal.

Isotope scanning (Fig. 44.7)

The uptake by the thyroid of a low dose of either radiolabelled iodine (I-131) or technetium-99m (99mTc, which is normally taken up like I-131) will demonstrate the distribution of activity in the whole gland. This test is inappropriate for distinguishing benign from malignant lesions because the majority (80 per cent) of cold swellings is benign and some (5 per cent) functioning or warm swellings will be malignant. Its principal value is in the toxic patient with a nodule or nodularity of the thyroid. Localisation of overactivity in the gland will differentiate between a toxic nodule with suppression of the remainder of the gland and toxic multi-nodular goitre with several areas of increased uptake with important implications for therapy. Routine isotope scanning is unnecessary.

Whole body scanning is used to demonstrate metastases but the patient must have all normally functioning thyroid tissue ablated either by surgery or by ablation with high-dose radioiodine before the scan is performed because thyroid cancer cannot compete with normal thyroid tissue in the uptake of iodine.

Thyroid autoantibodies

Serum titres of antibodies against thyroid peroxidase and thyroglobulin are useful in determining the cause of thyroid dysfunction and swellings. Autoimmune thyroiditis may be associated with thyroid toxicity, failure or euthyroid goitre. Titres of greater than 1:100 are considered significant but a proportion of patients with histological evidence of lymphocytic (autoimmune) thyroiditis is seronegative.
Hypothyroidism

A scheme for classifying hypothyroidism is given in Table 44.2.

Cretinism (foetal or infantile hypothyroidism)

Sporadic cretinism is due to complete or near complete failure of thyroid development (partial failure causes juvenile myxoedema): the parents and other children may be perfectly normal. In endemic areas, goitrous cretinism is common, and is due to maternal and foetal iodine deficiency. Immediate diagnosis and treatment with thyroxine within a few days of birth are essential if physical and mental development are to be normal, or if further deterioration is to be prevented when damage has already occurred in utero. Hypothyroidism occurs in 1 in 4000 live births and for this reason, in the UK, there is routine biochemical screening of neonates for hypothyroidism using TSH assay on a simple heel-prick blood sample. Women under treatment with antithyroid drugs may give birth to a hypothyroid infant.

Adult hypothyroidism

The term myxoedema should be reserved for severe thyroid failure and not applied to the much commoner mild thyroid deficiency.

The signs of thyroid deficiency are:

- bradycardia;
- cold extremities;
- dry skin and hair;
- periorbital puffiness;
- hoarse voice;
- bradykinesis — slow movements;
- delayed relaxation phase of ankle jerks.

The symptoms are:

- tiredness;
- mental lethargy;
- cold intolerance;
- weight gain;
- constipation;
- menstrual disturbance;
- carpal tunnel syndrome.

Comparison of the facial appearance with a previous photograph may be helpful.

Thyroid function tests

Thyroid function tests (Table 44.1) show low T4 and T3 levels with a high TSH (except in the rare event of pituitary failure). High serum titres of antithyroid antibodies are characteristic of autoimmune disease.

Treatment

Oral thyroxine (0.10—0.20 mg) as a single daily dose (because of its prolonged action) is curative. Caution is required in the elderly or those with cardiac disease and the replacement dose is then commenced at 0.05 mg daily and cautiously increased. If a rapid response is required, triiodothyronine (20 mg three times a day) may be used. The signs and symptoms of hypothyroidism are accentuated. The facial appearance (Fig. 44.11) is typical, and there is often supraclavicular puffiness, a malar flush and a yellow tinge to the skin. Myxoedema coma occurs in neglected cases and carries a high mortality; the body temperature is low and the patient must be warmed slowly; 1 g of intravenous hydrocortisone (in divided doses) should be given daily, and intravenous triiodothyronine in slowly increasing doses.

Autoimmune thyroiditis

The so-called primary or atrophic myxoedema is now considered to be an autoimmune disease similar to chronic lymphocytic (Hashimoto’s) thyroiditis (see below) but without goitre formation from TSH stimulation. Because of the delay in diagnosis the hypothyroidism is usually much more severe than in goitrous autoimmune thyroiditis.

Dyshormonogenesis and goitrogens

Genetically determined deficiencies in the enzymes controlling the synthesis of thyroid hormones, if severe, are responsible for goitre formation with hypothyroidism. If of moderate degree, a simple (euthyroid) goitre results. Similarly goitrogens may produce a goitre with, or without, hypothyroidism.

A number of nonendemic goitrous cretins has been born to a group of itinerant tinkers living in Scotland who intermarry (Hutchison, Scotland). This was due to a deficiency of the enzyme dehalogenase. When thyroglobulin is broken down, uncoupled iodotyrosines are liberated as well as T3 and T4. They are broken down by the enzyme dehalogenase and the iodine retained within the thyroid. If dehalogenase is deficient, iodotyrosines pass into the blood, and are excreted in the urine and this may result in iodine deficiency and goitre formation. Another classic example of dyshormonogenesis is Pendred’s syndrome, where goitre is associated with congenital deafness. This is due to a deficiency of peroxidase, the enzyme responsible for organification of trapped iodine. Defects in thyroglobulin synthesis are also recognised in dyshormonogenesis.
Thyroid enlargement

The normal thyroid gland is impalpable. The term goitre (Latin, *guttur* = the throat) is used to describe *generalised* enlargement of the thyroid gland. A discrete swelling (nodule) in one lobe with no palpable abnormality elsewhere is termed an *isolated* (or *solitary*) swelling. Discrete swellings with evidence of abnormality elsewhere in the gland are termed *dominant*.

A scheme for categorising thyroid enlargement is given in Table 44.3.

Simple goitre

**Aetiology**

Simple goitre may develop as a result of stimulation of the thyroid gland by TSH, either as a result of inappropriate secretion from a microadenoma in the anterior pituitary (which is rare), or in response to a chronically low level of circulating thyroid hormones. The most important factor in endemic goitre is dietary deficiency of iodine (see below) but defective hormone synthesis probably accounts for many sporadic goitres (see below). TSH is not the only stimulus to thyroid follicular cell proliferation and other growth factors including immunoglobulins exert an influence. The heterogeneous structural and functional response in the thyroid resulting in characteristic nodularity may be due to the presence of clones of cells particularly sensitive to growth stimulation.

**Iodine deficiency**

The daily requirement of iodine is about 0.1—0.15 mg. In nearly all districts where simple goitre is endemic, there is a very low iodide content in the water and food. Endemic areas are in the mountainous ranges, such as the Rocky Mountains, the Alps, the Andes and the Himalayas. In Great Britain endemic goitre is found in the Mendips, Chilterns, Cotswolds and the Pennine chain of Derbyshire and Yorkshire. Endemic goitre is also found in lowland areas where the soil lacks iodide or the water supply comes from far away mountain ranges, e.g. the Great Lakes of North America, the Plains of Lombardy, the Struma valley and the Nile valley and the Congo.

Calcium is also goitrogenic and goitre is common in low-iodine areas on chalk or limestone, e.g. Derbyshire and Southern Ireland. Although iodides in food and water may be adequate, failure of intestinal absorption may produce iodine deficiency (McCarrison).

**Defective hormone synthesis**

**Enzyme deficiency/dyshormonogenesis.** It is probable that enzyme deficiencies of varying severity are responsible for many sporadic goitres, i.e. in nonendemic areas. There is often a family history suggesting a genetic defect. Environmental factors may compensate in areas of high iodine intake, for example goitre is almost unknown in Iceland where the fish diet is rich in iodine. Similarly a low intake of iodine encourages goitre formation in those with a metabolic predisposition.

**Goitrogens.** Well-known goitrogens are the vegetables of the brassica family (cabbage, kale and rape) which contain thiocyanate, drugs such as para-aminosalicylic acid (PAS) and, of course, the antithyroid drugs. Thiocyanates and perchlorates interfere with iodide trapping; carbimazole and thioracil compounds interfere with the oxidation of iodide and the binding of iodine to tyrosine.

Surprisingly enough, iodides in large quantities are goitrogenic because they inhibit the organic binding of iodide and produce an iodide goitre.

**The natural history of simple goitre**

**Stages in goitre formation are:**

- persistent growth stimulation causes diffuse hyperplasia; all lobules are composed of active follicles and iodine uptake is uniform. This is a diffuse hyperplastic goitre, which may persist for a long time but is reversible if stimulation ceases;
- later, as a result of fluctuating stimulation, a mixed pattern develops with areas of active lobules and areas of inactive lobules;
- active lobules become more vascular and hyperplastic until haemorrhage occurs, causing central necrosis and leaving only a surrounding rind of active follicles;
- necrotic lobules coalesce to form nodules filled with either iodine-free colloid or a mass of new but inactive follicles;
- continual repition of this process results in a nodular goitre. Most nodules are inactive and active follicles are present only in the internodular tissue.

**Diffuse hyperplastic goitre**

Diffuse hyperplasia corresponds to the first stages of the natural history. The goitre appears in childhood in endemic areas but, in sporadic cases, it usually occurs at puberty when metabolic demands are high — puberty goitre (Fig. 44.12). If TSH stimulation ceases, the goitre may regress, but tends to recur later at times of stress such as pregnancy. The goitre is soft, diffuse and may become large enough to cause discomfort. A colloid goitre is a late stage of diffuse hyperplasia when TSH stimulation has fallen off and when many follicles are inactive and full of colloid (Fig. 44.13).

**Nodular goitre**

Nodules are usually multiple, forming a multinodular goitre. Occasionally, only one macroscopic nodule is found, but microscopic changes will be present throughout the gland:

this is one form of a clinically solitary nodule. Nodules may be colloid or cellular, and cystic degeneration and haemorrhage are common, as is subsequent calcification. Nodules appear early in endemic goitre and later (between 20 and 30 years) in sporadic goitre, although the patient may be unaware of the goitre until the late 40s or 50s. All types of simple goitre are far more common in the female than in the male and the presence of oestrogen receptors in normal thyroid tissue and in nodular goitre is relevant.

**Diagnosis** is usually straightforward. The patient is euthyroid: the nodules are palpable and often visible; they are smooth, usually firm and not hard, and the goitre is painless and moves freely on swallowing. Hardness and irregularity, due to calcification, may simulate carcinoma. A

| Simple goitre | Aetiology | Iodine deficiency | Defective hormone synthesis | The natural history of simple goitre | Diffuse hyperplastic goitre | Nodular goitre | Diagnosis |
painful nodule, sudden appearance or rapid enlargement of a nodule raises suspicion of carcinoma but is usually due to haemorrhage into a simple nodule. Differential diagnosis from autoimmune thyroiditis may be difficult.

**Investigations.** Tests of thyroid function are necessary to exclude mild hyperthyroidism, and the estimation of titres of thyroid antibodies to differentiate from autoimmune thyroiditis. Plain radiographs of the chest and thoracic inlet may show calcification and tracheal deviation or compression.

**Complications.** *Tracheal obstruction* is due to gross lateral displacement, or compression in a lateral or anteroposterior plane by retrosternal extension of the goitre (Fig. 44.14). Acute respiratory obstruction may follow haemorrhage into a nodule impacted in the thoracic inlet.

**Secondary thyrotoxicosis.** Many patients with nodular goitres experience transient episodes of mild hyperthyroidism. The incidence is difficult to estimate, but figures as high as 30 per cent have been suggested.

**Carcinoma,** which is usually of follicular pattern. It is uncommon but an increased incidence has been reported from endemic areas.

**Prevention and treatment of simple goitre**

In endemic areas, e.g. Switzerland, parts of the USA and Argentina, the incidence of goitre has been strikingly reduced by the introduction of iodised salt.

In the early stages a hyperplastic goitre may regress if thyroxine is given in a dose of 0.15—0.2 mg daily for a few months.

The nodule stage of simple goitre is irreversible. Most patients with multinodular goitre are asymptomatic and do not require operation. Operation may be indicated on cosmetic grounds if the goitre is unsightly. Retrosternal extension with actual or incipient tracheal compression is an indication for operation, as is the presence of a dominant area of enlargement which may be neoplastic.

There is a choice of surgical treatment: (a) total thyroidectomy with immediate and life-long replacement of thyroxine; or (b) some form of partial resection to conserve sufficient functioning thyroid tissue to subserve normal function whilst eliminating the risk of hypoparathyroidism which accom-panies total thyroidectomy. Partial resection aims to remove the bulk of the gland, leaving up to 8 g of relatively normal tissue in each remnant. The technique is essentially the same as described for toxic goitre, as are the postoperative complications. More often, however, the multinodular change is asymmetrically distributed, with one lobe more significantly involved than the other. Under these circumstances total lobectomy on the more affected side is the appropriate management with either subtotal resection or no intervention on the less affected side. In many cases the causative factors persist and recurrence is likely. Reoperation for recurrent nodular goitre is more difficult and hazardous and for this reason many thyroid surgeons favour total thyroidectomy in younger patients. When a unilateral lobectomy alone has been performed for asymmetric goitre, reoperation is straightforward should it become necessary on the remaining lobe.

After subtotal resection it has been customary to give thyroxine to suppress TSH secretion with the aim of preventing recurrence. Whether this is either necessary or effective is uncertain, although the evidence of benefit in endemic areas is better than elsewhere. There is some evidence that recur-rence after surgery may reduce in size after treatment with radioactive iodine.

**Clinically discrete swellings**

Discrete thyroid swellings (thyroid nodules) are common and are present in 3—4 per cent of the adult population in the UK and USA. They are three to four times more frequent in women than men.

**Diagnosis**

A discrete swelling in an otherwise impalpable gland is termed isolated or solitary, whereas the preferred term for a similar swelling in a gland with clinical evidence of gener-alised abnormality in the form of a palpable contralateral lobe or generalised mild nodularity is *dominant.* About 70 per cent of discrete thyroid swellings are clinically isolated and about 30 per cent dominant. The true incidence of isolated swellings is somewhat less than the clinical estimate. Clinical classification is inevitably subjective and overesti-mates the frequency of truly isolated swellings. When such a gland is exposed at operation or examined by ultrasonography, computed tomography (CT) or magnetic resonance imaging (MRI), clinically impalpable nodules are often detected. The true frequency of thyroid nodularity compared with the clinical detection rate by palpation is shown in (Fig. 44.15). Establishing the presence of such minor abnormality is unnecessary because the management of discrete swellings, be they isolated or dominant, is similar.

The importance of discrete swellings lies in the risk of neoplasia compared with other thyroid swellings. Some 15 per cent of isolated swellings prove to be malignant, and an additional 30—40 per cent are follicular adenomas. The remainder are non-neoplastic largely consisting of areas of colloid degeneration, thyroiditis or cysts. Although the inci-dence of malignancy or follicular adenoma in clinically domi-nant swellings is approximately half that of truly isolated swellings, it is substantial and cannot be ignored.

**Investigation**

**Thyroid function.** The thyroid functional status should be established by estimation of serum thyroid hormones and TSH. If hyperthyroidism associated with a discrete swelling is confirmed biochemically, it indicates either a ‘toxic adenoma’ or a manifestation of toxic multinodular goitre. The combination of toxicity and nodularity is important and constitutes the only indication for isotope scanning to localise the area(s) of hyperfunction.

**Autoantibody titres.** The autoantibody status is important in determining which swellings may be a manifestation of chronic lymphocytic thyroiditis.

**Isotope scan.** Isotope scanning used to be the mainstay of investigation of discrete thyroid swellings to determine the functional activity relative to the surrounding gland according to isotope uptake.

On scanning, swellings are categorised as ‘hot’ (over-active), ‘warm’ (active) or ‘cold’ (underactive). A hot nodule is one that takes up isotope, while the surrounding thyroid tissue does not. Here the surrounding thyroid tissue is inactive because the nodule is producing such high levels of thyroid hormones that TSH secretion is suppressed. A warm nodule takes up isotope and so does normal thyroid tissue about it. A cold nodule takes up no isotope (Fig. 44.7).

About 80 per cent of discrete swellings are cold but only 15 per cent prove to be malignant and the use of this criterion as an indication for
operation lacks discrimination. Routine isotope scanning has been abandoned except when toxicity is associated with nodularity.

**Ultrasonography** was formerly widely used as a noninvasive supplement to clinical examination in determining the physical characteristics of thyroid swellings. Although ultrasonography can demonstrate subclinical nodularity and cyst formation, the former is clinically irrelevant and the latter apparent at aspiration, which should be routine in all discrete swellings.

**Fine-needle aspiration cytology (FNAC).** FNAC has established itself as the investigation of choice in discrete thyroid swellings. FNAC has excellent patient compliance, is simple and quick to perform in the outpatient department and is readily repeated. This technique, developed in Scandinavia some 30 years ago, has become popular in the rest of Europe and North America in the last 20 years.

Thyroid conditions that may be diagnosed by FNAC include colloid nodules (Fig. 44.16), thyroiditis, papillary carcinoma (Fig. 44.17), medullary carcinoma, anaplastic carcinoma and lymphoma. FNAC cannot distinguish between a benign follicular adenoma (Fig. 44.18) and follicular carcinoma as this distinction is dependent not on cytology but on histological criteria, which include capsular and vascular invasion.

Although FNAC has been reported as highly accurate by Lowhagen and his colleagues at the Karolinska Hospital, who were its pioneers, and by other authors, high accuracy has not always been reproducible, especially when results are analysed critically. There are very few false positives with respect to malignancy but there is a definite false-negative rate with respect to both benign and malignant neoplasia.

FNAC is less reliable in cystic than in solid swellings, often yielding only cyst fluid with macrophages and degenerate cells. After aspiration a further sample should be taken from the cyst wall, for cytology. Relatively few cysts are permanently abolished by one or more aspirations and, because of the risk of malignancy, recurrent cysts should be removed.

**Radiology.** Chest and thoracic inlet radiographs are only necessary when there is clinical evidence of tracheal deviation or compression or retrosternal extension.

Other scans. CT and MRI scans give excellent anatomical detail of thyroid swellings but have no role in the first line of investigation. They are occasionally useful in assessing recurrent and retrosternal swellings. The increased use of these imaging modalities in other head and neck swellings has created a new clinical conundrum which has been termed the 'Thyroid Incidentaloma'. These are clinically unsuspected and impalpable thyroid swellings which with few exceptions require no further investigation or surgery.

**Indirect laryngoscopy** to determine the mobility of the vocal cords is widely used preoperatively, although usually for medicolegal rather than clinical reasons.

**Large-bore needle (Trucut) biopsy.** Trucut biopsy has a high diagnostic accuracy but has poor patient compliance and may be associated with complications such as pain, bleeding, tracheal and recurrent laryngeal nerve damage. It has little application in routine assessment except in locally advanced, surgically unresectable malignancy (either anaplastic carci-noma or lymphoma) when Trucut biopsy may avoid operation.

The main indication for operation is the presence of neoplasia which includes follicular adenoma as well as malignant swellings. The reason for advocating the removal of all follicular neoplasms is that it is seldom possible to distinguish between a follicular adenoma and carcinoma cytologically. The distinction usually depends on histological evidence of capsular or vascular invasion and FNAC cannot make this distinction, although on occasion cellular nuclear features may be so abnormal as to suggest malignant change. On this basis, some 50 per cent of isolated and 25 per cent of dominant swellings should be removed on the grounds of neoplasia. Even when the cytology is negative, the age and sex of the patient and the size of the swelling may be relative indications for surgery, especially when a large swelling is responsible for symptoms. Some patients are happier to have a swelling removed even when cytology is negative.

There are useful clinical criteria to assist in selection for operation according to the risk of neoplasia and malignancy. Hard texture alone is not reliable since tense cystic swellings may be suspiciously hard but a hard, irregular swelling with any apparent fixity, which is unusual, is highly suspicious. Evidence of recurrent laryngeal nerve paralysis, suggested by hoarseness and a nonocclusive cough, and confirmed by indirect laryngoscopy, is almost pathognomonic. Deep cervical lymphadenopathy along the internal jugular vein in association with a clinically suspicious swelling is almost diagnostic of papillary carcinoma. In most patients, however, such features are absent but there are risk factors associated with sex and age. The incidence of thyroid carcinoma in women is about three times that in men, but a discrete swelling in a male is much more likely to be malignant than in a female and it is seldom justifiable to avoid removing such a swelling in a man. The risk of carcinoma is increased at either end of the age range and a discrete swelling in a teenager of either sex must be provisionally diagnosed as carcinoma. The risk increases as age advances beyond 50 years, and more so in males.

**Thyroid cysts**

Routine FNAC (or ultrasonography) shows that over 30 per cent of clinically isolated swellings contain fluid and are cystic or partly cystic. Tense cysts may be hard and mimic carcinoma. Bleeding into a cyst often presents with a history of sudden painful swelling which resolves to a variable extent over a period of weeks if untreated. Aspiration yields altered blood but reaccumulation is frequent. About 50 per cent of cystic swellings are the result of colloid degeneration, or of uncertain aetiology, because of an absence of epithelial cells in the lining. Although most of the remainder are the result of involution in follicular adenomas (Fig. 44.19) some 10—15 per cent of cystic follicular swellings are histologically malignant (30 per cent in males and 10 per cent in females). Papillary carcinoma is often associated with cyst formation (Fig. 44.20).

Most patients with discrete swellings, however, are females aged 20—40 years in whom the risk of malignancy, although significant, is low and the indications for operation are not clear cut. FNAC is the most appropriate investigation to aid selection.

The indications for operation in isolated or dominant thyroid swellings are listed in Table 44.4.

**Retrosternal goitre**

Very few retrosternal goitres arise from ectopic thyroid tissue; most arise from the lower pole of a nodular goitre. If the neck is short and the pretracheal muscles are strong, as in men, the negative intrathoracic pressure tends to draw these nodules into the superior mediastinum.

**Clinical features**

A retrosternal goitre is often symptomless and is discovered on a routine chest radiograph. There may, however, be severe symptoms: dyspnoea, particularly at night, cough and stridor (harsh sound on inspiration). Many of these patients may attend a chest clinic with a diagnosis of asthma before the true nature of the problem is discovered;
• dysphagia;

• engorgement of neck veins and superficial veins on the chest wall. In severe cases there may be obstruction of the superior vena cava (Fig. 44.21);

• recurrent nerve paralysis is rare. The goitre may also be malignant or toxic.

Radiographs show a soft-tissue shadow in the superior mediastinum — sometimes with calcification — and often causing deviation and compression of the trachea (Fig. 44.14). Radiographs of the thoracic inlet give better definition than a chest radiograph. Significant tracheal compression and obstruction may be demonstrated objectively by a flow—volume loop pulmonary function test in which the rate of flow is plotted against the volume of air inspired and then expired. Deterioration in flow due to increase in tracheal compression either acutely or in the long term may be used to monitor progression of the disease and indicate the need for surgery. The changes are reversed by operation (Fig. 44.22).

Treatment

If obstructive symptoms are present in association with thyrotoxicosis it is unwise to treat a retrosternal goitre with antithyroid drugs or radioiodine as these may enlarge the goitre. Resection can almost always be carried out from the neck and a midline sternotomy is hardly ever necessary. The cervical part of the goitre should first be mobilised by ligation and division of the superior thyroid vessels, and by ligature and division of the middle thyroid veins and the inferior thyroid artery. The retrosternal goitre can then be delivered by traction and finger mobilisation. Haemorrhage is rarely a problem because the goitre takes its blood supply with it from the neck. The recurrent laryngeal nerve should be identified if possible before delivering the retrosternal goitre, as it may be abnormally displaced and is particularly vulnerable to injury from traction or tearing. If a large multinodular goitre cannot be delivered intact from the retrosternal position it may be broken with the fingers and delivered piecemeal, but this should never be done if the lesion is solitary and there is the possibility of carcinoma.
Hyperthyroidism

Thyrotoxicosis

The term thyrotoxicosis is retained because hyperthyroidism, i.e. symptoms due to a raised level of circulating thyroid hormones, is not responsible for all manifestations of the disease.

Clinical types are:

- diffuse toxic goitre (Graves’ disease);
- toxic nodular goitre;
- toxic nodule;
- hyperthyroidism due to rarer causes.

Diffuse toxic goitre

Graves’ disease — a diffuse vascular goitre appearing at the same time as the hyperthyroidism, usually in the younger woman and frequently associated with eye signs. The syndrome is that of primary thyrotoxicosis (Fig. 44.23). The whole of the functioning thyroid tissue is involved, and the hypertrophy and hyperplasia are due to abnormal thyroid-stimulating antibodies (TsAb).

Toxic nodular goitre

A simple nodular goitre is present for a long time before the hyperthyroidism, usually in the middle-aged or elderly and very infrequently associated with eye signs. The syndrome is that of secondary thyrotoxicosis.

In many cases of toxic nodular goitre, the nodules are inactive, and it is the internodular thyroid tissue that is overactive. However, in some toxic nodular goitres, one or more nodules are overactive and here the hyperthyroidism is due to autonomous thyroid tissue as in a toxic adenoma.

Toxic nodule

This is a solitary overactive nodule, which may be part of a generalised nodularity or a true toxic adenoma. It is auto-nomous and its hypertrophy and hyperplasia are not due to TsAb. Because TSH secretion is suppressed by the high level of circulating thyroid hormones, the normal thyroid tissue surrounding the nodule is itself suppressed and inactive.

Histology

The normal thyroid gland (Fig. 44.24) consists of acini lined by flattened cuboidal epithelium and filled with homogeneous colloid. In hyperthyroidism (Fig. 44.25) there is hyperplasia of acini, which are lined by high columnar epithelium. Many of them are empty and others contain vacuolated colloid.

Clinical features

The symptoms are:

- tiredness;
- emotional lability;
- heat intolerance;
- weight loss;
- excessive appetite;
- palpitations.

The signs of thyrotoxicosis are:

- tachycardia;
- hot, moist palms;
- exophthalmos;
- lid lag/retraction;
- agitation;
- thyroid goitre and bruit.

Symptomatology

Thyrotoxicosis is eight times commoner in females than in males. It may occur at any age. The most significant symptoms are loss of weight in spite of a good appetite, a recent preference for cold, and palpitations. The most significant signs are the excitability of the patient, the presence of a goitre, exophthalmos, and tachycardia or cardiac arrhythmia.

The goitre in primary thyrotoxicosis is diffuse and vascular, it may be large or small, firm or soft, and a thrill and a bruit may be present. The onset is abrupt, but remissions and exacerbations are not infrequent. Hyperthyroidism is usually more severethan in secondary thyrotoxicosis.
but cardiac failure is rare. Manifestations of thyrotoxicosis not due to hyperthyroidism per se, e.g. orbital proptosis, ophthalmoplegia and pretibial myxoedema, may occur in primary thyrotoxicosis.

In secondary thyrotoxicosis the goitre is nodular. The onset is insidious and may present with cardiac failure or atrial fibrillation. It is characteristic that the hyperthyroidism is not severe. Eye signs other than lid lag and lid spasm (due to hyperthyroidism) are very rare.

Cardiac rhythm. A fast heart rate, which persists during sleep, is characteristic. Cardiac arrhythmias are super-imposed on the sinus tachycardia as the disease progresses, and they are commoner in older patients with thyrotoxicosis because of the prevalence of coincidental heart disease. Stages of development of thyrotoxic arrhythmias are:

- multiple extrasystoles;
- paroxysmal atrial tachycardia;
- paroxysmal atrial fibrillation;
- persistent atrial fibrillation, not responsive to digoxin.

Myopathy. Weakness of the proximal limb muscles is commonly found if looked for. Severe muscular weakness (thyrotoxic myopathy) resembling myasthenia gravis occurs occasionally. Recovery proceeds as hyperthyroidism is controlled.

Eye signs. Some degree of exophthalmos is common (Fig. 44.23). It may be unilateral. True exophthalmos is a proptosis of the eye, caused by infiltration of the retrobulbar tissues with fluid and round cells, with a varying degree of retraction or spasm of the upper eyelid. (Lid spasm occurs because the levator palpebrae superioris muscle is partly innervated by sympathetic fibres.) This results in widening of the palpebral fissure so that the sclera may be seen clearly above the upper margin of the iris and cornea (above the 'limbus').

Spasm and retraction usually disappear when the hyperthyroidism is controlled. They may be improved by 3-adrenergic blocking drugs, e.g. guanethidine eye drops. Oedema of the eyelids, conjunctival injection and chemosis are aggravated by compression of the ophthalmic veins (Fig. 44.26). Weakness of the extraocular muscles, particularly the elevators (inferior oblique), results in diplopia. In severe cases, papilloedema and corneal ulceration occur. When severe and progressive, it is known as malignant exophthalmos (Fig. 44.27) and the eye may be destroyed. Graves' ophthalmopathy is an autoimmune disease in which there are antibody-mediated effects on the ocular muscles.

Exophthalmos tends to improve with time. Sleeping propped up and lateral tarsorrhaphy will help to protect the eye but will not prevent progression. Hypothyroidism increases proptosis by a few millimetres and should be avoided.

Improvement has been reported with massive doses of prednisone. Intraorbital injection of steroids is dangerous because of the venous congestion, and total thyroid ablation has not proved effective. When the eye is in danger, orbital decompression may be required (see Dysthyroid exophthalmos). Pretibial myxoedema (Fig. 44.28) is a thickening of the skin by a mucin-like deposit, nearly always associated with true exophthalmos, past or present hyperthyroidism, and high levels of TsAb.

Diagnosis of thyrotoxicosis

Most cases are readily diagnosed clinically. Difficulty is most likely to arise in the differentiation of mild hyperthyroidism from an anxiety state when a goitre is present. In these cases, the thyroid status is determined by the diagnostic tests described earlier. A TRH test is rarely indicated.

T3 thyrotoxicosis is diagnosed by estimating the free T3. It should be suspected if the clinical picture is suggestive but routine tests of thyroid function are within the normal range. A thyroid scan is essential in the diagnosis of an autonomous toxic nodule.

Thyrotoxicosis should always be considered in:

- children with a growth spurt, behaviour problems or myopathy;
- tachycardia or arrhythmia in the elderly;
- unexplained diarrhoea;
- loss of weight.

Principles of treatment of thyrotoxicosis

Nonspecific measures are rest and sedation and, in established thyrotoxicosis, should be used only in conjunction with specific measures—the use of antithyroid drugs, surgery and radioiodine.

Antithyroid drugs

Those in common use are carbimazole and propylthiouracil. Beta-adrenergic blockers, such as propranolol and nadolol, may also be used. Iodides, once thought to reduce the vascularity of the thyroid, should only be used as immediate preoperative preparation in the 10 days before surgery. Antithyroid drugs are used to restore the patient to a euthyroid state and to maintain this for a prolonged period in the hope that a permanent remission will occur, i.e., that production of TsAb will diminish or cease. It should be noted that antithyroid drugs cannot cure a toxic nodule. The overactive thyroid tissue is autonomous and recurrence of the hyperthyroidism is certain when the drug is discontinued.

Advantages

No surgery and no use of radioactive materials.

Disadvantages

- Treatment is prolonged and the failure rate after a course of 1.5—2 years is at least 50 per cent. Recently there has been a trend towards the use of shorter courses (6 months) of these drugs.
- It is impossible to predict which patient is likely to go into a remission. [Attempts have been made to predict which patients might relapse after
a 6-month course of antithyroid drugs on the basis of human leucocyte antigen (HLA) status and the presence of TsAb production.]  

• Some goitres enlarge and become very vascular during treatment—even if thyroxine is given at the same time. This is probably due to TsAb stimulation during the prolonged course of treatment and not a direct effect of the drug.  

• Very rarely, there is a dangerous drug reaction, e.g. agranulocytosis or aplastic anaemia. In the event of agranulocytosis, the patient should be instructed to discontinue treatment, if a sore throat develops, until the white cell count has been checked.

Initially, 10 mg of carbimazole is given three or four times a day, and there is a latent interval of 7—14 days before any clinical improvement is apparent. It is most important to maintain a high concentration of the drug throughout the 24 hours by spacing the doses at 8- or 6-hourly intervals. When the patient becomes euthyroid, a maintenance dose of 5 mg two or three times a day is given for another 12—18 months. If tri-iodothyronine (20 jg up to four times daily) or thyroxine (0.1 mg daily) is given in conjunction with anti-thyroid drugs, there is less danger of producing iatrogenic thyroid insufficiency or an increase in the size of the goitre (‘block and replacement treatment’).

Surgery

In diffuse toxic goitre and toxic nodular goitre with overactive inter nodular tissue, surgery cures by reducing the mass of overactive tissue. Cure is probable if the thyroid tissue can be reduced below a critical mass. This may result in a reduction of TsAb or it may be that circulating TsAb, however high its level, can only produce limited hypertrophy and hyperplasia when the mass of thyroid tissue is small. In the autonomous toxic nodule, and in toxic nodular goitre with overactive autonomous toxic nodules, surgery cures by removing all of the overactive thyroid tissue: this allows the suppressed normal tissue to function again.

Advantages

The goitre is removed, the cure is rapid and the cure rate is high if surgery has been adequate.

Disadvantages

• Recurrence of thyrotoxicosis occurs in approximately 5 per cent of cases.  

• Every operation carries a morbidity but with suitable preparation and an experienced surgeon the mortality is negligible.  

• Postoperative thyroid insufficiency occurs in 20—45 per cent of cases.  

• Long-term follow-up is highly desirable as the few patients who develop recurrence may do so at any time in the future. In addition, although it is usually apparent within a year or two, thyroid failure may also he a late development.  

• Parathyroid insufficiency: this should he permanent in less than 0.5 per cent.

Radioiodine

Radioiodine destroys thyroid cells and, as in thyroidectomy, reduces the mass of functioning thyroid tissue to below a critical level.

Advantages

No surgery and no prolonged drug therapy.

Disadvantages

• Isotope facilities must be available.  

• There is a high and progressive incidence of thyroid insufficiency which may reach 75—80 per cent after 10 years. This is due to sublethal damage to those cells not actually destroyed by the initial treatment and this eventually causes failure of cellular reproduction.  

• Indefinite follow-up is essential.

There is no convincing evidence that radioiodine has been responsible for genetic damage, leukaemia, damage to the foetus if given inadvertently in early pregnancy, or carcinoma in the adult. In some clinics, radioiodine is given to almost all patients over the age of 25, i.e. when development is complete. Follow-up requirements are reduced if a total ablative dose of radioiodine is administered followed by routine replacement treatment with thyroxine. In the UK, reluctance to prescribe radioiodine under the age of 45 has faded. The dose of radioiodine varies between 300 and 600 MBq. Response is slow, but a substantial improvement is to he expected in 8—12 weeks. Accurate dosage is difficult and, should there be no clinical improvement after 12 weeks, a further dose is given. Two or more doses are necessary in 20—3 0 per cent of cases.

Choice of therapeutic agent

Each case must be considered individually. Below are listed guiding principles on the most satisfactory treatment for a particular toxic goitre at a particular age: these must however be modified according to the facilities available and the personality, intelligence and wishes of the individual patient, business or family commitments and any other coexistent medical or surgical condition.

Diffuse toxic goitre

Over 45: radioiodine. Under 45: surgery for the large goitre, antithyroid drugs for the small goitre. As mentioned above, radioiodine is being increasingly used in younger patients, particularly when their families are complete.

Large goitres are uncomfortable and remission with antithyroid drugs is less likely than in the small goitre.

Toxic nodular goitre

Surgery. Toxic nodular goitre does not respond as well or as rapidly to radioiodine or antithyroid drugs as does a diffuse toxic goitre, and the
goitre itself is often large and uncomfortable and enlarges still further with antithyroid drugs.

**Toxic nodule**

Surgery or radioiodine. Resection is easy, certain and without morbidity. Radioiodine is a good alternative over the age of 45 because the suppressed thyroid tissue does not take up iodine and there is thus no risk of delayed thyroid insufficiency.

**Recurrent thyrotoxicosis after surgery**

In general radioiodine, but antithyroid drugs may be used in young women intending to have children. Further surgery has no place.

**Failure of previous treatment with antithyroid** drugs or radioiodine. Surgery or thyroid ablation with 

unintelligent patients cannot be trusted to take drugs regularly if they feel well, and are unlikely to attend follow-up clinics indefinitely, which is essential after radioiodine or surgical therapy.

**Special problems in treatment**

**Pregnancy.** Radioiodine is absolutely contraindicated because of the risk to the foetus. The danger of surgery is miscarriage; and that of anti-thyroid drugs is of inducing thyroid insufficiency in the mother, and because both TSH and antithyroid drugs cross the placenta, of the baby being born goitrous (Fig. 44.28) and hypothyroid. The risk of either surgery in the second trimester, in competent hands, or careful estimation of antithyroid drugs, is very small and the choice is exactly as in the uncomplicated case.

**Postpartum hyperthyroidism.** Pregnancy may lead to an exacerbation of a variety of autoimmune diseases in the postpartum period. Postpartum hyperthyroidism may be a problem in a patient previously diagnosed with hyperthyroidism or may occur in a patient without any previous history of thyroid disease.

**Children.** Radioiodine is contraindicated because of the theoretical risk of inducing thyroid carcinoma. There is an increased risk of recurrence after thyroidectomy because thyroid cells are highly active in the young. Children and adolescents should be treated with antithyroid drugs until the late teens, failing which total or near-total thyroidectomy by an expert surgeon should be undertaken.

**Thyrotoxic cardiac.** This is a patient with severe cardiac damage due wholly or partly to hyperthyroidism. The patient is usually middle aged or elderly with secondary thyrotoxicosis and the hyperthyroidism is not very severe. The cardiac condition is far more significant than the hyperthyroidism, but this must be rapidly controlled to prevent further cardiac damage. Betablockade (propranolol) can assist rapid control of cardiac effects.

Radioiodine is the treatment of choice together with antithyroid drugs started either before or after and continued until the radioiodine has had an effect (usually 6 weeks).

**High titres of thyroid antibodies.** Their presence indicates lymphatic infiltration of the goitre, i.e. a diffuse or focal thyroiditis, and a liability to spontaneous remission.

These patients are best treated conservatively but if medical treatment fails, definitive treatment by operation or radioiodine is not contra-indicated. Steroids may help to reduce pain and swelling.

**Proptosis of recent onset.** There is a conventional view that to termi-nate thyrotoxicosis abruptly by thyroidectomy or radioiodine when proptosis is recent may induce malignant exophthalmos. Whilst there is no real proof of this it is reasonable to treat these patients with anti-thyroid drugs until the proptosis has been static for 6 months.

**Hyperthyroidism due to other causes**

**Thyrotoxicosis factitia.** (Usually seen in health ‘cranks’ or those given thyroid extract as ‘a tonic’.) Hyperthyroidism may be induced by taking thyroxine, but only if the dosage exceeds the normal requirements of 0.15—0.25 mg a day. Doses below the normal requirements simply suppress normal hormone production by the thyroid. cretinism

**Jod-Basedow thyrotoxicosis.** (Jod =German for iodine= Basedow. In European countries diffuse toxic goitre is often called Basedow’s disease.) Large doses of iodide given to a hyperplastic endemic goitre which is iodine avid may producetemporary hyperthyroidism, and very occasionally persistent hyperthyroidism.

In sub acute or acute forms of autoimmune thyroiditis or de Quervain’s thyroiditis (see later), mild hyperthyroidism mayoccur in the early stages due to liberation of thyroid hormones from damaged tissue.

**A large mass of secondary carcinoma** will rarely produce sufficient hormone to induce mild hyperthyroidism.

**Neonatal thyrotoxicosis** occurs inbabies born to hyperthyroid mothers or to euthyroid mothers whohave had thyrotoxicosis. High TsAb titres are present in both motherand child because TsAb can cross the placental barrier. The hyperthyroidism gradually subsides after 3—4 weeks’ time as the TsAb titres fall in the baby’s serum.

**Surgery for thyrotoxicosis**

**Preoperative preparation** (Fig. 44.30)

Traditional preparation aims to make the patient euthyroid or near euthyroid at operation. The thyrotoxic state istetermined byclinical assessment, i.e. by improvement in previous symptoms and by objective signs such as gain in weight and lowering of the pulse rate, and by serial estimations of the thyroid profile.

Preparation is as an out-patient and only rarely is admis-sion to hospital necessary on account ofsevere symptoms at presentation or failure to controlthe hyperthyroidism. Failure to control with antithyroid drugs is unusual but may bedue to uneven dosage.i.e. not taking the drug at 6- or 8-hourly intervals.

Carbimazole 30—40 mg a day is the drug of choice for preparation. When euthyroid — after 8—12 weeks— the dose may be reduced...
mg 8-hourly and the addition of thyroxine may facilitate maintenance of the euthyroid state. The last dose of carbimazole may be given on the evening before surgery. Iodides are not used alone because, if the patient needs preoperative treatment, a more effective drug should be given. Iodides may be given with carbimazole for 10—14 days immediately before operation but their use is of doubtful value and has been given up in many centres.

An alternative method of preparation that appears to be safe is to abolish the clinical manifestations of the toxic state, using beta-blocking drugs. This results in very rapid control and operation may be arranged within a week or two. The appropriate drugs are propranolol 40 mg three times daily or, preferably, the longer acting nadolol 160 mg once daily. Clinical response to beta-blockade is rapid and the patient may be reassessed within days; if clinically euthyroid, an operation date may be arranged; if not, the dose of beta-blocker is increased with early reassessment. Quite often larger doses are necessary.

Beta-blockers act on the target organs and not on the gland itself. Propranolol inhibits the peripheral conversion of 14 to 13. Long-acting betablockers, e.g. nadolol, are now also available and are administered once daily. They do not interfere with synthesis of thyroid hormones, so that hormone levels remain high during treatment and for some days after thyroidectomy. It is, therefore, important to continue to give the drug for 7 days postoperatively.

The addition of iodine for 10 days before operation gives an additional measure of safety in case the early morning dose of beta-blocker on the day of operation is mistakenly omitted (Plummer).

Propranolol or nadolol control symptoms very rapidly and have additional value in combination with carbimazole in the immediate treatment of patients with very severe hyper-thyroidism.

Subtotal thyroidectomy

Preoperative investigations to be carried out and recorded are:

- thyroid function tests;
- indirect laryngoscopy — it is a matter for local protocols whether this is routine. The outcome should have little impact on the operation because every recurrent laryngeal nerve must be routinely and obsessionally preserved;
- thyroid antibodies;
- serum calcium estimation;

an isotope scan before preoperative preparation is necessary in patients with toxic nodular goitre if total thyroidectomy is not planned. The surgeon should know which nodules, if any, are autonomous and active in order to ensure their resection. A scan is of no value in diffuse toxic goitre when uptake, for practical purposes, is uniform. The diagnosis of a single toxic nodule can only be made by demonstrating that the nodule is active and the remaining thyroid tissue suppressed.

The extent of the resection depends on the size of the gland, the age of the patient, the experience of the surgeon, the need to minimise the risk of recurrent toxicity and the wish to avoid postoperative thyroid replacement. Thus young patients with small glands are at greatest risk of recurrence even with very small remnant sizes. There is an increasing trend towards total thyroidectomy which simplifies subsequent management and rapidly achieves a perma-nent euthyroid state on thyroxine replacement. In contrast, a patient with a large goitre who wishes to avoid postoperative medication is suitable for subtotal thyroidectomy.

Technique. General anaesthesia is administered through an endotracheal tube and good muscle relaxation obtained. The patient is supine on the operating table with the table tilted 15 degrees at the head end to reduce venous engorgement. A sandbag is placed transversely under the shoulders and the neck extended (with care particularly in the elderly) to make the thyroid gland more prominent. A skin crease incision is made midway between the notch of the thyroid cartilage and the suprasternal notch. Flaps of skin, subcutaneous tissue and platysma are raised upwards to the superior thyroid notch and downwards to the suprasternal notch. The deep cervical fascia is divided in the midline between the sternothyroid muscles down to the plane of the thyroid capsule. The muscles are not divided as a routine but may be if greater exposure is required. The sternothyroid muscle is mobilised off the thyroid lobes. In 30 per cent of patients, middle thyroid veins passing directly into the internal jugular vein require ligation and division. The main blood supply is the superior thyroid artery which must be ligated securely. The lobe is then free to rotate out of its bed. The inferior thyroid arteries are not routinely ligated to preserve parathyroid blood supply. The recurrent laryngeal nerve should be identified in its course in the operative field. It should first be sought below the level of the inferior thyroid artery as it passes obliquely upwards and forwards. This course (Fig. 44.31), oblique to the trachea and oesophagus, is accentuated by mobilisation of the thyroid lobe. If not immediately seen, the nerve can usually be palpated as a taut strand. At a higher level the nerve lies between the branches of the inferior thyroid artery. The nerve passes into the larynx immediately behind the inferior eur of the thyroid cartilage which is therefore a very important landmark. If the right nerve cannot be found in its usual course, an anomalous (noncurrent) nerve, present in 1 per cent of cases, should be suspected; this arises from the vagus trunk and usually passes from behind the carotid sheath, curving medially, forwards and upwards, and may be mistaken for the inferior thyroid artery. The parathyroid glands are protected by identification on careful inspection of the goitre before resection and by avoiding ligatures and sutures close to the hilum of identified glands. The use of diathermy in this area should be avoided as heat conduction may devascularise the parathyroids or damage the recurrent laryngeal nerves (Fig. 44.12). If a parathyroid gland is inadvertently excised or devascularised, it should be autotransplanted in several fragments within the sternomastoid muscle. Subtotal resection of each lobe is carried out, leaving a remnant of between 4 and 5 g on each side. Absolute haemostasis is secured by ligation of individual vessels and by suture of the thyroid remnants to the tracheal fascia. The pretracheal muscles and cervical fascia are sutured and the wound is closed with or without suction drainage to the deep cervical space.

Postoperative complications

Haemorrhage. A tension haematoma deep to the cervical fascia (Fig. 44.33) is usually due to slipping of a ligature on the superior thyroid artery: occasionally haemorrhage from a thyroid remnant or a thyroid vein may be responsible. It may, on rare occasions, be necessary to re open the wound in the ward to relieve tension before the patient to theatre to evacuate the haematoma and to tie off a bleeding vessel.

A small subcutaneous haematoma or collection of serum may form under the skin flaps and should be evacuated or aspirated in the following 72 hours. This should not be confused with the potentially life-threatening deep tension haematoma.

Respiratory obstruction. This is very rarely due to collapse or kinking of the trachea. Most cases are due to laryngeal oedema. The most important cause of laryngeal oedema is a tension haematoma. However, trauma to the larynx by anaesthetic intubation and surgical manipulation is an important contributory factors — particularly if the goitre is very vascular — and may cause laryngeal oedema without a
The incidence of thyroid failure is much lower amid that disease refer to UK experience arid may be different elsewhere in the world. In iceland, for example, an area of high dietary iodine intake, the attendances at the thyroid clinic.

Such systems in Scotland and Wales have been shown to be extremely cost-effective and dramatically reduce the number of patient time after operation. Follow-up should therefore he for life.

Even when there are clinical features of failure, thyroxine should he withheld if possible during the first 6 months. Most patients who indication for treatment during the first year as the majority of patients with early subclinical failure, which is common, ultimately regains normality. To screen for parathyroid insufficiency, the serum calcium should be measured at the first review attendance 4—6 weeks after operation.

Indirect laryngoscopy has been advised as a routine before leaving hospital. Alternatively, it may he avoided when the voice is normal and the endotracheal tube can he left in place for several days; steroids are given to reduce oedema and a tracheostomy is rarely necessary. Intubation in the presence of laryngeal oedema may be very difficult and should be carried out by an experienced anaesthetist; repeated unsuccessful attempts may increase obstruction and cause serious cerebral anoxia (Wade). In an emergency, its far safer for the inexperienced surgeon to perform a needle tracheostomy as a temporary measure; a Medicut 12G needle (diameter 2.3 mm) is highly satisfactory.

Recurrent laryngeal nerve paralysis may be unilateral or bilateral, transient or permanent (Chapter 43). Transient paralysis occurs in about 3 per cent of nerves at risk and recovers in 3 weeks to 3 months. Permanent paralysis is extremely rare if the nerve has been identified at operation.

Thyroid insufficiency. This usually occurs within 2 years, but it is sometimes delayed for 5 years or more. It is often insidious and difficult to recognise. The incidence is considerably higher than used to be thought and figures of 20—45 per cent have been reported after operations on diffuse toxic goitres and toxic nodular goitres with intermodular hyperplasia. It represents a change in the autoimmune response from stimulation to destruction of thyroid cells. There is, however, a definite relationship between the estimated weight of the thyroid remnant and the development of thyroid failure after subtotal thyroidectomy for Graves’ disease. Thyroid insufficiency is rare after surgery for a toxic adenoma because there is no autoimmune disease present.

Parathyroid insufficiency is due to removal of parathyroid glands, or infarction through damage to the parathyroid end-artery; often both factors occur together. Vascular injury is probably far more important than inadvertent removal. The incidence of this condition should be less than 0.5 per cent and most cases present dramatically 2—5 days after operation, but very rarely the onset is delayed for 2—3 weeks or a patient with marked hypocalcemia is asymptomatic.

Thyrotoxic crisis (storm) is an acute exacerbation of hyperthyroidism. It occurs if a thyrotoxic patient has been inadequately prepared for thyroidectomy, and is now extremely rare. Very rarely, a thyrotoxic patient presents in a crisis amid this may follow an unrelated operation. Symptomatic and supportive treatment is for dehydration, hyperpyrexia and restlessness. This requires the administration of intravenous fluids, cooling the patient with ice packs, administration of oxygen, diuretics for cardiac failure, digoxin for uncontrolled atrial fibrillation, sedation and intra-venous hydrocortisone. Specific treatment is by carbimazole 10—20 mg 6-hourly, Lugol’s iodine 10 drops 8-hourly by mouth or sodium iodide 1 g intravenously (i.v.). Propranolol 40 mg 6-hourly orally will block adverse beta-adrenergic effects. This agent may be given by careful intravenous administration (1—2 mg) under precise electrocardiographic control.

Wound infection. A subcutaneous or deep cervical abscess should he drained.

Hypertrophic or keloid scar is more likely to form if the incision overlies the sternum. Intradermal injections (If corticosteroid should he given at once and repeated monthly if necessary.

Stitch granuloma. This may occur with or without sinus formation and is seen after the use of nonabsorbable suture material. Absorbable ligatures and sutures must be used throughout thyroid surgery. Some surgeons use a subcuticular absorbable skin suture rather than the traditional skin clips or staples. Skin staples should be removed in less than 48 hours.

Postoperative care

Indirect laryngoscopy has been advised as a routine before leaving hospital. Alternatively, it may be avoided when the voice is normal and the cough occlusive. About 25 per cent of patients develop transient hypocalcaemia and, if associated symptoms are severe, intravenous calcium gluconate or oral calcium may be necessary, although this is unusual. To screen for parathyroid insufficiency, the serum calcium should be measured at the first review attendance 4—6 weeks after operation.

After operation, stability in terms of thyroid function takes time. It is important that biochemical (subclinical) thyroid failure should not he aim indication for treatment during the first year as the majority of patients with early subclinical failure, which is common, ultimately regains normality. Even when there are clinical features of failure, thyroxine should he withheld if possible during the first 6 months. Most patients who develop thyroid failure do so within the first 2 years, but there is a continuing incidence thereafter. Recurrent thyrotoxicosis may occur at any time after operation. Follow-up should therefore he for life.

Once a stable situation has been achieved, follow-up after thyroid surgery may be carried out by an automated computer-activated system. Such systems in Scotland and Wales have been shown to be extremely cost-effective and dramatically reduce the number of patient attendances at the thyroid clinic.

The incidences quoted for thyroid failure (20—45 per cent) and recurrent thyrotoxicosis (5 per cent) after subtotal thyroidectomy for Graves’ disease refer to UK experience and may be different elsewhere in the world. In iceland, for example, an area of high dietary iodine intake, the incidence of thyroid failure is much lower amid that of recurrent toxicity much higher than in the UK.
Neoplasms of the thyroid

Thyroid neoplasms are classified in Table 44.5.

Benign tumours

Follicular adenomas present as clinically solitary nodules and the distinction between a follicular carcinoma and an adenoma can only be made by histological examination: in the adenoma there is no invasion of the capsule or of pericapsular blood vessels. Treatment is, therefore, by wide excision —preferably a lobectomy. The remaining thyroid tissue is normal so that prolonged follow-up is unnecessary. It is doubtful whether there is such an entity as a papillary adenoma and all papillary tumours should be considered as malignant even if encapsulated.

Malignant tumours

The vast majority of primary growths is carcinomas (Table 44.6). Dunhill classified them histologically as differentiated and undifferentiated: and the differentiated carcinomas are now subdivided into follicular and papillary. Secondary growths are rare but blood-borne metastases occur (Figs 44.34 and 44.35). Blood-borne metastases more usually occur from primary carcinomas of breast, colon and kidney and from melanomas.

Aetiology of malignant thyroid tumours

Differentiated thyroid carcinoma, particularly papillary, frequently follows accidental irradiation of the thyroid in childhood. The incidence of follicular carcinoma is high in endemic goitrous areas, possibly owing to TSH stimulation. Malignant lymphomas can present in a patient known to have autoimmune thyroiditis, so that the lymphocytic infiltration in the autoimmune process may be an aetiological factor. Indeed, it is likely that all lymphomas of the thyroid arise in glands affected by such thyroiditis.

Clinical features of thyroid neoplasms

The annual incidence is about 3.7 per 100,000 of the population and the sex ratio is three females to one male. The mortality should only be of the order of 2—3 per cent. The commonest presenting symptom is a thyroid swelling (Fig. 44.36) and a 5-year history is far from uncommon in indiffentiated growths. Enlarged cervical lymph nodes may be the presentation of papillary carcinoma. Recurrent laryngeal nerve paralysis may be a presenting feature of locally advanced disease.

Anaplastic growths are usually hard, irregular and infiltrating. A differentiated carcinoma may be suspiciously firm and irregular, but is often indistinguishable from a benign swelling. Small papillary tumours may be impalpable (occult carcinoma) — even when lymphatic metastases are present (so-called lateral aberrant thyroid). Pain, often referred to the ear, is frequent in infiltrating growths.

Diagnosis of thyroid neoplasms

Diagnosis is obvious on clinical examination in most cases of anaplastic carcinoma, although Riedel's thyroiditis (see later) is indistinguishable. The localised forms of granulomatous thyroiditis and lymphadenoid goitre may simulate carcinoma. It is not always easy to exclude a carcinoma in a multinodular goitre, and solitary nodules, particularly in the young male, are always suspect. Failure to take up radio-iodine is characteristic of almost all thyroid carcinomas [only very rarely will differentiated carcinoma (primary or secondary) take up 123I in the presence of normal thyroid tissue], but occurs also in degenerating nodules and all forms of thyroiditis. Thyroid antibody titres are often raised in carcinoma. The role of FNAC in preoperative diagnosis has already been discussed. No diagnostic test is absolutely certain, and exploration with excision in the form of lobectomy is essential when doubt. Incisional biopsy may cause seeding of cells and local recurrence, and is most inadvisable in an inoperable carcinoma. In an anaplastic and obviously inoperable carcinoma, however, incisional or needle biopsy is justified.

Papillary carcinoma

Most papillary tumours contain a mixture of papillary and colloid-filled follicles, and in some the follicular structure predominates. Nevertheless, if any papillary structure is present, the tumour will behave in a predictable fashion as a papillary carcinoma. Histologically the tumour shows papillary projections and characteristic pale, empty nuclei (Orphan Annie-eyed nuclei) (Fig. 44.37). Papillary carcinomas are very seldom encapsulated. Multiple foci may occur in the same lobe as the primary tumour or, less commonly, in both lobes. They may be due to lymphatic spread in the rich intrathyroidal lymph plexus, or to multicentric growth. Spread to the lymph nodes is common but blood-borne metastases are unusual unless the tumour is extrathyroidal. The term extrathyroidal indicates that the primary tumour has infiltrated through the capsule of the thyroid gland.

Occult carcinoma

Papillary carcinoma may present as an enlarged lymph node in the jugular chain with no palpable abnormality of the thyroid. The primary tumour may be no more than a few millimetres in size and is termed occult. Such primary foci of papillary carcinoma may also be discovered in thyroid tissue resected for other reasons, e.g. Graves' disease. The term occult is now applied to all papillary carcinomas less than 1.5 cm in diameter. These have an excellent prognosis and are regarded as of little clinical significance.

Follicular carcinoma

These appear to be macroscopically encapsulated but microscopically there is invasion of the capsule and of the vascular spaces in the capsular region (Fig. 44.38). Multiple foci are seldom seen and lymph node involvement is much less common than in papillary carcinoma. Blood-borne metastases are almost twice as common and the eventual mortality rate is twice as high (Fig. 44.39). Hurthle cell tumours are a variant of follicular neoplasm in which oxyphil (Hurthle, Askanazy) cells predominate histologically. It is doubtful whether Hurthle cell neoplasms are ever benign and they may be associated with a poorer prognosis.

Differences between papillary and follicular carcinoma

The major differences between papillary (including mixed papillary and follicular) and follicular carcinoma have been set out by Cady on the basis of an analysis of 40 years’ experience at the Lahey Clinic (Table 44.7).

Prognosis in differentiated thyroid carcinoma

The prognosis of differentiated thyroid carcinoma, although influenced by histological type, is much more dependent on age, the presence of
extrathyroidal spread or major capsular transgression (in follicular carcinoma), and the size of the tumour. Recently, several scoring systems based on multi-factorial analysis of risk factors from retrospectively gathered data have been devised. On the basis of age, tumour spread, size and histology, these allow separation of patients into low- and high-risk groups with 25-year mortality rates of 2 per cent and 46 per cent, respectively. With regard to age, the prognosis is much worse in males over the age of 40 years and in females over 50 years. Distant metastatic disease is obviously an adverse prognostic factor but lymph node metastases are not associated with worse prognosis. Definitions of low- and high-risk groups based on data from the Lahey Clinic are given in Table 44.8.

Patients in the low-risk group account for 90 per cent of cases of differentiated thyroid carcinoma.

**Surgical treatment**

There is continuing disagreement on the most appropriate operation for differentiated thyroid carcinoma. The con-serve approach advocates lobectomy with isthmusectomy in most patients with total thyroidectomy reserved for specific indications (viz, those with bilateral disease or judged to be in a high-risk category). The more radical approach advocates routine total thyroidectomy often as a staged procedure depending on the pathological findings of the initial lobectomy.

The case for a policy of total thyroidectomy is theoretically based on the prevalence of multifocality in papillary carci-noma and on the feasibility thereafter of using radioiodine scanning to detect metastases, the thyroid having been ablated (Fig. 44.40). However, the clinical significance of multifocality is low as local recurrence is infrequent after unilateral resection. In addition, in those selected patients in whom scanning may be indicated, the remaining thyroid tissue may be ablated safely with a preliminary dose of radioiodine. Most importantly there is no evidence that the long-term results of routine total thyroidectomy as a policy are better than those of more conservative operations, and there is a substantial risk of permanent hypoparathyroidism. Clearly the risk of parathyroid damage varies according to expertise and the frequency with which the operation is done but, even at the Mayo Clinic, where thyroid surgery is frequently and expertly done, the rate of hypoparathyroidism is significant (Hay).

The large majority of patients with differentiated carci-noma, particularly since 90 per cent fall into a group with a 2 per cent mortality rate, is appropriately treated by lobectomy with isthmusectomy on the affected side. At the same time clinically obvious nodes, which may be paratracheal, peritracheal or in the jugular chain, are removed. If the jugular nodes are extensively involved in tracheal or in the jugular chain, they are removed. These are removed. It is unnecessary to remove the main trunks of the inferior thyroid arteries. Instead, the individual arterial branches supplying the thyroid gland should be ligated close to the thyroid, preserving the parathyroid blood supply. The recurrent laryngeal nerve is carefully exposed throughout the dissection. It is particularly vulnerable close to where it angulates posteriorly to enter the larynx, at which site it is intimately related to the lateral thyroid ligament (ligament of Berry).

When there is clinically obvious bilateral disease at operation, bilateral resection is clearly indicated and bilateral resection may also be indicated in the few patients classified as high risk, although the evidence at present for improved prognosis is rather weak. Retrospective analysis of outcome in 860 patients with papillary carcinoma treated at the Mayo Clinic between 1946 and 1970 showed improved survival in high-risk patients undergoing bilateral resection, compared with lobectomy alone, although the difference was not statistically significant (Hay). There was no advantage for total compared with near-total thyroideectomy in which 1—2 g of thyroid tissue is preserved on the contralateral side to protect the blood supply to one or more parathyroid glands.

**Surgical operations**

**Isthmusectomy.** Swellings confined to the thyroid isthmus, including small differentiated carcinomas, may be appropriately removed by resec-tion of the isthmus alone. Isthmusectomy is also an effective method of relieving tracheal obstruction and obtaining tissue for diagnosis in anaplastic carcinoma and lymphoma.

**Thyroid lobectomy.** Total lobectomy on the affected side together with isthmusectomy is the appropriate operation for removal of a dis-crete thyroid swelling and for most patients with differentiated carci-noma. The procedure, if performed meticulously by an experienced surgeon, is associated with very little risk of postoperative complications such as recurrent laryngeal nerve injury. The parathyroid glands should be seen and preserved in situ if possible; although the intact glands on the contralateral side will ensure normal function, removal of the contralateral lobes may occasionally be necessary in the future. It is unnecessary to ligate the main trunks of the inferior thyroid arteries. Instead, the individual arterial branches supplying the thyroid gland should be ligated close to the thyroid, preserving the parathyroid blood supply. The recurrent laryngeal nerve is carefully exposed throughout the dissection. It is particularly vulnerable close to where it angulates posteriorly to enter the larynx, at which site it is intimately related to the lateral thyroid ligament (ligament of Berry).

**Near-total thyroidec-tomy.** This consists of total thyroid lobectomy on the affected side, with conservation of 1—2 g of thyroid tissue on the contralateral side, which preserves the blood supply to one or both parathyroids.

**Total thyroidec-tomy.** The technique is essentially that of bilateral lobectomy and, if meticulous, the risk of complications is very low except for permanent hypoparathyroidism. The risk of hypopara-thyroidism is variable but may be appreciable even in experienced hands.

**Additional measures**

**Thyroxine.** It is standard practice to prescribe thyroxine in a dose of 0.1—0.2 mg daily, to suppress endogenous TSH production, for all patients after operation for differentiated thyroid carcinoma on the basis that some tumours are TSH dependent. Suppression of the TSH level should be confirmed by measurement. Failure of suppression to a level of <0.1 IU/litre may indicate an inadequate dose of thyroxine or more usually that the patient is noncompliant. However, suppressive thyroxine is probably not of value in follicular carcinoma, and is unlikely to be of benefit in low-risk patients treated by lobectomy. Thyroid hormone replacement is obviously necessary after total thyroidectomy and in the majority of patients after near-total thyroidec-tomy, and is usually given in the form of thyroxine. Patients with potential or actual distant metastases who may require repeated radioiodine administration for scanning and therapy should be given triiodothyronine (60—80 mg/day) because it is much shorter acting, and on stopping it, increased TSH secretion and thyroid avidity for iodine recover quickly so that radioiodine may be given after several days. The patient is thereby spared weeks of developing thyroid insufficiency after stopping thyroxine before radioiodine may be given.

**Radioiodine.** If metastases take up radioiodine they may be detected by scanning and may be treated with large doses of radioiodine. For effective scanning, all thyroid tissue must have been ablated by either surgery or preliminary radioiodine and the patient must be hypothyroid to improve uptake. The indications for scanning after operations for differentiated carcinoma are disputed, but it is probably only indicated in patients with unresctable local recurrence or metastatic disease, high-risk patients, and in those with a rising serum thyroglobulin level. In addition, if metastases take up radioiodine they are likely to be suppressed as effectively by treatment with thyroxine as by radioiodine. Cases in which suppression has failed and radioiodine has given permanent control appear to be uncommon.

If metastases have been treated, the scan should be repeated at annual intervals and further therapeutic doses of radioiodine given as
necessary. Solitary distant metastases may be treated by external radiotherapy.

**Thyroglobulin.** The measurement of serum thyroglobulin is of value in the follow-up and in the detection of metastatic disease in patients who have undergone surgery for differentiated thyroid cancer. This measurement may obviate the need for serial radioactive iodine scanning but when a rise occurs, a scan will be indicated to confirm and locate the metastatic disease. Thyroglobulin levels are, however, only an adjunct to careful clinical palpation of the neck because local recurrence detectable clinically may be present with a low thyroglobulin.

**Undifferentiated (ana plastic) carcinoma**

This occurs mainly in elderly women and is much less often diagnosed now than in the past when many thyroid lymphomas were mistakenly classified histologically as anaplastic carcinomas. Local infiltration is an early feature of these tumours with spread by lymphatics and by the bloodstream. They are extremely lethal tumours and survival for more than 1—2 years after presentation is most unusual. In most cases death occurs within months rather than within years. An attempt at curative resection is only justified if there is no infiltration through the thyroid capsule and no evidence of metastases. Many of these aggressive lesions present in an advanced stage with tracheal obstruction and require urgent tracheal decompression. The trachea may be decompressed and tissue obtained for histology by isthmusectomy. Tracheo-stomy is best avoided. Radiotherapy should be given in all cases and may provide a worthwhile period of palliation as may combination chemotherapy [including doxorubicin (Adriamycin)].

**Medullary carcinoma**

These are tumours of the parafollicular (C)-cells derived from the neural crest and not from the cells of the thyroid follicle as are other primary thyroid carcinomas. The cells are not unlike those of a carcinoid tumour and there is a characteristic amyloid stroma (Fig. 44.41). High levels of serum calcitonin (>0.08 ng/ml) are produced by many medullarv tumours. These levels fall after resection of a tumour and will rise again if the tumour recurs. This is a valuable tumour marker in the follow-up of patients with this disease. Diarrhoea is a feature in 30 per cent of cases and this may be due to 5-hydroxytryptamine or prostaglandins produced by the tumour cells.

Some tumours are familial and may account for 10—20 per cent of all cases. Medullary carcinoma may occur in combination with adrenal phaeochromocytoma and hyper-parathyroidism (usually due to hyperplasia) in the syndrome known as multiple endocrine neoplasia type ha (MEN IIa). The familial form of the disease frequently affects children and young adults whereas the sporadic cases occur at any age with no sex predominance. When the familial form is associated with prominent mucosal neuromas involving the lips, tongue (Fig. 44.42) and inner aspect of the eyelids, with occasionally a Marfanoid habitus, the syndrome is referred to as MEN type Iib.

Involvement of lymph nodes occurs in 50—60 per cent of cases of medullary carcinoma and blood-borne metastases are common. As would be expected, tumours are not hormone dependent and do not take up radioactive iodine. The course of the tumour is unpredictable; in general, life expectancy is excellent if the tumour is confined to the thyroid gland, good as long as metastases are confined to the cervical lymph nodes and poor once blood-borne metastases are present.

Treatment is by total thyroidectomy and resection of involved lymph nodes with either a radical or modified radical neck dissection. Familial cases are now detected by genetic screening for the RET oncogene mutations which identifies individuals who will develop medullary cancer later in life (Fig. 44.43). The genetic tests are supplemented by estimating serum calcitonin levels in the basal state and after stimulation by either calcium or pentagastrin. A rise in calcitonin levels under these circumstances should lead to a prophylactic thyroidectomy but even then the disease may be beyond the preinvasive C-cell hyperplasia stage (Fig. 44.44).

Phaeochromocytoma must be excluded by measurement of urinary catecholamine levels (Chapter 45) in all cases before embarking upon thyroid surgery to avoid the potential hazards associated with this condition.

**Malignant lymphoma**

In the past, many malignant lymphomas were diagnosed as small round-cell anaplastic carcinomas. Response to irradiation is good (Fig. 44.45) and radical surgery is unnecessary once the diagnosis is established by biopsy. Although the diagnosis may be made or suspected on FNAC, sufficient material is seldom available for immunocytochemical classification, and large-needle (Trucut) or open biopsy is usually necessary. In patients with tracheal compression, isthmusectomy is the most appropriate form of biopsy. The prognosis is good if there is no involvement of cervical lymph nodes. Rarely the tumour is part of widespread malignant lymphoma disease, and the prognosis in these cases is worse.
Thyroiditis

Chronic lymphocytic (autoimmune) thyroiditis

This common condition is usually associated with raised titres of thyroid antibodies. Not infrequently there is a family history of other autoimmune disease. It commonly presents as a multinodular goitre with established or subclinical thyroid failure, although it may present as a discrete swelling. Features of chronic lymphocytic (focal) thyroiditis are commonly present on histological examination in association with other thyroid disease — notably toxic goitre. Primary myxoedema without detectable thyroid enlargement represents the end stage of the pathological process.

Clinical features

As might be expected from the varied histological picture (above), the onset, the thyroid status and the type of goitre vary profoundly from case to case. The onset may be insidious and asymptomatic, or so sudden and painful that it resembles the acute form of granulomatous thyroiditis. Mild hyperthyroidism may be present initially, but hypothyroidism is inevitable and may develop rapidly or extremely slowly. The goitre is usually lobulated, and may be diffuse or localised to one lobe. It may be large or small, and soft, rubbery or firm in consistency — depending upon the cellularity and the degree of fibrosis. The disease is commonest in women at the menopause, but may occur at any age. Papillary carcinoma and malignant lymphoma are occasionally associated with autoimmune thyroiditis.

Diagnosis

Biochemical tests of thyroid function vary with the thyroid status and are of diagnostic value only if hypothyroidism is present. Significantly, raised titres of one or more thyroid antibodies are present in over 85 per cent of cases. Nevertheless, differential diagnosis from nodular goitre, carcinoma and malignant lymphoma of the thyroid is not always easy. FNAC is the most appropriate investigation although abundant lymphocytes may make the cytological distinction between autoimmune thyroiditis and lymphoma difficult (Fig. 44.46). When there is doubt about neoplastic disease, which may coexist with thyroiditis, operation is necessary.

Treatment

Full replacement dosage of thyroxine should be given for hypothyroidism and if the goitre is large or symptomatic, because some (under TSH stimulation) may subside with hormone therapy. More minor manifestations of the condition such as a small goitre with raised antibody titres, or histological evidence of thyroiditis in association with other thyroid disease, do not justify thyroxine replacement if thyroid function is biochemically normal; however, long-term surveillance is necessary because of the risk of late thyroid failure. Occasionally the goitre increases in spite of hormone treatment and in these circumstances there may be a favourable response to steroid therapy. Thyroidectomy may be necessary if the goitre is large and causes discomfort. The clinician must, however, be cautious when a lymphocytic goitre increases in size and becomes unresponsive to thyroxine as this may be due to the development of malignant lymphoma.

Granulomatous thyroiditis (subacute thyroiditis — de Quervain’s thyroiditis)

This is due to a virus infection. (An epidemic reported from Israel was due to a mumps virus.) In a typical subacute presentation there is pain in the neck, fever, malaise and a firm, irregular enlargement of one or both thyroid lobes. There is a raised erythrocyte sedimentation rate and absent thyroid antibodies, the serum T4 is high, normal or slightly raised, and the 123I uptake of the gland is low. The condition is self-limiting and in a few months the goitre has subsided; subsequent hypothyroidism is rare. Thirty-five per cent of cases are asymptomatic but for the presence of the goitre. If diagnosis is in doubt, it may be confirmed by FNAC, radioactive iodine uptake and by a rapid symptomatic response to prednisone. The specific treatment for the acute case with severe pain is to give prednisone 10—20 mg daily for 7 days and the dose is then gradually reduced over the next month.

Riedel’s thyroiditis

This is very rare, accounting for 0.5 per cent of goitres. Thyroid tissue is replaced by cellular fibrous tissue which infiltrates through the capsule into adjacent muscles, paratracheal connective tissue and the carotid sheaths. It may occur in association with retroperitoneal and mediastinal fibrosis and is most probably a collagen disease. The goitre may be unilateral or bilateral and is very hard and fixed. The differential diagnosis from anaplastic carcinoma can only be made with certainty by biopsy, when a wedge of the isthmus should also be removed to free the trachea. If unilateral, the other lobe is usually involved later and subsequent hypothyroidism is common.
Further reading

Parathyroid glands

**Anatomy.** The parathyroid glands, four in number, are small, oval in shape, commonly about 0.5 cm in size, soft, mobile, yellowish brown in colour and arranged in pairs — most often closely applied to the thyroid gland, either within or closely applied to its capsule. The upper pair is more constant in position than the lower: 80 per cent are found on the posterolateral aspect of the thyroid, immediately above the termination of the inferior thyroid artery, close to the cricothyroid articulation. Most of the remaining 20 per cent are posterolateral to the upper pole of the thyroid lobe. The lower pair is more variable in position: 40 per cent are found at the lower pole of the thyroid and 40 per cent are within the thymic tongue (Fig. 45.1). The remaining 20 per cent are variable in site, most often some distance lateral to the thyroid, and less often in the mediastinal thymus a few centimeters below the sternal notch or, very occasionally, ectopically situated near the carotid sheath, sometimes as high as the carotid bifurcation. Each gland has a delicate capsule and is supplied by a single leash of blood vessels clearly seen running in the subcapsular plane (Fig. 45.2). Very often, parathyroid glands are associated with or embedded within a pad of fat, which gives a useful clue to identification.

**Histology.** The stroma consists of a rich sinusoidal capillary network with islands of secretory cells interspersed with fat cells. The glandular cells are of two types. The ‘chief’ or ‘principal’ cells are small with vesicular nuclei and poorly staining cytoplasm. ‘Water-clear’ cells, derived from the chief cells, are found in hyperplastic and neoplastic glands. The ‘oxyphil’ cells are less numerous and larger, with granular cytoplasm and deeply staining nuclei.

**Physiology.** The chief cells of the parathyroids produce parathormone, the hormone being released directly into the bloodstream. The circulating level of parathormone can be measured by radioimmuno-assay, which is sufficiently reliable to distinguish between high and low levels. Facilities for obtaining the estimation are widely available.

**Parathormone:**

- stimulates osteoclastic activity, thereby increasing bone resorption by mobilizing calcium and phosphate;
- increases the reabsorption of calcium by the renal tubules, thus reducing the urinary excretion of calcium;
- augments the absorption of calcium from the gut;
- reduces the renal tubular reabsorption of phosphate, thus promoting phosphaturia.

Parathyroid hormone is an 84 amino acid peptide which has a short half-life before degradation into amino-terminal and carboxy-terminal fragments, with the amino-terminal fragment having biological activity. The amino-terminal fragment retains biological activity with a half-life of minutes and the carboxy-terminal fragment a half-life of hours. Available assays measure either the intact hormone, the amino- or carboxy-terminal or ‘mid-portion’ fragments.

**Calcitonin (Copp)** is secreted by the parafollicular cells of the thyroid (thyrocalcitonin). It lowers the serum calcium and affects calcium storage in bones; quite the opposite action of parathormone.

**Parathyroid hormone-related protein (PTH-rP)**

is a hypercalcaemic factor with similar bioactivity to that of parathyroid hormone. Since its isolation from cancer cell lines and carcinoma of the breast, strong evidence has emerged that it is an important hormonal mediator of cancer-associated hypercalcaemia in patients with solid tumours. Plasma PTH-rP 1—86 concentrations may be measured by a two-site immunoradiometric assay.
Hypoparathyroidism

Parathyroid tetany, due to hypocalcaemia, is a rare complication of subtotal thyroidectomy (less than 1 per cent) but a more common complication of total thyroidectomy. At these operations, some of the parathyroid glands may be removed or have their blood supply temporarily embarrassed. It may also occur after surgery to the parathyroids themselves. Symptoms usually appear on the second or third postoperative day, and are temporary. Milder forms of hypoparathyroidism have been described in the follow-up of thyroidectomised patients. Permanent hypoparathyroidism, most commonly encountered following radical thyroidectomy for cancer, requires constant supervision and treatment. Tetany in the newborn may occur within the first few days of life in the child born of a mother with undiagnosed hypoparathyroidism.

Spontaneous hypoparathyroidism is an unusual form of autoimmune disease.

Clinical features

The first symptoms are tingling and numbness in the face, fingers and toes. In extreme cases, cramps in the hands and feet are very painful; the extended fingers are flexed at their metacarpophalangeal joints, with the thumb strongly adducted; the toes are plantar-flexed and the ankle joints extended — the so-called carpopedal spasm. Spasm of the muscles of respiration results in not only pain and stridor, but also dread of suffocation. In infancy, the symptoms of tetany may be mistaken for epilepsy, although there is no loss of consciousness.

Latent tetany may be demonstrated by the following.

• Chvostek’s sign. Tapping over the branches of the facial nerve at the angle of the jaw will produce twitching at the corner of the mouth, the ala of the nose and the eyelids.

• Trousseau’s sign. A sphygmomanometer cuff applied to the arm and inflated above the systolic blood pressure for not more than 2 minutes will produce carpal spasm.

Treatment

In acute cases the symptoms may be relieved speedily by the slow intravenous injection of 10—20 ml of a 10 per cent solution of calcium gluconate. This may be repeated until the patient’s circulating calcium level has been stabilised. For longer-term management, the absorption of calcium is enhanced by oral administration of the most active metabolite of vitamin D — 1,25-dihydroxycholecalciferol \([1,25(\text{OH})_2\text{D}_3]\). Its major action is on the gut, promoting active absorption of calcium and phosphorus, raising calcium levels to normal within a week. Magnesium supplements may occasionally be needed. Serum calcium levels must be estimated daily and the dosage adjusted as appropriate.
Hyperparathyroidism

Hyperparathyroidism is a more common condition than had been previously believed

• The symptomatic presentation may vary but the increased use of auto analysers has resulted in ‘asymptomatic’ hypercalcaemic patients being the largest group.

• A corrected serum calcium concentration above the upper limit of normal and a simultaneous elevation of serum parathyroid hormone level are mandatory for the diagnosis.

• Surgery should only be performed by an experienced parathyroid surgeon.

Long-term follow-up is essential as there is a significant increase in risk of death from cardiovascular disease. Hyperparathyroidism is associated with an increased secretion of parathyroid hormone. This occurs in:

• **Primary hyperparathyroidism**, which is an unstimulated and inappropriately high parathyroid hormone secretion for the concentration of plasma ionised calcium, and is due to adenoma or hyperplasia, and very rarely carcinoma.

  A single adenoma is the commonest finding (multiple in 6 per cent). The whole gland is usually considerably enlarged, darker in colour, firmer and more vascular than normal; in some a rim of normal parathyroid tissue may be seen surrounding the adenoma. The histological appearances are the same as in hyperplasia, with a predominance of chief and water-clear cells. Carcinoma of the parathyroids is extremely rare, less than 1 per cent. It tends to invade locally and recur after operation. Blood-borne metastases have been described.

• **Secondary hyperparathyroidism** is associated with chronic renal failure or malabsorption syndromes. The stimulus for the hyperplasia is chronic hypocalcaemia. All four glands are involved.

• **Tertiary hyperparathyroidism** is a further stage in the development of reactive hyperplasia where autonomy occurs as the parathyroids no longer respond to physiological stimuli.

Clinical features

Hyperparathyroidism, rarely found in the first decade of life, is commoner in women than men, and most commonly found between the ages of 20 and 60 years. The clinical features vary enormously, even when the biochemical changes are similar.

**Asymptomatic cases**

The most common presentation is the detection of unsuspected and asymptomatic hypercalcaemia by routine biochemical screening.

*Bones, stones, abdominal groans and psychic moans’*

Only 50 per cent of patients suffer from any of these.

**Nonspecific symptoms**

Nonspecific symptoms include muscle weakness, thirst, polyuria, anorexia and weight loss — a challenge to the astute clinician!

**Bone disease**

There may be generalised decalcification of the skeleton, as in osteitis fibrosa cystica (von Recklinghausen’s disease), single or multiple cysts, or pseudotumours of any bone. The latter are particularly common in the jaw bones. Early radiological changes first appear in the skull and in the phalanges (Fig. 45.4), with loss of density and subperiosteal erosions. Many patients presenting with vague pains in the bones and joints are mistakenly diagnosed as rheumatic.

**Renal stones**

Hyperparathyroidism must be considered in every patient presenting with renal tract stone or nephrocalcinosis (Fig. 45.5), and even in those cases of renal colic where no stone can be demonstrated.

**Dyspeptic cases**

Patients with nausea, vomiting and anorexia are relatively common. Peptic ulcer and pancreatitis are not infrequently found in association with hyperparathyroidism, but the relationship is not as yet fully understood.

**Psychiatric cases**

Psychiatric cases are not uncommon; women, complaining of tiredness, listlessness and with obvious personality changes, are often wrongly labelled ‘neurotic’ or ‘menopausal’. Patients have been admitted to mental institutions because of irrational behaviour.

**Acute hyperparathyroidism**

This diagnosis is difficult and only too often made after death. Nausea and abdominal pain is followed by severe vomiting, dehydration, oliguria and finally coma. The serum calcium is very high. Treatment is urgent after rehydration, which is vital. Biphosphonates (disodium etidronate and pamidronate) are specific inhibitors of bone resorption. They are highly effective given parenterally and may also be used in the preoperative, short-term medical management of severe hypercalcaemia in primary hyperparathyroidism.

Clinical examination and investigation

Clinical examination may be unrewarding but the cause of dehydration or confusion may be found in the eyes. *Corneal calcification* may be detected. It begins on the lateral and medial borders of the limbus (which distinguishes it from arcus senilis) and is best seen through a hand lens by the light of a bright torch reflected off the iris. Less common is *band keratopathy* in which a transverse band of calcification forms across the front of the cornea, and *conjunctival calcification* where redness of the eye also occurs. Hypertension may be present in up to 50 per cent of cases. There may be electrocardiographic changes with a shortened QT interval, primarily by an effect on the length of the S—T
A parathyroid adenoma is very seldom palpable in the neck. The diagnosis is confirmed with the following biochemical findings:

- elevation of serum calcium (upper limit of normal 2.6 mmol/litre). Serum calcium occurs as calcium ions complexed to citrate and bound to albumin. Therefore the serum albumin concentration should be known in order to apply a correction factor: corrected serum calcium (mmol/litre) = measured serum Ca (mmol/litre) + (40 — A) x 0.02, where A = serum albumin (g/litre);

- diminution of serum phosphorus (lower limit of normal 0.8 mmol/litre);

- increased excretion of calcium in the urine (upper limit of normal 62 mmol per 24 hours for females, 75 mmol for males);

- elevation of the serum alkaline phosphatase in cases with bone disease;

- elevation of serum parathormone concentration.

The diagnosis of hyperparathyroidism largely depends on confirmed hypercalcaemia, exclusion of other causes of hypercalcaemia (see below) and a raised parathormone level. Present day immunoradiometric assays (upper limit of normal varies according to the laboratory) for biologically active intact parathormone are highly reliable and a raised level is even more reliable. Detectable levels of parathormone within the normal range, in the presence of hypercalcaemia, are suggestive of the diagnosis.

Preoperative localisation

Provided the surgeon is experienced in parathyroid surgery, preoperative localisation tests may do little to enhance the ability to detect 95 per cent of abnormal glands at surgery. However, a multimodal approach combining thallium—technetium isotope scanning, neck ultrasonography and magnetic resonance imaging (MRI) may yield precise information which will clearly facilitate surgery and reduce unnecessary dissection of tissue. Localisation tests are particularly indicated before re-exploration when the initial operation has failed, but may also be helpful to less experienced surgeons.

- The simplest localisation test is an ultrasonic scan but results vary according to the skill and experience of the investigator.

- Computerised tomography is of most value in localising a lesion in the mediastinum rather than the neck.

- Thallium—technetium isotope subtraction imaging may locate up to 90 per cent of parathyroid adenomas before surgery (Fig. 45.6). Like ultrasonography, subtraction scintigraphy is more accurate the larger the adenoma, and is inaccurate in parathyroid hyperplasia.

- MRI is improving rapidly with some centres reporting up to 64 per cent detection prospectively. A low signal is obtained from the parathyroid glands on a T1-weighted image while a T2-weighted image appears in early studies to produce good contrast resolution from the surrounding tissues.

- Invasive techniques such as selective angiography and selective venous sampling may be helpful in locating an abnormally situated gland after a failed initial exploration.

Differential diagnosis

Other causes of hypercalcaemia must be remembered and excluded. They are:

- secondary cancer in bone (breast, prostate, bronchus, kidney and thyroid);

- carcinoma with endocrine secretion (bronchus, kidney and ovary);

- multiple myeloma;

- vitamin D intoxication;

- sarcoidosis;

- thyrotoxicosis;

- immobilisation;

- medication: thiazide diuretics, lithium.

The differential diagnosis presents no problem if the parathormone level is estimated. In none of the above-mentioned conditions will parathormone be detectable in the blood.

Treatment

The only corrective treatment is surgical removal of the overactive gland or glands. In symptomatic patients, the indications for operation are clearcut. Many patients, however, in whom hypercalcaemia has been discovered incidentally, are not overtly symptomatic and a decision in favour of operation is more difficult.

Preoperative treatment is not usually necessary except in acute cases, when rapid correction of dehydration and electrolyte imbalance is necessary, with a careful daily check on the serum calcium. Drugs used would have been discussed earlier.

A recent international survey of operative strategy shows that the approach is changing. Removal of the adenoma with biopsy of the other glands has been supplanted by removal of the adenoma, a peroperative histological diagnosis and then biopsy of one normal gland. If the peroperative biopsy is that of a hyperplastic gland, then removal of all four glands with auto transplantation is indicated. Approximately 90 per cent of cases of primary hyperparathyroidism are associated with single-gland disease (adenoma). Ten per cent of cases are associated with multiple-gland disease, either hyperplasia or more than one adenoma. Adenomas, single or multiple, are removed.

In approximately 10 per cent of cases even the most experienced surgeon in this field may find difficulty in locating a parathyroid adenoma.

Parathyroid tissue can be successfully autotransplanted into the arm, a useful technique to avoid repeated potentially difficult explorations of
the neck. The indications are tertiary hyperparathyroidism in patients undergoing chronic renal dialysis, and recurrent hyperparathyroidism. The technique is to excise all of the parathyroid tissue from the neck and to implant eight 1-mm³ fragments into a pocket in the forearm muscle mass, marking the site with nonabsorbable sutures. Postoperative vitamin D and calcium replacement therapy is required for varying periods. Recurrent hypercalcaemia is an indication for exploration of the implantation site and to excise further parathyroid tissue.

Prognosis

With successful surgery in severe cases, bones will recalcify and pseudotumours resolve. Renal stones will not disappear, but the incidence of recurrence after surgical removal is reduced and deterioration in renal function is prevented. Psychiatric patients show an early and often remarkable recovery. Many patients who are not overtly symptomatic beforehand are aware of an improvement in well-being after correction of hypercalcaemia. In a small minority of cases, hyperparathyroidism recurs after several years and may warrant further surgery. In some of these, autotransplantation (above) offers reasonable prospects of control; Wells has reported excellent results when auto transplantation has been used for recurrent and familial hyperparathyroidism.

Hypertension associated with hyperparathyroidism is common, but the mechanism is unclear.

Long-term survival has been studied in 900 patients in Sweden. Despite successful surgery for primary hyperparathyroidism, the risk of premature death from cardiovascular and malignant diseases remained significant. Thus long-term follow-up is important as this indicates that primary hyperparathyroidism causes damage that is not reversed by surgery.

Patients with persistent and recurrent primary hyperparathyroidism are a difficult management problem. For patients in whom initial exploration fails, reoperation is associated with a higher morbidity and a greater chance of failure. Accurate diagnosis and review of the initial pathology are essential, a family history of multiple endocrine neoplasia should be excluded, together with occult malignancy. Preoperative venous sampling of the neck and thorax is particularly valuable in localising a missed adenoma which is the most common cause of failure at the first operation.

Mild asymptomatic hypercalcaemia is a relative contraindication to further surgery but regular follow-up is mandatory. With an experienced surgeon, up to 90 per cent of missed lesions may be found but persistent postoperative hypercalcaemia may occur in up to 10 per cent of patients and recurrent laryngeal nerve injury is seen in about 6 per cent.

Parathyroid carcinoma

Parathyroid carcinoma is a rare condition to be considered when a high serum calcium is associated with a palpable lump in the neck. At operation it has a characteristic grey—white colour and is adherent because of local invasion of adjacent soft tissue. The best results are obtained by early recognition, avoiding rupture of the tumour capsule, and aggressive surgical management including ipsilateral thyroid lobectomy. Surgical clips should be used to outline the tumour bed for postoperative radiotherapy.

Multiple endocrine neoplasia syndrome — APUD cells

Always consider that a patient with hyperparathyroidism may also have multiple endocrine adenomas. The cells involved, irrespective of the site, have the common chemical characteristics of amine precursor uptake and decarboxylation and are thus known as APUD cells. The disorder is inherited as an autosomal dominant, the manifestations in any one family tend to be similar and all members of the family should be investigated.

Type I

This most common variant involves the parathyroid glands (90 per cent), pancreatic islets (80 per cent), pituitary (65 per cent), thyroid and adrenal cortex. There is hyperplasia of the parathyroid glands and a chromophobe adenoma of the pituitary which may result in increased prolactin production or acromegaly. The pancreatic tumour may produce gastrin (the Zollinger—Ellison syndrome) or insulin, glucagon, somatostatin or vasoactive intestinal peptide (VIP) causing watery diarrhoea. Treatment is surgical excision.

Type Ila

A genetic abnormality located on chromosome 10 has been identified in MEN type ha syndrome. Fifty per cent have parathyroid hyperplasia. The associated lesions may be a medullary carcinoma of thyroid, which produces calcitonin, and a phaeochromocytoma. The latter should be excluded or be the first priority for treatment before exploration of the neck (see also Chapter 44).

Type IIb

This is differentiated from type Ila because of additional neurological abnormalities. Mucosal neuromas produce ‘lumpy and bumpy’ lips (Fig. 44.42) or eyelids, and there is a characteristic Marfanoid facial appearance. Megacolon and ganglioneuromatosis are also found (see also Chapter 44).
Adrenal glands

Surgical anatomy

At birth, the adrenal glands have attained nearly adult proportions. Fully developed, each weighs about 4 g, but the left is a little larger than the right. A deeper yellow colour and a firmer consistency enable the gland to be distinguished from the adjacent fat. Each rests on the superior, anterior and medial aspects of the superior pole of the corresponding kidney, and presents the appearance of a French Liberty cap worn at a rakish angle.

Although intimately related anatomically, the adrenal cortex and the adrenal medulla are quite separate internal secretory glands.

The adrenal glands are supplied by several adrenal arteries, rendering them remarkably vascular, but only one vein drains each gland. On the right side the adrenal vein is short and enters the inferior vena cava, while on the left it empties into the left renal vein [which communicates through the azygos vein with the left intercostal, internal mammary and vertebral veins (Anson)]. This dissimilarity of the right and left venous flow determines, to some extent, the location of metastases from malignant tumours of these glands.

Diagnostic investigations

Computerised tomography (CT) has been a significant advance in imaging the adrenal glands and in the detection of adrenal masses with an accuracy of 90 per cent (Fig. 45.7). Ultrasonography can detect most adrenal masses larger than 2 cm in diameter, but is operator and machine dependent and less accurate, especially in obese patients. CT has made invasive techniques, such as selective retrograde venography and selective arteriography, almost obsolete. In those cases where CT findings are inconclusive and functional information is required, isotope scanning (see below) and differential venous sampling for hormone levels may be indicated.

A radiograph or CT scan of the pituitary fossa showing an enlarged pituitary fossa is suggestive of a basophil adenomas of the pituitary gland with excess adrenocorticotropic hormone (ACTH) pituitary secretion.

Adrenal gland scintigraphy using NP-59 \(^{131}I-6\text{-iodomethyl-19Norchest-5(10)EN-3beta-ol}\) is of value in addition to CT. In a benign functioning adrenal tumour there is uptake with suppression of the contra lateral gland. By contrast adrenocortical carcinoma does not usually concentrate the isotope and, as a result of contra lateral gland suppression, there is little uptake. Bilateral adrenal hyperplasia produces the opposite result with a prominent bilateral image.

MR is of value particularly for small lesions.

Adrenal cortex

The adrenal cortex is made up (if the following layers from without inwards: the zona glomerulosa, the zona fasciculata and the zona reticularis.

Physiology. At least 50 steroid compounds have been isolated from the adrenal cortex. These hormones exhibit various types of activity which, for practical purposes, can be arranged in three groups.

Mineralocorticoids are concerned in the maintenance of water and electrolytic balance. A deficiency of these hormones produces sodium diuresis, potassium retention and dehydration; an excess results in hypertension, oedema, cardiac dilatation and hypokalaemia. Aldosterone is the most important of these ‘salt-regulating’ hormones (see Conn’s syndrome later).

Glucocorticoids are concerned with the metabolism of proteins and carbohydrates, favouring the formation of the latter from the body’s storehouse of the former. This conversion is known as gluconeogenesis. The best known of these are hydrocortisone (also known as cortisol) and cortisone (which is converted in the body to hydrocortisone). The therapeutic application of these hormones falls under two headings.

- In endocrine deficiencies. Hydrocortisone is the logical need in adrenocortical insufficiency and after bilateral adrenalectomy.

- In nonendocrine disease. Hydrocortisone or synthetic analogues, such as prednisone and betamethasone, are used in the treatment of a diversity of diseases, including allergic conditions, granulomatous disorders, blood diseases and the collagenoses. Hydrocortisone is used in the treatment of hypocorticism and shock (Chapter 4) and is an effective antiallergic agent in a number of skin diseases and eye conditions.

Sex hormones. Androgenic and oestrogenic hormones are produced by the adrenal cortex. Excessive secretion of androgens due to adrenal enzyme deficiencies or tumours causes virilism in females or, rarely, excessive secretion of oestrogens brings about effeminacy in males.

Interhormonic action. The anterior lobe of the pituitary gland secretes ACTH which stimulates the adrenal cortex, whereas the cortisol of the adrenal cortex inhibits the secretion of ACTH. ACTH secretion is also controlled by higher cerebral centers and the hypothalamic corticotrophin-releasing hormone (CRH).

Tests of adrenocortical activity

The tests are of two types, those that confirm the presence of a change in cortisol production and those that indicate a cause. No tests should be interpreted in isolation but all the results of the investigations should be considered together.

Plasma electrolytes. Sodium levels are raised and potassium is low in a hyper functioning adrenocortical lesion with the opposite in Addison’s disease, but changes in Addison’s disease may not occur until the patient is approaching crisis.

Plasma cortisol levels. Diurnal variation with a maximum value at 8.00 am. may be lost both in Cushing’s syndrome, where all levels are high, and in insufficiency when levels are low.

Plasma ACTH levels. Low plasma levels are found with adrenal tumours and high levels with a pituitary lesion or ectopic ACTH production. The ratio of ACTH to related peptides such as beta-lipotrophin may facilitate the distinction between pituitary Cushing’s and ectopic ACTH production.

Plasma aldosterone levels. The concentration of aldosterone is only one-thousandth that of cortisol, and both dietary sodium and posture may change the value. Plasma renin levels should be measured along with aldosterone to differentiate between primary and secondary hyperaldosteronism.
Urinary steroid excretion. Cortisol secretion rate. The daily output of cortisol is a precise measure of adrenocortical activity, but is routinely performed in only a few centres. Adult levels are reached by 18 years of age and after 40 years fall gradually, to be halved by 70 years of age. The average excretion is higher in Caucasian males. The daily output may be determined by the administration of a small amount of radioactive-labelled cortisol, which is metabolised and excreted, and the urinary radioactivity measured. The normal range is 5—28 mg per 24 hours, with high levels in Addison’s syndrome and low levels in adrenal insufficiency.

Urinary cortisol excretion. The cortisol excretion in a 24-hour urine sample is probably the best screening test for adrenocortical oversecretion.

17-Oxosteroids or ketosteroids. These reflect androgen output, and excretion is increased in many women with virilising syndromes.

Dexamethasone suppression test. Dexamethasone is 25 times more potent than cortisol. Dexamethasone 0.5 mg is administered 6-hourly for 2 days and causes a marked decrease in urinary steroid excretion by inhibiting ACTH production, and thus cortisol, without contributing greatly to the total urinary steroid output. In Cushing’s syndrome, no effect is produced by the dose. Larger doses of up to 2 mg 6-hourly will, over several days, reduce urinary steroid excretion if the overactivity is secondary to bilateral adrenal hyperplasia, but not with an adrenal tumour, which is autonomous. Measurement of the plasma cortisol at 9.00 a.m. after the administration of 2 mg dexamethasone the previous midnight serves as a convenient screening test for Cushing’s syndrome.

Metyrapone test. This differentiates between excess ACTH production and a lesion in the adrenal cortex causing Cushing’s syndrome. Metyrapone inhibits the biosynthesis of cortisol so plasma levels fall. If the pituitary—adrenal axis is intact, this results in an increase in ACTH production and stimulation of the adrenal cortex. The basal levels of 17-oxosteroids and ketosteroids in the urine are measured for 2 days, 750 mg of metyrapone is given per 4 hours and a 24-hour urine collection completed. A normal response is a two to fourfold increase in the urinary steroids over basal levels. A diminished response in Cushing’s syndrome indicates a primary adrenal lesion.

Synacthen test. Tetracosactrin (Synacthen) 250 pg is given intra-muscularly and blood cortisol measured at 30 and 60 minutes. In normal subjects the basal plasma cortisol should be greater than 60 pg/litre and be at least 70 pg/litre after stimulation. In Addison’s disease the response is impaired.

Disorders of adrenocortical function

Acute hypocorticism. Adrenal apoplexy in the newborn. Extensive haemorrhage into one or both adrenals may be a cause of death in infants within the first few days of birth. The condition may occur after a long and difficult labour, and particularly when resuscitative procedures have to be employed to combat asphyxia neonatorum. The haemorrhage into the adrenals follows necrosis of the innermost layer of the cortex, which always occurs at birth, possibly as a result of sudden withdrawal of the female sex hormone (oestrogen). Adrenal crisis in the newborn produces signs of profound shock. A mass may be palpable in one or both renal regions. Intravenous fluid therapy with hydrocortisone, or failing the latter, cortisone intramuscularly, offers the only hope.

Waterhouse—Fridrichsen syndrome. Massive bilateral adrenal cortical haemorrhage occurs in cases of fulminating meningococcal septicaemia and in some cases of streptococcal, staphylococcal or pneumococcal septicaemia. Most cases occur in infants and young children, but it can happen in adults with severe haemorrhage or burns. The onset is catastrophic, with rigors, hyperpyrexia, cyanosis and vomiting. Petechial haemorrhages into the skin which coalesce rapidly into purpuric blotsches are a constant feature. Profound shock follows, and before long the patient passes into coma. The condition is one of overwhelming sepsis that pursues a galloping course, death occurring in most cases within 48 hours of the onset of symptoms unless correct treatment is given without delay.

Unilateral haemorrhage causing a lesser degree of systemic upset and not associated with infections has been described. This type of case resembles a perinephric abscess or other upper abdominal acute condition.

Confirming the diagnosis. It is futile to await the result of a blood culture. Bilateral tenderness 5 cm below the costal margin, clear urine (oliguria is often present) and an absence of signs in the lungs help to call attention to the adrenal glands. In meningococcal infection the diplococcus may be demonstrated by smears obtained from a punctured petechial spot in the skin.

Treatment. Antibiotic therapy must be given intensively by the intravenous route. Hydrocortisone 100 mg is given intravenously (i.v.), or intramuscularly (i.m.) if venous access is difficult. Up to 400 mg hydrocortisone may be required in the first 24 hours. No mineralocorticoid is needed as the weak intrinsic salt-retaining action of hydro-cortisone suffices at this dosage. Oral medication may be commenced after the first day and then over about 4 days reduced to a maintenance level. Oxygen should also be administered. Following such treatment, improvement often sets in within 3 hours, and a number of patients has recovered.

Crises of infantile hypocorticism. See later.

Following bilateral adrenalectomy. If precautions are taken, acute hypocorticism is unusual in the postoperative period. Treatment is to give 300 mg hydrocortisone on the first day. Most patients achieve a maintenance dose of 30 mg/day. After about 3 weeks fluocorticisone 0.1 mg may be given.

Postoperative adrenal haemorrhage. Adrenal haemorrhage is a rare unexpected cause of deterioration and sudden death in the postoperative period. In some cases the left adrenal gland is damaged during radical gastrectomy for carcinoma (Fox). In other cases, when adrenal haemorrhage is bilateral, there is no evidence of operative injury, they are usually associated with intra-abdominal sepsis, pneumonia, coagulation defects and cancer. Thrombosis of the adrenal veins is the cause of infarction of glands.

Chronic hypocorticism (Addison’s disease)

This is due to adrenocortical insufficiency consequent on progressive destruction with lymphocytic infiltration of the zona reticularis, the zona fasciculata, the zona glomerulosa and the medulla of the adrenal glands, in that order. In about 60 per cent of cases the condition is believed to be due to an autoimmune disease, sometimes in association with autoimmune thyroiditis (Chapter 44) and pernicious anaemia. Tuberculosis, meta-static carcinoma and amyloidosis account for the remaining 40 per cent.

Clinical features

Addison’s disease usually commences in the third or fourth decade. Sometimes it is the terminal event in cases of adrenogenital hyperplasia. The sex distribution is about equal. The leading features are muscular weakness and a low blood pressure. Irregular dusky pigmentation of the skin, due to deposits of melanin, appears at points of pressure, e.g. garter or belt, and in the flexion creases. Pigmentation of mucous membranes, particularly of the mouth, is often striking. When fully established, the course of the disease is punctuated by crises of acute
adrenocortical insufficiency (see above).

**Treatment**

Treatment is medical. In long-term management, most patients require 20—30 mg hydrocortisone in divided doses, with fludrocortisone 0.1 mg daily as mineralocorticoid replacement. Signs of overtreatment include hypertension, hypokalaemia and oedema; those of under treatment, fatigue and hypotension. Where relevant, chemotherapy is mandatory for tuberculosis (Chapter 8).

**Prognosis**

By the use of replacement corticosteroids, the expectation of life of a patient suffering from Addison’s disease has been extended from up to 3 years to many years.

**Hypercorticism**

The various forms of adrenal cortical hyperfunction are classified according to the age at onset:

- **infantile**;
- **prepubertal**;
- **adult**;
- **postmenopausal**;
- **primary aldosteronism** (Conn’s syndrome) can occur at any age.

**Infantile hypercorticism**

Androgenic excess during intrauterine life is one form of pseudo-hermaphroditism in the female child. The condition is present at birth; sometimes the enlarged clitoris and a varying degree of hypospadias make it difficult to determine the infant’s sex. The 17-ketosteroid content of the urine may be sufficiently elevated to substantiate a diagnosis of a female with adrenal hyper function. If this is not the case, it is justifiable to perform sex determination by a skin biopsy before the age of 1 year. Female pseudohermaphroditism with virilism is invariably associated with disease of the adrenal cortex, usually bilateral hyperplasia of the cortex. Hormonal studies have shown that there is a congenital failure of the adrenal glands to synthesise glucocorticoids. Owing to this lack, these infants are liable to acute phases of adrenal insufficiency during stress or infection, or to suffer from periodic hypoglycemic attacks. They need corticosteroid replacement, not only in the emergency, but as long-term therapy, thereby inhibiting the secretion of excessive androgens. In the absence of such treatment, the epiphyses join early, the patients are dwarfed, menstruation does not occur and the breasts do not develop. These tendencies are corrected by hydrocortisone given orally, 25 mg or more daily, the dose being determined by 17-ketosteroid estimations (Simpson). Hirsutism is moderated, but not necessarily abolished. The treatment should be commenced early if good results are to be obtained.

**Prepubertal hypercorticism**

There is never any doubt as to the sex of the infant at birth and during the very early years of life the child is normal. The symptoms commence at about the age of 5 or 6 years.

*In the female.* Pubic and axillary hair appear, but there is no gross enlargement of the clitoris. The child is short in stature, the legs being especially stunted, but she looks much older than she is. Puberty is often precocious, menstruation, if it occurs, being scanty. There is a deepening of the voice at this time.

*In the male.* The term ‘infant Hercules’ is descriptive. He is extremely short, muscular and hirsute. The genitalia assume adult proportions and spermatoozaoa are often present in the seminal fluid.

*In both sexes,* 17-ketosteroid content of the urine is increased. A very high reading supports the diagnosis of an adrenocortical tumour, which must always be excluded. In both males and females, with a later onset or the passage of time, the features of Cushing’s syndrome become superadded.

**Treatment.** This is identical to that of Cushing’s syndrome.

**Postpubertal or adult hypercorticism (Cushing’s syndrome)**

Postpubertal or adult hypercorticism (Cushing’s syndrome) is due to an excessive endogenous production of glucocorticoids, mainly hydrocortisone. It is an uncommon condition, often suspected but seldom confirmed. Pituitary-dependent Cushing’s syndrome is the commonest form of endogenous hypercorticism accounting for up to two-thirds of all cases. An adrenal adenoma accounts for 20 per cent and carcinoma (which may be bilateral) 5 per cent. In the remainder there is no discernible structural alteration in the glands and the condition is due to an ectopic source of an ACTH-like substance being secreted, by either a benign tumour (e.g. bronchial carcinoid) or a malignant tumour of bronchus, mediastinum or pancreas. NonACTH-dependent primary adrenocortical hyperplasia is a rare cause of Cushing’s syndrome. Alcoholism also must be considered.

*In its typical form,* Cushing’s syndrome is exogenous and is seen in patients treated with large doses of cortisol over long periods for nonendocrine diseases, particularly rheumatoid arthritis, and in patients receiving transplants.

**Clinical features.** The female to male ratio is at least 3:1. The great majority of cases (excluding those induced by cortisone therapy) occurs in females between 15 and 30 years of age, in whom it produces highly characteristic features. Although the patient’s weight is not necessarily increased, there is a deposition of fat in certain situations. The face becomes rubicund, rounded like a full moon, and the lips are pursed. The abdomen becomes protuberant, the neck thick, the supraclavicular fossae obliterated and a roll of fat appears over the region of the vertebra prominens (buffalo hump). The arms, and especially the legs, are relatively thin, the muscular development is poor, and the patient complains of increasing weakness. As the disease progresses, so the general contour becomes more and more that of a ‘lemon on match-sticks’ (Fig. 45.8). Consequent upon the inhibitory effect of the hypercorticism on fibrous tissue, the skin becomes of tissue-paper consistency and inelastic. Exceedingly characteristic are purple-red striae distentiae, mostly on the abdomen (Fig. 45.9), of a texture that can be likened to an...
overstretched garter. Ecchymoses are frequent and bruising occurs on the slightest trauma. Acne is common and there is a low resistance to skin infections. Often there is increased growth of lanugo hair, but hirsutism is usually absent. Amenorrhoea is usual or, in the male, impotence. Owing to a negative calcium balance, the matrix of bone becomes thin and severe osteoporosis results. Pathological fractures, particularly compression fracture of a vertebra, are common, and this is sometimes the first reason for the patient seeking advice. Mild glycosuria is often present. Hypertension is frequent and eventually congestive heart failure supervenes. In about 60 per cent of cases, various psychoses occur.

Cushing’s syndrome is rare in children; when it occurs, the patient is nearly always a female and an adrenal tumour is usually the cause.

A subgroup, probably due to an excessive secretion of adrenal androgens (adrenogenital syndrome), commences between the ages of 15 and 25 and is confined to females. One of the first indications of its onset is amenorrhoea or oligomenorrhea. There follows an excessive growth of hair on the face (Fig. 45.10), acne, atrophy of the breasts, alteration in bodily contour and muscular development, deepening of the voice and enlargement of the clitoris. Jewish and Spanish women are more prone to this affliction than those of other races.

Arrhenoblastoma of the ovary
This rare condition occurs between puberty and the menopause and also causes hirsutism. It may also arise in a suprarenal ‘rest’.

Screening tests. There are three simple tests (see above) which may be used to screen patients suspected to have Cushing’s syndrome:

• plasma cortisol levels and diurnal rhythm;
• 24-hour urinary free cortisol excretion;
• overnight dexamethasone suppression test.

Each of these tests is highly discriminating with false-positive and false-negative results in only about 5 per cent of cases. However, patients with severe or chronic illness or alcoholism may have elevated midnight plasma cortisol levels and may fail to show overnight suppression after dexamethasone.

Definitive diagnosis. Suspected Cushing’s syndrome may be confirmed by the low-dose dexamethasone suppression test (see above), which is highly reliable.

Differential diagnosis. After the diagnosis of Cushing’s syndrome has been established, it is necessary to determine the cause of adrenocortical hyperfunction. In general, adrenal hyperfunctioning tumours and ectopic ACTH-secreting tumours function autonomously and are unaffected by hormonal manipulation. In contrast, the feedback mechanism in pituitary Cushing’s is functioning although it is abnormal. Thus appropriate investigations (see above) are the high-dose dexamethasone suppression test, measurement of plasma ACTH levels and the metyrapone test, which has largely been replaced by plasma ACTH assay. Nearly all patients with adrenal tumours and with the ectopic ACTH syndrome, in contrast to pituitary Cushing’s, fail to suppress with a high dose of dexamethasone and suppression is indicative of Cushing’s disease. In addition, patients with Cushing’s disease or the ectopic ACTH syndrome have detectable or elevated plasma ACTH levels, whereas cortisol-producing adrenal tumours suppress pituitary ACTH secretion and plasma levels are extremely low. A high plasma ACTH level after high-dose dexamethasone indicates autonomous ACTH secretion by a nonpituitary tumour, whereas if the ACTH level is low it indicates the presence of an adrenocortical tumour that has suppressed ACTH secretion by the normal pituitary.

Localisation studies. CT accurately identifies virtually all adrenal tumours in patients with Cushing’s syndrome and has replaced other techniques. It is also the most reliable method of detecting nodules in the lungs, mediastinum and pancreas, which are potential sites of ectopic ACTH production. Pituitary CT has also replaced other techniques for the detection of pituitary microadenomas in Cushing’s disease, although only 50 per cent of such adenomas are identified. Bilateral selective inferior petrosal venous sampling for ACTH levels is a valuable but technically difficult method of confirming and localising pituitary-dependent Cushing’s disease if CT is unhelpful.

Treatment. Trans-sphenoidal pituitary adenectomy in skilled hands is now the treatment of choice for pituitary lesions. External pituitary irradiation is less reliable in terms of long-term remission but is more successful in children. Yttrium-90 implantation is an alternative form of pituitary irradiation. Bilateral total adrenalectomy is a reliable procedure for patients with Cushing’s disease in whom pituitary treatment has failed.

The treatment of an adrenal tumour is surgical resection and resection of benign ectopic ACTH-secreting tumour is curative. Many, however, are malignant and widely disseminated when Cushing’s syndrome becomes clinically apparent.

Nelson’s syndrome
Hyperpigmentation and pituitary enlargement occur in about 20 per cent of cases after bilateral adrenalectomy and are avoided by selective pituitary microsurgery.

Prognosis. Most patients are alive 20 years after successful resection of an adrenal adenoma, but survival beyond 5 years is rare with a carcinoma (Welbourn). Pituitary microadenectomy in expert hands results in cure in about 80 per cent of patients very rarely, the adrenogenital syndrome appears in youths and men. Owing to excessive production of oestrogenic hormones by the adrenal cortex, gynaecomastia, atrophy of the testicles and psychosexual signs of effeminacy appear (adrenal feminism).

Postmenopausal hypercorticism
Postmenopausal hypercorticism is usually characterised by the growth of a beard (the bearded woman of the circus) and is often accompanied by mental aberration. A lesser degree of hirsutism is almost a natural accompaniment of the ageing process, particularly in dark-haired females, and it is difficult to draw the line between the normal and the pathological. Thus it is that operative treatment is usually disappointing.

Primary aldosteronism
Primary aldosteronism (Coon’s syndrome) is a surgically correctable type of hypertension found in 1—2 per cent of all hypertensive patients. It is characterised by autonomous excessive aldosterone secretion which leads to sodium retention and a fall in serum potassium. The latter causes the typical associated features of the syndrome, namely episodes of muscular weakness associated with polyuria and polydipsia. The plasma sodium is high and the potassium is low, but simple administration of potassium does not relieve the condition. Renin and angiotensin levels are depressed. The cause is either an aldosterone-secreting adrenal adenoma or bilateral adrenocortical hyperplasia (less common). CT and adrenal scanning with radioactive-labelled cholesterol are the appropriate localisation tests to distinguish between them. When these fail, adrenal venous sampling with measurement of aldosterone to cortisol ratios is the next step. Unilateral adrenalectomy is the treatment for an
aldosterone-producing adenoma and has a high cure rate, whereas surgery has been disappointing in adrenocortical hyperplasia and these patients are generally managed medically.

Secondary aldosteronism
Secondary aldosteronism is associated with cirrhosis of the liver, and renal artery stenosis with high levels of renin and angiotensin.

The incidental adrenal mass — ‘incidentaloma’
CT and MRI have resulted in increasing numbers (up to 1 per cent) of adrenal tumours being identified in the course of abdominal imaging for the investigation of other conditions. The finding may represent an adrenal tumour but more probably a benign lesion. Opinion is divided about management but essentially functioning lesions are excised whereas nonfunctioning lesions are managed according to size. Lesions less than 3 cm in size should be followed 3-monthly for a time by CT and excised if they enlarge, whereas those larger than 3 cm should be excised to exclude malignancy.

Adrenalectomy for hypercorticism
It is essential that all patients who are to be subjected to adrenalectomy are supported intra operatively and postoperatively by adrenocortical hormone replacement therapy, irrespective of the extent of adrenal resection.

Corticosteroid therapy
Corticosteroids are started when anaesthesia is induced. There is no advantage of one steroid over another except for their different durations of action. Hydrocortisone is very short acting, prednisolone intermediate and dexamethasone long acting. Each may be given intravenously or intramuscularly.

During the first 24 hours after induction of anaesthesia, the patient should receive no more than 300 mg hydrocortisone, 60 mg prednisolone or 6 mg dexamethasone. The dosage should be halved each day until a maintenance dose orally (hydrocortisone 30 mg, prednisolone 5 mg or dexamethasone 0.5 mg) is reached. Fludrocortisone 0.1 mg daily (replacing aldosterone) is usually added to the maintenance dose of corticosteroid to regulate fluid and salt balance.

After total adrenalectomy the patient should always carry a card stating the dosage of corticosteroid being received. Any stress (e.g. further operation or infection) is an indication to increase the dosage.

Operation
When an adrenal tumour has been demonstrated pre-operatively, excision of that adrenal gland alone is carried out.

Posterior approach
An ample posterolateral incision, such as is used for nephrectomy (Chapter 64), is used. After subperiosteal resection of the 12th rib, the lower border of the pleura is defined and protected. The incision is extended through the bed of the 12th rib to reveal the perinephric fat, within which the adrenal gland is identified, as described below. Sometimes an approach through the bed of the 11th rib, reflecting the pleura upwards, is preferred. (See also Anterior approach, below.)

On the right side the suprarenal vein is short and may be torn from the vena cava if it is not identified and ligated at an early stage of the dissection. By finger and gauze dissection, keeping close to the gland, the gland is freed from below and behind, upwards, ligating and dividing bleeding vessels as they are encountered, until it is suspended only by its main vascular pedicle near its apex.

Anterior approach
The adrenal glands are approached through either a curved transverse incision or a long midline incision. The left adrenal gland is approached first by cutting along the lateral leaf of the lienorenal ligament and then curving downwards and medially, so as to enable a wide peritoneal flap to be reflected. By retracting the spleen downwards and medially, the adrenal gland comes into view. The fascia over its lateral border is -incised, and by gauze dissection the blood vessels of the gland are defined, ligated and divided, thus freeing the gland, which is removed. Alternative approaches can be made by an ‘up and under’ dissection of the mesocolon and pancreas, or through the lesser sac. The right adrenal gland is more deeply situated. The peritoneum is incised lateral to the duodenum and above the upper pole of the kidney. The flap of peritoneum is raised to expose the anterior surface of the adrenal gland as it lies against the bare surface of the liver. The fascia covering the lateral surface of the gland is incised. A finger can then be inserted above the upper pole of the gland into the space between the two layers of fascia enclosing the gland (Fig. 45.11). This prevents the gland from becoming displaced upwards, which otherwise it is prone to do. The anterior fascial layer is then incised transversely and the gland can be dissected under vision, as on the left side. After removal, each gland should be inspected to check its completeness, and each adrenal bed must be searched for the presence of accessory adrenal tissue, which is present in 32 per cent of cases. If this important step is omitted, failure of the operation is not unlikely.

Thoracoabdominal approach
For removal of a large adrenal tumour (>10—15 cm in diameter) a thoracoabdominal incision gives the wide exposure necessary for radical resection en bloc which may involve removal of the ipsilateral kidney or spleen and tail of the pancreas.

Laparoscopic adrenalectomy
Laparoscopic adrenalectomy is a developing technique which may in selected patients, particularly patients with Coon’s syndrome, provide an alternative operative approach using a full lateral decubitus transperitoneal flank approach. It is claimed that such a technique offers a less painful postoperative recovery, with the in-patient stay reduced from a mean of 8 days for open surgery to 3—4 days. This must be offset against a doubling of the operating time, a possible increased incidence of wound infection and port site hemia formation.

Left adrenalectomy. Start by dissecting the splenoparietal ligament close to the diaphragm to permit a complete mobilisation of the spleen to the right with the tail of the pancreas. Dissection of 5 cm of the splenic vein, when used as a landmark, permits exposure of the renal vein: which leads to the main and accessory adrenal veins. They can be safely divided between clips. The right side of the gland is dissected up to the diaphragm with clipping of the middle and upper arterial pedicles. The adrenalectomy is achieved by dissection of the fat and the gland is extracted in a bag.
Right adrenalectomy. The fundamental step of the procedure is the section of the hepatoparietal ligament far to the right allowing an upwards mobilisation of the liver. Then dissect towards the vena cava using this structure as a landmark to find the renal vein which is the inferior limit of the dissection. The main adrenal vein is doubly clipped and divided. The third step is to look for an accessory adrenal vein joining a subhepatic vein above the main adrenal vein. The adrenal arteries, superior, middle and the main inferior one coming from the renal artery, are dissected on the right side of the vena cava. The last step is straightforward coagulation, vessel clipping and dividing as on the left side.

Adrenal medulla

Physiology. The medulla of the adrenal glands (chromaffin tissue), which is developed, together with sympathetic nerves, from ectoderm, is grey in colour and connected intimately, both anatomically and functionally, with splanchnic nerves. Chromaffin tissue is so called because the large polyhedral cells of which it is composed contain granules that stain yellow with chromic acid. These granules are the internal secretion of the adrenal medulla itself, for they can be observed being extruded in toto into radicles of the adrenal vein. The secretion consists of the catecholamines, adrenaline and noradrenaline. In health, 80 per cent of the output is adrenaline and 20 per cent is noradrenaline. However, in hyper functioning medullary tumour (phaeochromocytoma) this ratio is completely reversed. Fear, anger, pain and effort give rise to an increased output in response to the stimuli received via the splanchnic nerves.

An amino acid peptide adrenomedullin has recently been isolated from human phaeochromocytoma. It has a structure similar to calcitonin gene-related peptide and amylin. Intravenous administration elicits a strong, long-lasting hypotensive effect. It has been detected in human plasma and vascular smooth muscle cells with specific receptors. It decreases blood pressure by lowering total peripheral resistance and increasing urine flow and urinary sodium excretion.

Actions of catecholamines. Catecholamines exert their effects through specific cell-surface receptors: alpha-receptors and beta-receptors (Table 45.1). These mediate the actions of the endogenously released catecholamines, noradrenaline and adrenaline, and some of the actions of dopamine. The receptors have quite different pharmacological properties and an organ may have more than one type. The complex actions of catecholamines include altering enzyme activity, metabolic pathways and the permeability of cell membranes to ions.

Pharmacological inhibitors of alpha stimulation (alpha-blockers) include the long-acting phenoxybenzamine (Dibenzyline) and short-acting phentolamine (Rogitine). Beta-blockers include propranolol (Inderal) and practolol (Eraldin).
Tumours of the adrenal medulla

Tumours of the adrenal medulla are classified as follows:

- Neoplasms of the sympathetic neurons:
  - Ganglioneuroma,
  - Neuroblastoma (sympatheticoblastoma);
- Neoplasm of chromaffin cells: phaeochromocytoma.

Those occurring at any age

A ganglioneuroma is relatively benign. This neoplasm is symptomless, grows to a large size and constitutes one of the varieties of retroperitoneal sarcoma (Chapter 56). Only 15 per cent involve the adrenal, the remainder occurring in any position along the sympathetic chain. If removed completely at a comparatively early stage, a cure may be expected.

Those occurring in infants and children

Neuroblastoma

Neuroblastoma is a malignant tumour of neural crest origin arising from sympathetic nervous tissue from the orbit to the pelvis. Three-quarters arise in the abdomen and half of these from the adrenal gland. It is the most common solid tumour of infancy and childhood, and by far the most common in the newborn. The incidence is approximately 1 per 10,000 live births. Ninety per cent of cases of neuroblastoma occur under the age of 8; over half occur in children under 2 years.

Clinical features. Three-quarters of patients present with an abdominal mass. Metastatic spread, via lymphatics and bloodstream, occurs at an early stage, and approximately 70 per cent of cases have metastases at the time of initial diagnosis (Fig. 45.12). Weight loss, failure to thrive, abdominal pain and distension, fever and anaemia may be present. Excessive catecholamine production may cause hypertension, flushing, sweating and general irritability. Some of these tumours produce VIP, which results in watery diarrhoea and hypokalaemia. Acute cerebellar ataxia characterised by opsomyoclonus and chaotic nystagmus or the ‘dancing eye syndrome is an unusual manifestation of neuroblastoma of unknown cause.

Diagnosis. Over 80 per cent of patients excrete catecholamine metabolites in the urine. The most common by-products assayed in the urine are vanillylmandelic acid (VMA) and homovanillic acid (HVA), and such measurements may be useful in monitoring the course of the disease.

Plain radiography shows fine, stippled calcification in 50 per cent of cases. Abdominal ultrasound examination shows the anatomical margins and extent of the disease, and is particularly helpful in evaluating the results of treatment.

CT demonstrates calcium in 80 per cent of cases and accurately evaluates intraspinal extension as well as hepatic and renal metastatic disease. MRI is a promising technique which may supersede CT in many patients. It will also evaluate bone marrow metastases.

Meta-iodobenzyl-guanidine (MIBG, see below) is metabolised by neuroblastoma cells and may be used for imaging, especially in small residual tumours not evident on other conventional imaging studies.

Bone-seeking isotope (technetium-99m), as well as demonstrating bone involvement, is also concentrated by 60 per cent of adrenal lesions.

Treatment. Although surgical excision is the mainstay of cure in localised disease, widespread disease at presentation often makes surgery inappropriate as the primary form of treatment. Multi drug chemotherapy and radiotherapy are instituted in advanced disease. Surgical excision is appropriate in disease confined to one side of the midline, or as a delayed treatment following control by chemotherapy and radiotherapy. However, the cure rate remains low with an overall survival rate of 30–35 per cent. Age has an important favourable influence on prognosis — the younger the patient the better the prognosis, and children in the first year of life have a long-term survival rate of 70 per cent.

Phaeochromocytoma

Phaeochromocytoma has been called the ‘10 per cent tumour’ because approximately 10 per cent are bilateral, malignant, extra-adrenal, multiple, familial and occur in children. Although 90 per cent of phaeochromocytoma arise in the adrenal medulla, they may be found anywhere along the paraganglionic system. The most common extra-adrenal site is the organ of Zuckerkandl at the aortic bifurcation and less common sites are the urinary bladder, renal hilum, chest and neck. Extra-adrenal tumours have a higher incidence of malignancy of 25–40 per cent. A phaeochromocytoma is a soft, vascular tumour usually less than 5 cm in diameter but occasionally very much larger. It is usually pink-tan in colour and is composed of large, differentiated, sympathetic ganglion cells and a few fibres, enclosed in a delicate capsule. It owes its name to the presence of chromaffin granules. This tumour occurs in both sexes, usually during early adult life or middle age. It produces, either intermittently or continuously, an excess of adrenaline, and especially of nor-adrenaline: the ratio of the latter to the former often being as high as 20:1 causing hypertension which is either paroxysmal or persistent. The latter predominates statistically and probably indicates a late stage of the disease. Consequently all patients under 60 years of age who suffer from sustained arterial hypertension deserve routine tests to confirm or exclude a phaeochromocytoma. Although not more than 0.5 per cent of cases of hypertension are caused by a phaeochromocytoma, at the Mayo Clinic, where routine diagnostic procedures are undertaken to confirm or exclude the presence of this tumour in all cases of hypertension, the percentage has been stated to be nearly 3 per cent. Untreated, it progresses to a fatal termination from cardiac dysrhythmia or cerebral haemorrhage.

The importance of phaeochromocytoma as a component of the multiple endocrine neoplasia syndromes MEN IIa and MEN IIb should be remembered (see earlier and Chapter 44).

Clinical features. A typical complaint is that of fear — ‘I thought I was going to die’. The most common symptoms, in order of frequency, are: headache (55 per cent), palpitation, vomiting, sweating, dyspnoea, weakness and pallor — i.e. the symptoms of adrenal overdosage. The paroxysmal attack may vary from a few minutes to some hours. The blood pressure may be very high and hyperglycaemia present. The symptoms may be mistaken for hyperthyroidism, hypo-calciumia, an acute anxiety state, paroxysmal atrial tachycardia and carcinoid syndrome. The main obstacle to the diagnosis of a phaeochromocytoma is the failure to think of it as a cause of the observed symptoms.
Diagnostic tests

The basis of the laboratory diagnosis is measurement of elevated catecholamines and their metabolites in urine and blood.

- **Urine studies.** Confirmation of the diagnosis is usually readily made by measurement of free catecholamines, VMA and metadrenalines (metanephrines) in 24-hour collections of urine. Patients with phaeochromocytoma usually excrete free catecholamines in excess of 100 µg/24 hours, VMA in excess of 7 mg/24 hours and metadrenalines in excess of 1.3 mg/24 hours. Laboratories vary in the reliance they place on these various estimations; at the Mayo Clinic, for example, most reliance is placed on urinary metadrenalines. False-positive elevations of metadrenaline excretion may occur in patients taking monoamine oxidase-inhibiting drugs, and in those who have recently had angiographic contrast studies.

- **Plasma catecholamines.** Sensitive assays are now available for plasma catecholamines and patients with phaeochromocytoma usually have total plasma catecholamines in excess of 1000 pg/ml. Such assays may be highly accurate in confirming the diagnosis, but plasma catecholamines may not be continuously elevated and many factors, including exercise, severe illness and the drug methyldopa, may influence the levels.

Localisation tests

- **Computerised tomography (Fig. 45.13)** is the method of choice for localisation with an accuracy of 90—95 per cent and has largely replaced more invasive and hazardous techniques such as arterio-ography and selective venous sampling. Because of their size, most adrenal phaeochromocytomas are also visible on ultrasound scanning.

- **Radionuclide imaging.** The development of a specific radionuclide for catecholamine precursors, iodine-labelled MIBG, has been a significant recent advance in the localisation of adrenal and ectopic phaeochromocytomas. Only abnormal areas of adrenergic tissue show uptake of MIBG and normal adrenals do not visualise. MIBG scanning may be particularly valuable in locating an ectopic phaeochromocytoma when CT shows normal adrenals (Fig. 45.14).

Preoperative preparation

Catecholamine-secreting tumours are a challenge to both the surgeon and anaesthetist. A patient with phaeochromocytoma is hypovolaemic because of the contraction of the vascular bed by excess circulating catecholamines. During surgery handling of the tumour may increase circulating catecholamine levels up to 600-fold causing large swings in blood pressure and cardiac arrhythmias. Severe hypotension may follow removal of the tumour. These dangers may be minimised by careful preoperative preparation. Effective blockade of the effects of high circulating catecholamines has significantly reduced the operative mortality and is mandatory. The alpha-adrenergic blocking drug phenoxybenzamine in an initial dose of 20—40 mg/day is increased until hypertension is controlled and mild orthostatic hypotension induced. Such preparation takes 1—3 weeks. In most centres a beta-blocking drug such as propranolol is added for 3—7 days before operation to control tachycardia and arrhythmias. Extra fluids should be given iv. to occupy the sudden expansion of the vascular bed when the tumour is removed, and a preoperative fluid ‘overload’ is advisable.

Operation

During surgery, intravenous infusions of alpha- and beta-blocking drugs are given, if required, as determined by the blood pressure, pulse rate and central venous pressure. The hazardous phases in the operation are during the induction of anesthesia, positioning of the patient on the operating table, when the tumour is manipulated, and immediately after removal of the tumour. Sodium nitroprusside, a direct peripheral vasodilator, is the drug of choice for the management of significant intraoperative hypertension.

Even though preoperative localisation is highly accurate, the possible multiplicity of tumours (intra- and extra-adrenal) and the need to avoid excessive tumour manipulation necessitate a generous transabdominal approach. The tumour should be manipulated as little as possible and the main adrenal vein ligated as a first step. Inadvertent rupture of the tumour should be avoided as this may result in local spread and recurrence of even apparently benign tumours.
Further reading

The Breast

Subjects covered in this chapter include anatomy, investigations of the breast, the nipple, benign and malignant disorders of the breast, breast reconstruction, screening for breast cancer, breast cancer genetics and the male breast.

Comparative and surgical anatomy

The protuberant part of the human breast is generally described as overlying the 2nd to the 6th ribs, and extending from the lateral border of the sternum to the anterior axillary line. Actually, a thin layer of mammary tissue extends considerably farther from the clavicle above to the 7th or 8th ribs below, and from the midline to the edge of latissimus dorsi posteriorly. This fact is important when performing a mastectomy, the aim of which is to remove the whole breast. The anatomy of the breast is illustrated in Fig. 46.1.

The axillary tail of the breast is of considerable surgical importance. In some normal cases it is palpable, and in a few it can be seen premenstrually or during lactation. A well-developed axillary tail is sometimes mistaken for a mass of enlarged lymph nodes or a lipoma.

The ligaments of Cooper are hollow conical projections of fibrous tissue filled with breast tissue, the apices of the cones being attached firmly to the superficial fascia and thereby to the skin overlying the breast. These ligaments account for the dimpling of the skin overlying a carcinoma.

The areola contains involuntary muscle arranged in concentric rings as well as radially in the subcutaneous tissue. The areolar epithelium contains numerous sweat glands and sebaceous glands, the latter of which enlarge during pregnancy and serve to lubricate the nipple during lactation (Montgomery’s tubercles).

The nipple is covered by thick skin with corrugations. Near its apex lie the orifices of the lactiferous ducts. The nipple contains smooth muscle fibres arranged concentrically and longitudinally; thus is an erectile structure which points outwards. Lymphatics of the breast drain predominantly into the axillary and internal mammary lymph nodes. The axillary nodes receive approximately 75 per cent of the drainage and are arranged in the following groups:

- lateral, along the axillary vein;
- anterior, along the lateral thoracic vessels;
- posterior, along the subscapular vessels;
- central embedded in fat in the centre of the axilla;
- interpectoral, a few nodes lying between the pectoralis major and minor muscles;
- apical, which lie above the level of the pectoralis minor tendon in continuity with the lateral nodes and receive the efferents of all the other groups.

The apical nodes are also in continuity with the supraclavicular nodes and drain into the subclavian lymph trunk which enters the great veins directly or via the thoracic duct or jugular trunk. The sentinel node is that lymph node designated as the first axillary node draining the breast.

The internal mammary nodes are fewer in number and lie along the internal mammary vessels deep to the plane of the costal cartilages.
Investigation of the breast

Although an accurate history and clinical examination are still the most important methods of detecting breast disease there are a number of investigations which can assist in the diagnosis as follows

Mammography (Fig. 46.2)

Soft tissue X-rays are taken by placing the breast in direct contact with ultrasensitive film and exposing it to low-voltage, high-amperage X-rays. The dose of radiation is approximately 0.1 Gy and therefore mammography is a very safe investigation.

Ultrasound

Ultrasound is particularly useful in young women with dense breasts in whom mammograms are difficult to interpret, and in distinguishing cysts from solid lesions (Figs 46.3 and 46.4). It can also be used to localise impalpable breast lumps.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) is of increasing interest to breast surgeons in a number of settings: it can be useful to distinguish scar from recurrence in women who have had previous breast conservation therapy for cancer (although it is not accurate within 9 months of radiotherapy because of abnormal enhancement); it is the gold standard for imaging the breasts of women with implants; it may prove useful as a screening tool in high-risk women; and it is being evaluated in the management of the axilla in both primary breast cancer and recurrent disease (Fig. 46.5).

Needle biopsy/cytology

Histology can be obtained using a fine needle such as a Trucut or Corecut biopsy device under local anaesthesia (Fig. 46.6). Cytology is obtained using a 21 or 23 Gauge needle and 10-ml syringe with multiple passes throughout the lump without releasing the negative pressure in the syringe. The aspirate is then smeared on to a slide which is air dried (Fig. 46.7). Fine needle aspiration cytology (FNAC) is the least invasive technique of obtaining a cell diagnosis and is very accurate if both operator and cytologist are experienced. However, false negatives do occur, mainly through sampling error, and invasive cancer cannot be distinguished from in situ disease.

Triple assessment

In any patient who presents with a breast lump or other symptoms suspicious of carcinoma, the diagnosis should be made by a combination of clinical assessment, radiological imaging and a tissue sample taken for either cytological or histological analysis (Fig. 46.8): the so-called triple assessment.
The nipple

Absence of the nipple is rare, and usually associated with amazia (congenital absence of the breast).

Supernumerary nipples not uncommonly occur along a line extending from the anterior fold of the axilla to the fold of the groin (Fig. 46.9). This constitutes the milk line of lower mammals.

Nipple retraction

This may occur at puberty or later in life. Retraction occurring at puberty, also known as simple nipple inversion, is of unknown aetiology. In about 25 per cent of cases it is bilateral. It may cause problems with breastfeeding and infection can occur, especially during lactation, owing to retention of secretions.

Treatment

Treatment is usually unnecessary, and it may spontaneously resolve during pregnancy or lactation. Simple cosmetic surgery can produce an adequate correction but has the drawback of dividing the ducts. Mechanical suction devices have been used to attempt to evert the nipple with some effect. Recent retraction of the nipple may be of considerable pathological significance. A slit-like retraction of the nipple may be due to duct ectasia and chronic periductal mastitis (Fig. 46.10a), but circumferential retraction, with or without an underlying lump, may well indicate an underlying carcinoma (Fig. 46.10b).

Cracked nipple

This may occur during lactation and be the forerunner of acute infective mastitis. If the nipple becomes cracked during lactation, it should be rested for 24—48 hours and the breast emptied with a breast pump. Feeding should be resumed as soon as possible.

Papilloma of the nipple

Papilloma of the nipple has the same features of any cutaneous papilloma (Fig. 46.11) and should be excised with a tiny disc of skin.

Retention cyst of a gland of Montgomery

These glands, situated in the areola, secrete sebum, and if they become blocked a sebaceous cyst forms.

Chancre of the nipple

This very rare condition usually occurs by infection from a syphilitic buccal ulcer in the mouth of the partner, although can be seen in the wet-nurse of a syphilitic baby. The mother of such an infant is immune to reinfection from her own child.

Eczema

Eczema of the nipples is a rare condition and is bilateral, and usually associated with eczema elsewhere on the body.

Paget's disease

Paget's disease of the nipple must be distinguished from the eczema.

Abnormal discharges from the nipple

Discharge can occur from one or more lactiferous ducts. Management depends on the presence of a lump (which should always be given priority in diagnosis and treatment) and of the presence of blood in the discharge or discharge from a single duct. Mammography is rarely useful except to exclude an underlying impalpable mass. Cytology may reveal malignant cells but a negative result does not exclude a carcinoma.

A clear, serous discharge may be 'physiological' in a parous woman or may be associated with a duct papilloma or mammary dysplasia.

A blood-stained discharge may be caused by duct ectasia or less commonly a duct papilloma or carcinoma. A duct papilloma is usually single and situated in one of the larger lactiferous ducts and is sometimes associated with a cystic swelling beneath the areola.

A black or green discharge is usually due to duct ectasia and its complications.

Treatment

Treatment must firstly be to exclude a carcinoma by occult blood test and cytology. Simple reassurance may then be sufficient, but if the discharge is proving intolerable an opera-tion to remove the affected duct or ducts can be performed. Figure 46.12 illustrates some causes of nipple discharge. Microdochectomy. It is important not to express the blood before the operation as it may then be difficult to identify the duct in theatre. A lacrimal probe or length of stiff nylon suture is inserted into the duct from which the discharge is emerging. A tennis raquet incision can be made to encompass the entire duct, or a periareolar incision used and the nipple flap dissected to reach the duct. The duct is then excised. A papilloma is nearly always situated within 4—5cm of the nipple orifice.

A cone incision of the major ducts (after Hadfield). When the duct of origin of nipple bleeding is uncertain or when there is bleeding or discharge from multiple ducts, the entire major duct system can be excised for histological examination without sacrifice of the breast form. A periareolar incision is made and a cone of tissue is removed with its apex lust deep to the surface of the nipple and its base on the pectoral fascia. The resulting defect is obliterated by a series of purse-string sutures. It is important to warn the patient that she will be unable to breast feed after this and may lose nipple sensation.
Benign breast disease

This is the most common cause of breast problems — up to 30 per cent of women will suffer from a benign breast disorder requiring treatment at some time in their lives. The most common symptoms are pain, lumpiness or a lump. The aim of treatment is to exclude cancer and, once this has been done, to treat any remaining symptoms.

Benign breast disorders can be classified in the following way:

- ANDI¹ (lumpy breasts, tenderness or a smooth lump):
  - cyclical nodularity and mastalgia, cysts, fibroadenoma;
- duct ectasia/periductal mastitis;
- pregnancy related:
  - galactocele,
  - puerperal abscess;
- congenital disorders:
  - inverted nipple,
  - supernumary breasts/nipples;
- nonbreast disorders:
  - Tietze’s disease;
- sebaceous cysts and other skin conditions.
against the point of the haemostat and its jaws are opened. All loculi that can be felt are entered.

Drainage of an intramammary abscess. The usual incision is sited in a radial direction over the affected segment, although if a circumareolar incision will allow adequate access to the affected area this should be preferred because of a better cosmetic result. The incision passes through the skin and the superficial fascia. A long haemostat is then inserted into the abscess cavity. Every part of the abscess is palpated against the point of the haemostat and its jaws are opened. All loculi that can be felt are entered.

Injuries of the breast

Haematoma

Haematoma, particularly a resolving haematoma, gives rise to a lump which, in the absence of overlying bruising, is difficult to diagnose correctly unless it is aspirated or incised.

Traumatic fat necrosis

Traumatic fat necrosis may be acute or chronic, and usually occurs in stout, middle-aged women. Following a blow, or even indirect violence (e.g. contraction of the pectoralis major), a lump, often painless, appears. This may mimic a carcinoma, even displaying skin tethering and nipple retraction, and biopsy is required for diagnosis. A history of trauma is not diagnostic as this may merely have drawn the patient's attention to a pre-existing lump.

Acute and subacute inflammations of the breast

Bacterial mastitis

Bacterial mastitis is the commonest variety of mastitis and nearly always commences acutely. Although associated with lactation in the majority of cases, it is not necessarily so. Of 100 consecutive cases of breast abscess, 32 occurred in women who were not lactating (De Jode). Some of these will be associated with an infected haematoma or with periductal mastitis and this will be discussed later.

Aetiology. Lactational mastitis is seen far less frequently than in former years. Most cases are caused by Staphylococcus aureus and, if hospital-acquired, are likely to be penicillin resistant. The intermediary is usually the infant; after the second day of life 50 per cent of infants harbour staphylococci in the nasopharynx.

'Cleansing the baby's mouth' with a swab is also an aetiologic factor. The delicate buccal mucosa is excoriated by the process; it becomes infected, and organisms in the infant's saliva are inoculated on to the mother's nipple.

Whilst ascending infection from a sore and cracked nipple may initiate the mastitis, in many cases the lactiferous ducts will first become blocked by epithelial debris leading to stasis — this theory is supported by the relatively high incidence of mastitis in women with a retracted nipple. Once within the ampulla of the duct, staphylococci cause clotting of milk and within this clot organisms multiply.

Clinical features. The affected breast, or more usually a segment of it, presents the classical signs of acute inflammation. Early on this is a generalised cellulitis, but later an abscess will form.

Treatment. During the cellulitic stage the patient should be treated with an appropriate antibiotic, e.g. flucloxacillin, and the breast rested, with feeding on the opposite side only. The infected breast should be emptied of milk using a breast pump. Support of the breast, local heat and analgesia will help to relieve pain.

If an antibiotic is used in the presence of undrained pus, an 'antibioma' may form. This is a large, sterile brawny oedematous swelling which may reach the knees when the patient is sitting. The condition is rarely unilateral. This tremendous overgrowth is apparently due to an alteration in the normal sensitivity of the breast to oestrogenic hormones, and some success in treating it with antioestrogens has been reported. Treatment is otherwise by reduction mammoplasty.

Drainage of an intramammary abscess. The usual incision is sited in a radial direction over the affected segment, although if a circumareolar incision will allow adequate access to the affected area this should be preferred because of a better cosmetic result. The incision passes through the skin and the superficial fascia. A long haemostat is then inserted into the abscess cavity. Every part of the abscess is palpated against the point of the haemostat and its jaws are opened. All loculi that can be felt are entered.
Finally, the haemostat having been withdrawn, a finger is introduced and any remaining septa are disrupted. The wound may then be lightly packed with ribbon gauze or a drain inserted to allow dependent drainage.

**Mastitis from milk engorgement**

Mastitis from milk engorgement is liable to occur around weaning time, and sometimes in the early days of lactation when one of the lactiferous ducts becomes blocked with epithelial debris. In the latter instance only a sector of the breast becomes indurated and tender.

**Chronic intramammary abscess**

Chronic intramammary abscess which follows inadequate drainage or injudicious antibiotic treatment is often a very difficult condition to diagnose: when encapsulated within a thick wall of fibrous tissue, the condition cannot be distinguished from a carcinoma without the histological evidence from a biopsy.

**Tuberculosis of the breast**

Tuberculosis of the breast, which is comparatively rare, is usually associated with active pulmonary tuberculosis or tuberculous cervical adenitis.

Tuberculosis of the breast (Fig. 46.19) occurs more often in parous women and usually presents with multiple chronic abscesses and sinuses and a typical bluish attenuated appearance of the surrounding skin. The diagnosis rests on bacteriological and histological examination. Treatment is with antituberculous chemotherapy. Healing is usual although often delayed, and mastectomy should be restricted to patients with persistent residual infection.

**Actinomycosis**

Actinomycosis of the breast is rarer still. The lesions present the essential characteristics of faciocervical actinomycosis.

**Syphilis of the breast**

A primary chancre of the nipple has been referred to (above). Secondary lesions of syphilis include diffuse syphilitic mastitis.

**Mondor's disease**

Mondor's disease is thrombophlebitis of the superficial veins of the breast and anterior chest wall (Fig. 46.20) although it has also been encountered in the arm.

In the absence of injury or infection, the cause of thrombophlebitis — like that of spontaneous thrombophlebitis in other sites — is obscure. The pathognomonic feature is a thrombosed subcutaneous cord, usually attached to skin. When the skin over the breast is stretched by raising the arm, a narrow, shallow subcutaneous groove alongside the cord becomes apparent. The differential diagnosis is lymphatic permeation from an occult carcinoma of the breast. The only treatment required is restricted arm movements, and in any case the condition subsides within a few months without recurrence, complications or deformity.

**Duct ectasia/periductal mastitis**

**Pathology**

This is a dilatation of the breast ducts associated with periductal inflammation, the pathogenesis of which is obscure and almost certainly not uniform in all cases, although the disease is much more common in smokers.

The classical description of the pathogenesis of duct ectasia asserts that the first stage in the disorder is a dilatation in one or more of the larger lactiferous ducts which fill with a stagnant brown or green secretion. This may discharge. These fluids then set up an irritant reaction in surrounding tissue leading to periductal mastitis or even abscess and fistula formation (Figs 46.21 and 46.22). In some cases a chronic indurated mass forms beneath the areola which mimics a carcinoma.

Fibrosis eventually develops which may cause slit-like nipple retraction.

An alternative theory suggests that periductal inflammation is the primary condition and anaerobic bacterial infection is found in some cases.

An association between recurrent periductal inflammation and smoking has been demonstrated which may suggest that arteriopathy is a contributing factor in its aetiology.

**Clinical features**

Nipple discharge (of any colour), a subareolar mass, abscess, mammary duct fistula and/or nipple retraction are the commonest symptoms (Fig. 46.23).

**Treatment**

In the case of a mass or nipple retraction, a carcinoma must be excluded by obtaining a mammogram and negative cytology or histology. If any suspicion remains the mass should be excised.

Antibiotic therapy may be tried, the most appropriate agents being flucloxacillin and metronidazole. However, surgery is often the only option likely to bring about cure of this notoriously difficult condition, and consists of excision of all of the major ducts (the Hadfield's operation).

**Aberrations of normal development and involution (ANDI)**

**Nomenclature**

The nomenclature of benign breast disease is very confusing. This is because over the last century a variety of clinicians and pathologists has chosen to describe a mixture of physiological changes and disease processes according to a variety of clinical, pathological and aetiological
terminology. As well as leading to confusion, patients were often unduly alarmed or overtreated by ascribing a pathological name to a variant of physiological development. To sort out this confusion, a new system has been developed and described by the Cardiff Breast Clinic — ANDI. (Many alternative terms have been applied to this condition including fibrocystic disease, fibroadenosis, chronic mastitis and mastopathy.)

**Aetiology**

The breast is a dynamic structure which undergoes changes throughout a woman’s reproductive life, and superimposed upon this, cyclical changes throughout the menstrual cycle. This is illustrated in Fig. 46.24. The pathogenesis of ANDI involves disturbances in the breast physiology extending from an extreme of normality to well-defined disease processes. There is often little correlation between the histological appearance of the breast tissue and the symptoms.

**Risk of malignancy developing in association with benign breast pathology**

These relative risks according to different histological features found at biopsy are illustrated in Table 46.1.

**Pathology**

The breast is a dynamic structure which undergoes changes throughout a woman’s reproductive life, and superimposed upon this, cyclical changes throughout the menstrual cycle. This is illustrated in Fig. 46.24. The pathogenesis of ANDI involves disturbances in the breast physiology extending from an extreme of normality to well-defined disease processes. There is often little correlation between the histological appearance of the breast tissue and the symptoms.

1. **Cyst formation.** Cysts are almost inevitable and very variable in size.
   - Fibrosis. Fat and elastic tissue disappears and is replaced by dense white fibrous trabeculae. The interstitial tissue is infiltrated with chronic inflammatory cells.
   - Hyperplasia of epithelium in the lining of the ducts and acini may occur with or without atypia.
   - Papillomatosis. The epithelial hyperplasia may be so extensive that it results in papillomatous overgrowth within the ducts.

**Clinical features**

The symptoms of ANDI include an area of lumpiness (seldom discrete) and/or breast pain (mastalgia).

- A benign discrete lump in the breast is commonly a cyst or fibroadenoma. True lipomas occur rarely.
- Lumpiness may be bilateral, commonly in the upper outer quadrant, or less commonly confined to one quadrant of one breast. The changes may be cyclical, with an increase in both lumpiness and often tenderness before a menstrual period.
- Noncyclical mastalgia is commoner in perimenopausal and postmenopausal women. It may be associated with ANDI or with periductal mastitis, or referred from, for example, a musculoskeletal disorder. About 10 per cent of breast cancers exhibit pain at presentation. Common breast symptoms are illustrated in Table 46.2.

**Treatment of lumpy breasts**

If the clinician is confident that he or she is not dealing with a discrete abnormality (and clinical confidence may be buttressed by mammography or ultrasound scanning if appropriate), then initially the woman can be offered firm reassurance. It is perhaps worthwhile reviewing the patient at a different point in the menstrual cycle, say 6 weeks after the initial visit, and often the clinical signs will have resolved by that time. There is a tendency for women with lumpy breasts to be rendered unnecessarily anxious and to be submitted to multiple random biopsies because the clinician lacks the courage of his or her convictions.

**Treatment of mastalgia**

Pronounced cyclical mastalgia may become a significant clinical problem where the pain and tenderness interfere with the woman’s life, disturb her sleep and impair sexual activity. Initially, firm reassurance that the symptoms are not associated with cancer will help the majority of women. A patient symptom diary will help her to chart the pattern of pain throughout the month and thus determine whether this is cyclical mastalgia. If reassurance is inadequate, then a planned escalation of treatment (as shown in Table 46.3) could be advised. Oil of evening primrose, in adequate doses given over 3 months, will help more than half of these women. For those with intractable symptoms a prolactin inhibitor such as danazol may be given. Very rarely it is necessary to prescribe an antioestrogen, e.g. tamoxifen or a luteinizing hormone-releasing hormone (LHRH) agonist, to deprive the breast epithelium of oestrogenic drive.

For noncyclical mastalgia it is important to exclude extramammary causes such as chest wall pain, and it may be necessary to carry out a biopsy on a very localised tender area which might be harbouring a subclinical cancer. Treatment may be with nonsteroidal analgesics or by injection with local anaesthetic of a ‘trigger spot’.

**Breast cysts**

These occur most commonly in the last decade of reproductive life due to a nonintegrated involution of stroma and epithelium. They are often multiple, may be bilateral and can mimic malignancy. Diagnosis can be confirmed by aspiration and/or ultrasound.

**Treatment**

A solitary cyst or small collection of cysts can be aspirated. If they resolve completely, and if the fluid is not bloodstained, no further treatment is required. However, 30 per cent will recur and require reaspiration. Cytological examination of cyst fluid is no longer practised routinely. If there is a residual lump or if the fluid is bloodstained, a local excision for histological diagnosis is advisable, as is also the case if the cyst repeatedly reforms.

**Galactocele**

Galactocele, which is rare, usually presents as a solitary, subareolar cyst, and always dates from lactation. It contains milk and in long-standing cases its walls tend to calcify. It can become enormous (Fig. 46.25).
Fibroadenoma

These usually arise in the fully developed breast during the 15—25-year period, although occasionally they occur in much older women. They arise from hyperplasia of a single lobule, and usually grow up to 2—3 cm in size. They are surrounded by a well-marked capsule and can thus be enucleated through a cosmetically appropriate incision. However, in a patient under 30 years these do not require excision unless associated with suspicious cytology, or if they become very large, or if the patient expressly desires the lump to be removed. Giant fibroadenomas occur occasionally during puberty. They are over 5 cm in diameter and are often rapidly growing, but in other respects are similar to smaller fibroadenomas and can be enucleated through a submammary incision.

Phyllodes tumour

These benign tumours, previously sometimes known as serocystic disease of Brodie or cystosarcoma phyllodes, usually occur in women over the age of 40 but can appear in younger women (Fig. 46.26). They present as a large, sometimes massive tumour, with an unevenly bosselated surface. Occasionally ulceration of overlying skin occurs owing to pressure necrosis. In spite of their size they remain mobile on the chest wall. Histologically there is a resemblance to a fibroadenoma, but despite the name of cystosarcoma phyllodes they are rarely cystic and only very rarely develop features of a sarcomatous tumour. These may metastasise via the bloodstream.

Treatment

Treatment for the benign type is enucleation in very young women or wide local excision. Massive tumours, recurrent tumours and those of the malignant type will require mastectomy.

When the diagnosis of carcinoma is in doubt

There will always be cases where the clinician cannot be sure whether a particular lump in the breast is an area of mammary dysplasia, a benign tumour or an early carcinoma.

If there is doubt on either clinical, cytological or radiological examination it is essential to obtain a tissue diagnosis. This is often possible by needle biopsy. In the advent of a negative result, open biopsy of the mass is necessary. Because of the possibility of reporting errors, the authors suggest that frozen section reporting should rarely be used and certainly should not form the basis for a decision to undertake amastectomy. Table 46.4 gives an algorithm for investigating any breast lump. Table 46.5 illustrates the features of three common lumps.
Carcinoma of the breast

Breast cancer is the commonest cause of death in middle-aged women in Western countries. In 1985, 719,000 new cases were diagnosed world-wide. In England and Wales one in 12 women will develop the disease during their lifetime.

Aetiological factors

1. Geographical. It occurs commonly in the Western world accounting for 3—5 per cent of deaths, yet is a rare tumour in Japan. In developing countries it accounts for 1—3 per cent of deaths.

2. Age. Carcinoma of the breast is extremely rare below the age of 20, but thereafter the incidence steadily rises so that by the age of 90 nearly 20 per cent of women are affected (Fig. 46.27).

   By age 25    1 in 19608    By age 60    1 in 24
   By age 30    1 in 2525    By age 65    1 in 17
   By age 35    1 in 622     By age 70    1 in 14
   By age 40    1 in 217     By age 75    1 in 11
   By age 45    1 in 93      By age 80    1 in 10
   By age 50    1 in 50      By age 85    1 in 9
   By age 55    1 in 33      Ever    1 in 8

   1987—1988 Cancer incidence rates, NCI, USA.

3. Gender. Less than 1 per cent of patients with breast cancer are male.

4. Genetic. It occurs more commonly in women with a family history of breast cancer than in the general population. Breast cancer related to a specific mutation accounts for about 5 per cent of breast cancers, yet has far-reaching repercussions in terms of counselling and attempted prevention in these women. This will be discussed more fully in a subsequent section.

5. Diet. Because breast cancer so commonly affects women in the ‘developed’ world, dietary factors may play a part in its causation. There is some evidence that there is a link between diets low in phyto-oestrogens. A high intake of alcohol is associated with an increased risk of developing breast cancer.

6. Endocrine. Breast cancer is commoner in nulliparous women and breast feeding in particular appears to be protective. Also protective is having a first child at an early age, especially if associated with late menarche and early menopause. It is known that in postmenopausal women, breast cancer is more common in the obese. This is thought to be because of an increased conversion of steroid hormones to oestradiol in the body fat. The role of exogenous hormones, in particular the oral contraceptive pill and hormone replacement therapy, in the development of breast cancer is more controversial, but it can be said with some authority that for most women the benefits of these treatments will far outweigh the small putative risk.

The increase in the likelihood of developing breast cancer associated with the above risk factors is usually quantified in terms of the relative risk (RR). Thus a RR of 2.0 means that the individual has twice the chance of developing breast cancer as the average for the population, whilst a RR of 0.5 indicates a risk reduction of 50 per cent.

Pathology

Breast cancer may arise from the epithelium of the duct system anywhere from the nipple end of major lactiferous ducts to the terminal duct unit which is in the breast lobule. It may be entirely in situ — an increasingly common phenomenon with the advent of breast cancer screening — or may be invasive cancer. The degree of differentiation of the tumour is usually described by three grades — well differentiated, moderately or poorly differentiated. Ductal carcinoma is the most common variant, but lobular carcinoma occurs in up to 10 per cent of cases, although this may be mixed. Rarer histological variants, usually carrying a better prognosis, include colloid carcinoma whose cells produce abundant mucin, medullary carcinoma with solid sheets of large cells often associated with a marked lymphocytic reaction and tubular carcinoma. Invasive lobular carcinoma is commonly multi-focal and/or bilateral.

Inflammatory carcinoma is a fortunately rare, highly aggressive cancer which presents as a painful, swollen breast, which is warm with cutaneous oedema. This is due to blockage of the subdermal lymphatics with carcinoma cells. Inflammatory cancer usually involves at least one-third of the breast and may mimic a breast abscess. A biopsy will confirm the diagnosis and show undifferentiated carcinoma cells.

In situ carcinoma is preinvasive cancer which has not breached the epithelial basement membrane. This was previously a rare, usually asymptomatic finding in breast biopsy specimens but is becoming increasingly common owing to the advent of mammographic screening — it accounts for 20 per cent of cancers detected by screening. In situ carcinoma may be ductal (DCIS) or lobular (LCIS), the latter often multifocal and bilateral. Both are markers for the later development of invasive cancer which will go on to develop in at least 20 per cent of cases. Although mastectomy is curative, this is overtreatment in many cases and the best treatment for in situ carcinoma is the subject of a number of clinical trials.

Paget’s disease of the nipple

Paget’s disease of the nipple (Fig. 46.28a and b) is a superficial manifestation of an underlying breast carcinoma. It presents as an eczema-like condition of the nipple and areola which persists in spite of local treatment. The nipple is eroded slowly and eventually disappears. If left, the underlying carcinoma will sooner or later become clinically evident. Thus nipple eczema should be biopsied if there is any doubt about its cause. Microscopically Paget’s disease is characterised by the presence of large, ovoid cells with abundant, clear, pale-staining cytoplasm in the Malpighian layer of the epidermis.

The spread of mammary carcinoma

1. Local spread. The tumour increases in size and invades other portions of the breast. It tends to involve the skin and to penetrate the pectoral muscles, and even the chest wall.

2. Lymphyatic metastasis occurs primarily to the axillary lymph nodes and to the internal mammary chain of lymph nodes. The site of the tumour within the breast does not dictate which nodes will be involved, e.g. medial tumours spread just as readily to the axillary nodes as do lateral tumours. The involvement of lymph nodes is not necessarily a chronological event in the evolution of the carcinoma, but rather a marker for the metastatic potential of that tumour. In advanced disease there may be involvement of supravclavicular nodes and of any contralateral
lymph nodes.

3. Spread by the bloodstream. It is by this route that skeletal metastases occur (in order of frequency) in the lumbar vertebrae, femur, thoracic vertebrae, rib and skull; they are generally osteolytic. Metastases may also occur in the liver, lung and brain, and occasionally the adrenal glands and ovaries.

**Clinical presentation**

While any portion of the breast, including the axillary tail, may be involved, breast cancer commences most frequently in the upper, outer quadrant (Figs 46.29 and 46.30). Most breast cancers will present as a hard lump, which may be associated with indrawing of the nipple. As the disease advances locally there may be skin involvement with peau d’orange (Fig. 46.31) or frank ulceration and fixation to the chest wall (Fig. 46.32). This is described as cancer-en-cuirasse. About 5 per cent of breast cancers in the UK will present with either locally advanced disease or symptoms of metastatic disease. This figure is nearer 20 per cent in the developing world. These patients must then undergo a staging evaluation so that the full extent of their disease can be ascertained. This will include a careful clinical examination, chest X-ray, serum alkaline phosphatase and gamma glutamine transaminase (GGT), with liver ultrasound if these are abnormal, and an isotope bone scan (Fig. 46.33). This is important for both prognosis and treatment — a patient with widespread visceral metastases may obtain an increased length and quality of survival from systemic hormone or chemotherapy, but she is not likely to benefit from surgery as she will die from her metastases before local disease becomes a problem. In contrast, patients with relatively small (less than 5 cm in diameter) tumours confined to the breast and ipsilateral lymph nodes rarely need staging beyond a good clinical examination as the pick-up rate for distant metastases is so low.

**Phenomena resulting from lymphatic obstruction in Staging of breast cancer**

**Advanced breast cancer**

Peau d’orange is due to cutaneous lymphatic oedema. Where the infiltrated skin is tethered by the sweat ducts it cannot swell, leading to an appearance like orange skin. Occasionally the same phenomenon is seen over a chronic abscess.

Late oedema of the arm is a troublesome complication of breast cancer treatment fortunately seen less often now that radical axillary dissection and radiotherapy are rarely combined. It does however occasionally still occur after either modality of treatment alone and appears anytime from months to years after treatment. There is usually no precipitating cause but recurrent tumour should be excluded as neoplastic infiltration of the axilla can cause arm swelling due to both lymphatic and venous blockage. This neoplastic infiltration is often painful due to nerve involvement.

An oedematous limb is susceptible to bacterial infections following quite minor trauma, and these require vigorous antibiotic treatment. Treatment of late oedema is difficult but limb elevation, elastic arm stockings and pneumatic compression devices can be useful.

Cancer-en-cuirasse

It may be associated with a grossly swollen arm. This usually occurs in cases with local recurrence after mastectomy, and occasionally is seen to follow the distribution of irradiation to the chest wall. The condition may respond to palliative systemic treatment but prognosis in terms of survival is poor.

Lymphangiosarcoma (Fig. 46.34) is a rare complication of lymphoedema with an onset many years following the original treatment. It takes the form of multiple subcutaneous nodules in the upper limb and must be distinguished from recurrent carcinoma of the breast. The prognosis is poor but some cases respond to cytotoxic therapy or irradiation. Interscapulothoracic (forequarter) amputation is sometimes indicated.

There are two traditional systems of classification for breast carcinoma which predominantly rely on clinical staging of the disease. These are the Manchester system and the Inter-national Union Against Cancer TNM (tumour, nodes, metases) staging system. These are illustrated in Table 46.6.

The TNM system was an attempt to allow a common language amongst oncologists world-wide, thus allowing accurate information exchange and evaluation of studies of treatment, as well as providing prognostic information to aid in the planning of treatment for the individual patient. However, this refinement of taxonomy in fact contributes little to any of these activities.

Further subdivisions in the TNM system now mean that there are seven T-stages, four N-stages and three M-stages, allowing for 180 possible combinations. Pathological lymph node staging depends on both the number of lymph nodes removed, thus the extent of surgery, and how assidious the pathologist is in looking for deposits of tumour within the nodes. ‘M’ staging depends on what investigations have been performed — thus will vary between centres. Consequently staging is observer biased.

Although prognosis broadly correlates with stage, other factors also influence prognosis and should be assessed, for example the Nottingham Prognostic Index includes not only tumour size and lymph node status but tumour grade.

Conventional staging will indicate broadly which treatment is required but again other factors may be equally important. For example, surgical treatment of a small stage I, or II (T1 or T2) breast tumour usually requires only wide local excision rather than mastectomy — but the latter may have to be performed if the breast is very small, the tumour central or multifocal, or for patient preference. Equally the use of adjuvant systemic therapy is decided on not only tumour size and lymph node status but also biological measures such as oestrogen receptor status, patient age and menopausal status, and in the case of tamoxifen this can be recommended irrespective of clinicopathological variables.

Thus as we gain more knowledge of the biological variables which affect prognosis it becomes increasingly clear that it is these factors (discussed in more detail below) rather than anatomical mapping which influence outcome and treatment. Perhaps a more pragmatic approach would be to classify patients according to the treatment that they require. This is shown in Table 46.7.

**Prognosis of breast cancer**

The best indicators of likely prognosis in breast cancer are still tumours size and lymph node status (Fig. 46.35). However, it is realised that some large tumours will remain confined to the breast for decades whereas some very small tumours are incurable at diagnosis. Hence the prognosis of a cancer depends not on its chronological age but on its invasive and metastatic potential. In an attempt to define which tumours will behave aggressively, and thus require early systemic treatment, a host of prognostic factors has been described. These include histological grade of the tumour, hormone receptor status, measures of tumours proliferation such as 5-phase fraction and thymidine-labelling index, growth factor analysis and oncogene or oncogene product measurements. Many others are under investigation but have proved of little
practical value in patient management.
Treatment of cancer of the breast

As has been indicated above, treatment will largely depend upon clinical stage of the disease at presentation including not only classical TMN staging but often other tumour characteristics such as tumour grade. Treatment of early breast cancer will usually involve surgery with or without radiotherapy. Systemic therapy such as chemotherapy or hormone therapy is added if there are adverse prognostic factors such as lymph node invasion indicating a high likelihood of metastatic relapse. At the other end of the spectrum locally advanced or metastatic disease is usually treated by systemic therapy to palliate symptoms, with surgery playing a much smaller role.

The multidisciplinary team approach

As in all branches of medicine good doctor—patient communication plays a vital role in helping to alleviate patient anxiety. Participation of the patient in treatment decisions is of particular importance in breast cancer where there may be uncertainty as to the best therapeutic option and the desire to treat the patient within the protocol of a controlled clinical trial. As part of the preoperative and postoperative manage-ment of the patient it is often useful to employ the skills of a trained breast counsellor and also to have available advice on breast prostheses, psychological support and physiotherapy, where appropriate. In many specialist centres the care of breast cancer patients is undertaken as a joint venture between the surgeon, medical oncologist, radiotherapist and allied health professionals such as the clinical nurse specialist.

Treatment of early breast cancer

The aims of treatment are:

1. ‘cure’: possible in some patients but recurrence up to 20 years after initial treatment is nor uncommon;
2. control of local disease in the breast and axilla;
3. conservation of local form and function;
4. prevention or delay of the occurrence of distant metastases.

Local treatment of early breast cancer

Local control is achieved through surgery and/or radiotherapy.

Surgery

Surgery still has a central role to play in the management of breast cancer but there has been a gradual shift towards more conservative techniques, backed up by clinical trials which have shown equal efficacy between mastectomy and local excision followed by radiotherapy. This followed a change in the model of breast cancer spread, which is no longer thought of as a centrifugal anatomical spread but rather that it is the presence of micrometastases which predetermines the outcome of the disease. It was initially hoped that avoiding mastectomy would help to alleviate the considerable psychological morbidity associated with breast cancer, but recent studies have shown that over 30 per cent of women develop significant anxiety and depression following both radical and conservative surgery. After mastectomy they tend to worry about the effect of the operation on their appearance and relationships whilst after conservative surgery women may remain fearful of a recurrence.

Mastectomy is now only strictly indicated for large tumours (in relation to the size of the breast), central tumours beneath or involving the nipple, multifocal disease, local recurrence or for patient preference. The radical Halstead mastectomy which included excision of the breast, axillary lymph nodes, pectoralis major and minor muscles is no longer indicated as it causes excessive morbidity with no survival benefit. Modified radical (‘Patey’) mastectomy is more commonly performed and thus is described below. Simple mastectomy involves removal of the breast only with no dissection of the axilla, except for the region of the axillary tail of the breast which usually has attached to it a few nodes low in the anterior group. Because no pathological staging of the axilla is performed with a simple mastectomy, it is often followed by radiotherapy to the axilla.

Patey’ mastectomy. The breast and associated structures are dissected en bloc (see Fig. 46.36) and the excised mass is composed of:

• the whole breast;
• a large portion of skin, the centre of which overlies the tumour, but always includes the nipple;
• all of the fat, fascia and lymph nodes of the axilla. The pectoralis minor muscle is either divided or removed to gain access to the upper two-thirds of the axilla. The axillary vein and nerves to serratus anterior and latissimus dorsi should be preserved.

The wound is drained using a wide-bore suction tube.

Early mobilisation of the arm is encouraged and physiotherapy helps normal function to return very quickly — most patients are able to resume light work or housework within a few weeks. Conservative breast cancer surgery is aimed at removing the tumour plus a rim of at least 1 cm of normal breast tissue. This is commonly referred to as a wide local excision or lumpectomy. A quadrantectomy involves removing the entire segment of the breast which contains the tumour. These are usually combined with axillary surgery, usually via a separate incision in the axilla, to either sample the axilla, remove nodes behind and lateral to pectoralis minor (level II) or perform a full axillary dissection (level III). A quadrantectomy, axillary dissection and radiotherapy is known as QUART and has been popularised by Professor Umberto Veronesi from Milan. Whilst it is recognised that there is a somewhat higher rate of local recurrence following conservative surgery, even if combined with radiotherapy, the long-term outlook in terms of survival is unchanged.

The role of axillary surgery is still debated, but it is accepted that the presence of metastatic disease within the axillary lymph nodes is still the best marker for prognosis. Treatment, of the axilla does not affect long-term survival, suggesting that the axillary nodes act not as a ‘reservoir’ for disease but as a marker for metastatic potential. An acceptable way to approach this problem in premenopausal women is to stage the axilla by operation as there is a good case for giving chemotherapy to lymph node-positive patients. In postmenopausal patients, tamoxifen is usually given regardless of axillary lymph node status. If mastectomy is performed it is reasonable to clear the axilla as part of the operation, but if a wide local excision is planned the surgeon may choose either operative dissection or postoperative radiotherapy. Axillary surgery should not be combined with radiotherapy to the axilla because of excess morbidity. Removal of the internal mammary lymph nodes is unnecessary.

Sentinal node biopsy is a technique currently under evaluation which may well prove the way forward in the future in the management of the...
axilla in patients with clinically node-negative disease. The sentinel node is localised peroperatively by the injection of patent blue dye and/or radioisotope-labelled albumin near the tumour. The marker will pass to the primary node draining the area, be detected visually or with a hand-held gamma camera, and sent for frozen section histological analysis. In patients in whom there is no tumour involvement of the sentinel node, it is hoped that further axillary dissection can be avoided as skip lesions are thought to occur in less than 3 per cent of patients.

Radiotherapy

Radiotherapy to the chest wall after mastectomy has been largely abandoned except in cases of extensive local disease with infiltration of the chest wall. It is conventional to com-bine conservative surgery with radiotherapy to the remaining breast tissue. However, there is currently doubt as to whether all patients undergoing conservative surgery should receive radiotherapy as most will not develop local recurrence and thus will be overtreated by adjuvant radiotherapy, which is not without morbidity and even long-term mortality from inadvertent irradiation to the myocardium. A UK national clinical trial is currently underway to try to ascertain whether there is a survival advantage with radiotherapy and to identify which patients are at highest risk of local relapse, and thus would benefit most from postoperative breast irradiation. Currently there is at least some evidence that those with extensive in situ carcinoma (or of course invasive cancer) at the margins of excision, patients under 35 years and those with multifocal disease.

Adjuvant systemic therapy

Over the last 25 years there has been a revolution in our understanding of the biological nature of carcinoma of the breast. It is now widely accepted that the outcomes of treat-ment are predetermined by the extent of micrometastatic disease at the time of diagnosis. Variations in the radical extent of local therapy might influence local relapse, but probably do not alter long-term mortality from the disease. However, systemic therapy targeted at these putative micro-metastases might be expected to delay relapse and prolong survival. As a result of many international clinical trials and recent world overview analyses, it can be stated with extreme statistical confidence that the appropriate use of adjuvant chemotherapy or hormone therapy will improve relapse-free survival by approximately 30 per cent, which ultimately translates into an absolute improvement in survival of the order of 10 per cent at 15 years. Bearing in mind how common the disease is in Northern Europe and the USA, this translates into figures of major public health importance.

Who to treat and with what are still questions for which absolute answers have yet to found, but the data from an overview of recent trials suggest that lymph node-positive and poor prognosis node-negative prememopausal women should be recommended adjuvant combined chemotherapy and that postmenopausal women will obtain a worthwhile benefit from about 5 years of tamoxifen, 20 mg daily.

Hormone therapy

Tamoxifen is the most widely used ‘hormonal’ treatment in breast cancer. Its efficacy as an adjuvant therapy was first reported in 1983 and it has now been shown to reduce the annual rate of recurrence by 25 per cent, with a 17 per cent reduction in the annual rate of death. The effect of tamoxifen is favourable in most cases except for oestrogen receptor ER-negative prememopausal women; postmenopausal women with oestrogen receptor-rich (positive) tumours achieve a greater reduction in the relative risk of relapse than oestrogen receptor-negative cases. The beneficial effects of tamoxifen in reducing the risk of tumours in the contralateral breast have also been observed. Trials studying the optimal duration of treatment are close to maturity and suggest that 5 years of treatment may be preferable to 2 years.

Other hormonal agents are being developed which may prove beneficial as adjuvant therapy, such as the LHRH agonists which induce a reversible ovarian suppression and thus are hoped to have the same beneficial effects as surgical or radiation-induced ovarian ablation in premenopausal women, and the oral aromatase inhibitors for postmenopausal women.

Chemotherapy

Chemotherapy using a regimen such as a 6-monthly cycle of cyclophosphamide, methotrexate and 5-fluorouracil (CMF) will achieve a 30 per cent reduction in the risk of relapse over a 10—15-year period. This treatment has been confined to prememopausal poor prognosis women (where its effects are likely to be due in part to a chemical castration effect) but is being increasingly offered to postmenopausal women with poor prognosis disease as well. Chemotherapy may be considered for node-negative patients if other prognostic factors such as tumour grade infer a high risk of recurrence. The effect of combining hormone and chemotherapy is still under investigation and is beginning to look promising.

High-dose chemotherapy with stem cell rescue for patients with heavy lymph node involvement is still considered experimental and should not be offered outside controlled trials.

Primary chemotherapy is being used in many centres for large but operable tumours that would traditionally require a mastectomy (and almost certainly postoperative adjuvant chemotherapy). The aim of this treatment is to shrink the tumour to enable breast-conserving surgery to be performed. This approach is successful in up to 80 per cent of cases, but is not associated with improvements in survival compared with conventionally timed chemotherapy.

Breast reconstruction

Despite an increasing trend toward conservative surgery, up to 50 per cent of women still require, or want, a mastectomy. These women can now be offered immediate or delayed reconstruction of the breast. Few contraindications to breast reconstruction exist — even those with a limited life expectancy may benefit from the improved quality of life, however patients do require counselling before this procedure so that their expectations of cosmetic outcome are not unrealistic.

The most common type of reconstruction is using a silicone gel implant under the pectoralis major muscle.

This may be combined with prior tissue expansion using an expandable saline prosthesis first (or a combined device — Fig. 46.37) which creates some ptosis of the new breast. If the skin at the mastectomy site is poor (for example following radiotherapy) or if a larger volume of tissue is required, a musculocutaneous flap can be constructed from either the latissimus dorsi muscle (an LD flap) or the contralateral transversus abdominis muscle (a TRAM flap — shown in Fig. 46.38). The latter gives an excellent cosmetic result in experienced hands but is a lengthy procedure and requires careful patient selection.

Nipple reconstruction is a relatively simple procedure which can be performed under a local anaesthetic. Alternatively the patient can be fitted with a prosthetic nipple. To achieve symmetry, the opposite breast may require a cosmetic procedure such as reduction or augmentation mammoplasty, or mastopexy. A breast reconstructive service can be offered by a suitably trained breast surgeon, a plastic surgeon or ideally a combined oncoplastic approach.
External breast prostheses which fit within the bra may also be recommended and some of these are illustrated in Fig. 46.39.
Screening for breast cancer

Because the prognosis of breast cancer is closely related to stage at diagnosis, it would seem reasonable to hope that a population screening programme which could detect tumours before they come to the patient’s notice may reduce mortality from breast cancer. A number of studies has indeed shown that breast screening by mammography in women over the age of 50 will reduce cause-specific mortality by up to 30 per cent. Following the publication in 1987 of the Forrest report the National Health Service in the UK has launched a programme of 3-yearly mammographic screening for women between the ages of 50 and 64. The introduction of this programme has undoubtedly improved the quality of breast cancer services but a number of questions remains unanswered including the value of screening women under 50 and the ideal interval between screenings. The psychological consequences of false alarms or false reassurances still need to be addressed and self-examination programmes which have failed to show any benefit for the population in terms of earlier or decreased mortality from breast cancer still remain controversial. Figure 46.40 illustrates some benefits and disadvantages of screening. The senior author remains doubtful regarding the value of a screening programme in terms of the wider implications of healthcare planning.
Familial breast cancer

Recent developments in molecular genetics and the identification of a number of breast cancer predisposition genes (BRCA1, BRCA2 and TPS3) have done much to stimulate interest in this fascinating area. Yet women whose breast cancer is due to an inherited genetic change actually account for less than 5 per cent of all breast cancers — that is about 1250 cases per year in the UK and 9000 cases in the USA. A much larger number of women will have a risk elevated above normal due to an as yet unspecified familial inheritance. These women have a risk of developing breast cancer two to 10 times above baseline.

The risks associated with family history are summarised in Table 46.8.

The BRCA1 gene has been cloned and is located on the long arm of chromosome 17 (17q). The gene frequency in the population is approximately 0.0006. BRCA2 is located on chromosome 13q. Women who are thought to be gene carriers may be offered breast screening (and ovarian screening in the case of BRCA1, which is known to impart a 50 per cent lifetime risk of ovarian cancer), usually as part of a research programme, or may be offered generic counselling and mutation analysis. Those who prove to be ‘gene positive’ have an 80 per cent risk of developing breast cancer, predominantly whilst premenopausal. Many will opt for prophylactic mastectomy, although this does not completely eliminate the risk.

For those with a positive family history who are unlikely to be carriers of a breast cancer gene, which will comprise the great majority of women, there is no currently proven preventive or screening manoeuvre, although these are under investigation. Thus these women are best served by being assessed and followed up, if necessary, in a properly organised research family history clinic.

Pregnancy

The effects of pregnancy on breast cancer are not well studied but it is thought that breast cancer presenting during pregnancy or lactation tends to be at a later stage — presumably because the symptoms are masked by the pregnancy — but in other respects it behaves in a similar way to breast cancer in a nonpregnant young woman, and should be treated accordingly. Thus treatment is similar with some provisos:

- radiotherapy should be avoided during pregnancy, making mastectomy a more frequent option than breast conservation surgery;
- chemotherapy should be avoided during the first trimester but is probably safe subsequently; most tumours are hormone receptor negative and so hormone treatment, which is potentially teratogenic, is not required. Becoming pregnant subsequent to a diagnosis of breast cancer appears not to alter likely outcome, but women are usually advised to wait at least 2 years, as it is within this time that recurrence most often occurs.

The risk of developing breast cancer with oral contraceptive use is only slight, and disappears 10 years after stopping the Pill.
Hormone-replacement therapy

Hormone-replacement therapy (HRT) does not appear to increase significantly the risk of developing breast cancer unless taken for prolonged periods (over 10 years), and perhaps in certain high-risk groups. HRT may, however, prolong symptoms of benign breast disorder and make mammographic appearances more difficult to interpret.

Patients who develop breast cancer whilst on HRT appear to have a more favourable prognosis. The consequences in terms of recurrence in women using HRT following breast cancer are unknown.
Treatment of advanced breast cancer

Breast cancer may occasionally present as metastatic disease without evidence of a primary tumour (that is with an occult primary). The diagnosis is made partly by exclusion of another site for the primary and may be confirmed by histology of the metastatic lesions. Treatment should be aimed at palliation of the symptoms and treating the breast cancer, usually by endocrine manipulation.

Locally advanced inoperable breast cancer

Locally advanced inoperable breast cancer, including inflammatory breast cancer, is usually treated with systemic therapy—either chemotherapy or hormone therapy.

Occasionally 'toilet mastectomy' or radiotherapy is required to control a fungating tumour, but often incision through microscopically permeated tissues makes the outcome worse than the original.

Metastatic carcinoma of the breast

Metastatic carcinoma of the breast will also require some form of palliative systemic therapy to alleviate symptoms. Hormone manipulation is often the first line because of its minimal side effects. It is particularly useful for bony metastases. However, only about 30 per cent of these tumours will be hormone responsive, and unfortunately even these will in time become resistant to this treatment. First-line hormone therapy for postmenopausal women is tamoxifen, and for premenopausal women ovarian suppression, but where resistance to these has developed, other hormonal agents can prove useful, with about half of the response rate seen in the first-line therapy. Synthetic progestagens such as medroxy-progesterone acetate ('Provera') aromatase inhibitors or the newer agents such as antiprogestins and pure antioestrogens are all candidates for this role.

Cytotoxic therapy is used, particularly in younger women or those with visceral metastases and rapidly growing tumours. A variety of regimens is available and although none prolongs survival, contrary to expectations quality of life and symptom control is often better with more aggressive treatments, responses being seen in up to 70 per cent of patients.

Local treatment may also prove useful for some metastatic disease such as radiotherapy for painful bony deposits and internal fixation of pathological fractures.
The male breast

Gynaecomastia

Idiopathic

Hypertrophy of the male breast may be unilateral or bilateral. The breasts enlarge at puberty and sometimes present the characteristics of female breasts (Fig. 46.41).

Hormonal

Enlargement of the breasts often accompanied stilboestrol therapy for prostate cancer — now rarely used. It may also occur as a result of a teratoma of the testis, in anorchism and after castration. Rarely it may he a feature of ectopic hormonal production in bronchial carcinoma and in adrenal and pituitary disease.

Associated with leprosy

Gynaecomastia is very common in men suffering from leprosy. This is possibly because of bilateral testicular atrophy, which is a frequent accompaniment of leprosy.

Associated with liver failure

Gynaecomastia sometimes occurs in patients with cirrhosis due to failure of the liver to metabolise oestrogens. It is associated with drugs that interfere with the hepatic metabolism of oestrogens, such as cimetidine.

Gynaecomastia may occur in patients with Klinefelter’s syndrome, a sex chromosome anomaly having XXY trisomy. It is also seen with certain drugs such as cimetidine, digitalis and spironolactone.

Treatment

Provided the patient is healthy and comparatively young, reassurance may be sufficient. If not mastectomy with preservation of the areola and nipple can be performed.

Carcinoma of the male breast

Carcinoma of the male breast (Figs 46.42 and 46.43) accounts for less than 2 per cent of all cases of breast cancer. The known predisposing causes include gynaecomastia and excess endogenous or exogenous oestrogen. As in the female it tends to present as a lump and is most commonly an infiltrating ductal carcinoma.

Treatment

Stage for stage the treatment is the same as for carcinoma in the female and prognosis depends upon stage at presentation. Adequate local excision, because of the small size of the breast, should always be with a mastectomy.
Other tumours of the breast

Lipoma

A true lipoma is very rare.

Sarcoma of the breast

Sarcoma of the breast is usually of the spindle-cell variety, and accounts for 0.5 per cent of malignant tumours of the breast. Some of these growths arise in an intracanalicular fibroadenoma or may follow previous radiotherapy, e.g. for Hodgkin’s lymphoma many years previously. It may be impossible to distinguish clinically a sarcoma of the breast from a medullary carcinoma, but areas of cystic degeneration suggest a sarcoma and on incising the neoplasm it is pale and friable. Sarcoma tends to occur in younger women between the ages of 30 and 40. Treatment is by simple mastectomy followed by radiotherapy. The prognosis depends on the stage and histological type.

Metastases

On rare occasions, cancer elsewhere may present with a metastasis in the breast. The breast is also occasionally infiltrated by Hodgkin’s disease and other lymphomas.

Thoracic trauma

Many of the surgically treatable conditions of the lung are treated at specialist thoracic centres and the only exposure to thoracic surgery that most surgeons have is dealing with thoracic trauma. The approach to treatment must be methodical and exact because the signs, particularly in the presence of other injury, may be easily missed. The guidelines produced by the American College of Surgeons Advanced Trauma Life Support (ATLS®) Group provide a thorough and unambiguous approach to trauma. The general principles of resuscitation and need for priorities are extensively discussed and will not be repeated here. However, the specific aspects of trauma management related to the thorax will be covered. Thoracic trauma is responsible for over 70 per cent of all deaths following road traffic accidents. Blunt trauma to the chest in isolation is fatal in 10 per cent of cases, rising to 30 per cent if other injuries are present. An increasing number of penetrating thoracic wounds is also seen from domestic and civil violence, with a mortality rate of 3 per cent for simple stabbing to 15 per cent for gunshot wounds.

Initial management

Early deaths after thoracic trauma are caused by hypoxemia, hypovolaemia and tamponade. The first steps in treating these patients should be to diagnose and treat these problems as early as possible because they may be readily corrected. Young patients have a large physiological reserve and serious injury may be overlooked until this reserve is used up; then the situation is critical and may be irretrievable. The best approach is to maintain a high index of suspicion and suspect the worst if life-threatening conditions are to be anticipated and treated. Early consultation with a regional thoracic centre is advised in cases of doubt. In an emergency it is essential that experienced help is summoned immediately.

The basic principles of resuscitation are securing the airway and restoring the circulating volume. Blood and secretions are removed from the oropharynx by suction. If the patient is unable to maintain his or her airway then an oropharyngeal airway followed by tracheal intubation (once a cervical spine injury is excluded) may be necessary.

A thorough inspection of the chest wall includes noting the frequency and pattern of breathing, external evidence of trauma and structural defects of the thorax. Palpation will detect surgical emphysema, paradoxical movement and a stobe-in chest. Auscultation and percussion should reveal the existence of a pneumothorax (there is decreased movement on the affected side with a hyperresonant percussion note, reduced breath sounds in the axilla and shift of the trachea to the opposite side) which requires emergency drainage (see Pneumothorax for a more detailed appraisal and see Chest drainage for advice on technique of drain insertion).

Once the patient has been stabilised then radiographs of the chest should be taken and further treatment decided on the basis of the patient’s condition and the radiographic result. It is rarely necessary to perform a thoracotomy in the resuscitation room but, in the case of tamponade from a penetrating injury, it might be life saving. However, the fact is that, even in experienced hands, the yield in terms of survival in this group of patients is very small. If there is profound hypotension as a result of cardiac tamponade, needle aspiration of the pericardium is life saving and may hold the situation long enough for more controlled surgery to be performed.

The components of chest injury in blunt trauma

Any combination of structures may be involved in varying degrees of severity. If the skeletal injuries are severe, underlying parenchymal injuries are likely to be in proportion; however, in younger flexible chests, or those restrained by seat belts, there may be little external evidence of the severity of internal damage.

Chest wall

Localised rib fracture due to direct trauma. A simple rib fracture may be serious in elderly people or in those with chronic lung disease who have little pulmonary reserve. Uncomplicated fractures require sufficient analgesia to encourage a normal respiratory pattern and effective coughing. Oral analgesia may suffice but intercostal nerve blockade with local anaesthesia may be very helpful. Chest strapping or bed rest is no longer advised and early ambulation with vigorous physiotherapy (and oral antibiotics if necessary) is encouraged. A chest radiograph is always taken to exclude an underlying pneumothorax. It is useful to confirm the skeletal injuries but routine chest radiography may miss rib fractures. However, once a pneumothorax and major skeletal injuries are excluded, the management is the same — the local control of chest pain.

Major chest wall trauma. Flail chest (Fig. 47.1). This occurs when several adjacent ribs are fractured in two places either on one side of the chest or either side of the sternum. The flail segment moves paradoxically, that is, inwards during inspiration and outwards during expiration, thereby reducing effective gas exchange. The net result is poor oxygenation from injury to the underlying lung parenchyma and paradoxical movement of the flail segment. The underlying lung injury with loss of alveolar function may result in deoxygenated blood passing into the systemic circulation. This creates a right-to-left shunt and prevents full saturation of arterial blood. In the absence of any other injuries and, if the segment is small and not embarrassing respiration, the patient may be nursed on a high-dependency unit with regular blood gas analysis and good analgesia until the flail segment stabilises. In the more severe case, endotracheal intubation is required with positive pressure ventilation for up to 3 weeks, until the fractures become less mobile. Thoracotomy with fracture fixation is occasionally appropriate if there is an underlying lung injury to be treated at the same time. An anterior flail segment with the sternum moving paradoxically with respiration can be stabilised by internal fixation but operative management is not usual for either.

First rib fracture. Fracture of the first rib should alert the clinician to a potentially serious chest injury. This rib is well protected and requires a considerable force to fracture and associated injuries to the great vessels, abdomen, head and neck are common. The mortality rate associated with a fracture of the first rib exceeds 30 per cent. Similar suspicions are raised when fractures of the sternum and scapula are seen. Fractures of the lower ribs may involve underlying abdominal viscera (spleen on the left and liver on the right). Intercostal artery bleeding may still be severe, resulting in haemothorax.

Fractures of the sternum (Fig. 47.2). This injury is now seen as a result of deceleration on to seat belts. Steering wheel injuries are now much less common. The injury is very painful even in the mild case where only the external plate of the sternum is fractured. However, there is a real risk of underlying myocardial damage and the patient should be observed in hospital with constant electrocardiogram (ECG) monitoring, analgesia and serial cardiac enzymes. Rupture of the aorta and associated cervical spine injuries also need to be excluded. Most cases need no specific treatment but paradoxical movement or instability of the chest may need more active management. It should be remembered that sternal fracture may occur during closed cardiac massage.

Vertebrea. The thoracic spine may be injured as one componet of multiple injury or in isolation. It is more usual for the cervical spine to be injured and this must be excluded before any manipulations or movements take place. Damage to the thoracic spine is likely to be associated with injuries to other thoracic viscera. The assessment and treatment of spinal injury are discussed in Chapter 33. However, the thoracic spine injury is a reminder that, in patients where the chest injury predominates, a quick screening neurological examination confirming the integrity of
the nerve supply to the lower limbs should be performed and documented.

**Pleura.** If the visceral pleura is breached (most commonly by a rib fracture) pneumothorax follows. Generation of post-tive pressure in the airways by coughing, straining, groaning or positive pressure ventilation will result in tension pneumo-thorax. The pleural space may also fill with blood as a result of injury anywhere in its vicinity. Remember that an erect chest radiograph is the only sure way to confirm or exclude the diagnosis of pneumothorax and should be obtained if at all possible. Early management of tension pneumo-thorax is life-saving. Good management of the pleural space pre-empts many later complications from clotted haemothorax, constriction of the lung and empyema. The diagnosis and management of a simple pneumothorax are discussed in detail later, but in the trauma situation it is imperative to consider tension pneumothorax and haemothorax.

Traumatic pneumothorax. Blunt trauma to the chest wall may result in a lung laceration from a rib fracture. All traumatic pneumothoraces require drainage through an under-water seal drain because of the possibility that they may become a tension pneumothorax with mediastinal shift and circulatory collapse. There is decreased air entry on the affected side and the trachea may be pushed over to the opposite side. There is an increased percussion note and reduced breath sounds. If a tension pneumothorax is suspected on clinical grounds, treatment is necessary before radiographs can be taken. A wide-bore needle introduced into the affected hemithorax will release any air undetension and is life saving. A wide-bore intercostal tube is introduced laterally and directed to the apex of the pleural cavity. A second drain may be introduced basally to drain blood. Chest drain insertion. Insertion of a chest drain is indicated when there is air or fluid in the pleural cavity (Fig. 47.3). The site of insertion is in the triangle of safety which is defined as the anterior border of the latissimus dorsi, the posterior border of the pectoralis major and the superior border of the fifth rib. The area chosen is infiltrated with local anaesthetic and an incision is made in the skin and subcutaneous tissues, sufficient to admit a finger easily. The intercostal muscles are separated with artery forceps and the pleura is punctured. The intercostal drainage tube is inserted with the stylette withdrawn; so as not to damage the underlying lung tissue. A large-bore tube is used for the drainage of blood and fluids, whereas a smaller-bore tube may be used for the removal of air.

Traumatic haemothorax. Drainage is essential because re-expansion of the lacerated lung compresses the torn vessels and reduces further blood loss. Drainage will also allow the mediastinal structures to return to the midline and relieve compression of the contralateral lung. If left, a dense fibro-thorax will result, with the possibility of an added empyema. The procedure is similar to drainage for pneumothorax but a wide-bore tube (>28 Fr) is required and a basal drain is sometimes necessary. Continuing blood loss in excess of 200 ml/hour may require urgent thoracotomy within the first few hours.

**Lung parenchyma**

Lung contusion. The underlying lung is often injured in moderate-to-severe blunt thoracic trauma and the area of contusion may be extensive. This usually resolves but lacerations with persistent air leak may require exploration by thoracotomy. It is important to prevent infection of the underlying lung by early mobilisation (if the patient’s condition permits), prophylactic antibiotics, suction drainage and physiotherapy. The importance of a good-quality posteroanterior erect chest radiograph following any trauma to the lung cannot be overemphasised (Fig. 47.4).

**Major airways**

Injuries to major bronchi are infrequently seen as the patient rarely survives the insult leading to major airway disruption. There is usually a combination of surgical emphysema, haemoptysis and pneumothorax. Chest drainage in spite of the addition of suction fails to re-inflate the lung and a persistent air leak may be present. Injury to the trachea requires considerable force and consequently less than a quarter of patients survive to reach hospital. The injury may be from direct trauma or the result of high intratracheal pressure against a closed glottis. There is hoarseness, dyspnoea and surgical empysema. The exact pattern of signs will depend on the site of the injury and whether or not the pleura has been breached. The treatment is exploration and repair if possible. Resection of lung should be avoided as a surprising degree of recovery may occur.

**Diaphragm**

Diaphragmatic rupture. The mechanism for diaphragmatic rupture is high-speed blunt abdominal trauma with a closed glottis. The sudden rise in intra-abdominal pressure breaches the weakest part of the abdominal wall, namely the diaphragm. This occurs much more commonly on the left hemidiaphragm (the right is protected by the liver). Colon and stomach may herniate into the thorax, displacing the lung. Bowel sounds may be heard in the chest and the chest radiograph may reveal bowel gas in the lung fields. A contrast study will confirm the diagnosis. Occasionally, the injury is overlooked and the patient presents some time later with a diaphragmatic hernia. Cases presenting acutely should be explored by thoracotomy not only to repair the diaphragm and prevent respiratory embarrassment, but to exclude injury to an underlying abdominal viscus such as the spleen. Penetrating injuries below the level of the eighth rib may penetrate the diaphragm and injure an underlying abdominal viscus.

**Oesophageal injury**

The oesophagus is rarely injured in blunt trauma. The management of penetrating trauma to the oesophagus is discussed in Chapter 50.

**Cardiac injury**

Major injuries to the heart and great vessels from blunt trauma are frequently fatal and the patient rarely survives long enough to reach hospital. The injuries that are encountered in the accident and emergency department are the following.

Myocardial contusion. This must be suspected when the sternum is fractured, although the true incidence is not known. Myocardial damage from trauma will give an ECG pattern similar to myocardial infarction and enzyme changes may occur. In severe trauma there may be arrhythmias and signs of heart failure. Patients with ECG changes and enzyme rises even in the absence of any problems should be nursed in a high-dependence area with full monitoring and resuscitation equipment available. There is no specific treatment in the uncomplicated case but the risk of fatal arrhythmia diminishes after 48 hours or until the enzymes have returned to normal and any ECG changes have resolved. Occlusion of the coronary arteries progressing to discrete, localised myocardial infarction has been documented.

Chamber rupture and valve blow-out. This is well described and is thought to occur if the ventricle is compressed just before systole at the point of maximal diastolic filling. Chamber rupture is likely to be fatal and those that do survive are likely to have an atrial rupture. Rupture of the mitral or tricuspid valve may not be immediately apparent, but a loud pansystolic murmur should arouse suspicion. Surgical treatment usually results in dramatic improvement in these patients.

**Aorta**

Aortic transection (Fig. 47.5). This is usually the result of a major deceleration injury (road traffic accident or a fall from a height) and the patient often has other injuries. However, only about 15 per cent of patients with aortic transection survive long enough to reach hospital. Of these,
two-thirds would die of late rupture within 14 days and the remainder would be at risk from rupture of a developing chronic false aneurysm. The site is remarkably consistent (Fig. 47.5a), presumably the anatomy of the aorta determining the site of rupture. The vessel is relatively fixed at the site of the ligamentum arteriosum, just distal to the left subclavian artery, and from there down is tethered to the vertebral column by intercostal arteries and mediastinal pleura. The shear forces from a sudden impact disrupt the intima and media, resulting in retraction. If the intima is not breached, the patient may be stable but the development of a left-sided pleural effusion is an ominous sign. Transection of the aorta must be suspected in all high-speed deceleration incidents. The clinical signs may be masked by concurrent injury but include intracapular pain, a murmur, hoarseness and radiofemoral delay of the arterial pulse. The condition may be completely asymptomatic. A good-quality posteroanterior chest radiograph showing widening of the mediastinum is very suspicious. Portable chest radiographs taken from the front (anterior) always magnify the mediastinal shadow and cause uncertainty. Aortography is the diagnostic investigation and should be available at most hospitals. Computerised tomography (CT) may be unhelpful and misleading because transections have little length and intimal lesions are missed on 1-cm slices (in marked contrast to aortic dissection where CT is a valuable investigation). Once the diagnosis is made the treatment is urgent exploration via a left thoracotomy through the fourth intercostal space. Control above and below the transection is vital and the aorta is repaired by direct suture or interposition graft (Fig. 47.6). There is a risk of paraplegia (12 per cent) with this procedure and this should be specifically mentioned to the patient and the relatives before surgery. A heparin-bonded shunt (Gott) to maintain lower body perfusion may reduce the risk of paraplegia. Cardiopulmonary bypass is unsafe because systemic heparinisation is required in an already multiply injured patient.

Management of blunt chest trauma

Most chest injuries where the heart is not injured are managed conservatively with underwater seal drainage if necessary, and oxygen and physiotherapy to help the patient to expectorate while the underlying lung parenchyma heals. In about 10 per cent of cases a thoracotomy is required. The indications for thoracotomy following blunt thoracic trauma are the following:

• 50–1000 ml of blood at the time of initial drainage is common and may need no further action, but greater volumes, especially if the blood is fresh, require intervention;
• continued brisk bleeding (>100 ml/15 minutes) from the intercostal drains indicates a serious breach of the lung parenchyma and urgent exploration is required;
• continued bleeding of >200 ml/hour for 3 or more hours may require thoracotomy under controlled conditions;
• rupture of the bronchus, aorta, oesophagus or diaphragm;
• cardiac tamponade (if needle aspiration is unsuccessful).

All explorations following trauma should have double-lumen tube endotracheal intubation to facilitate surgery on the injured side and to protect the undamaged lung.

If transfer is undertaken, the patient must be stabilised before the journey. All lines must be secured and ECG monitoring available. Chest drains must not be clamped during transfer and a medically qualified person should accompany the patient.

Penetrating injury

In some aspects, penetrating thoracic injury is simpler to deal with than blunt trauma because the wound is visible and the structures at risk can be quickly assessed. A defect in the chest wall through to the pleura is a ‘sucking wound’. The underlying lung collapses and air moves in and out of the thorax with each breath. Emergency treatment involves sealing the wound and intercostal drainage. Definitive treatment may then follow. It is important to establish the path or track of bullet and stab wounds in the chest as there may be damage to the heart, great vessels, and the diaphragm and abdominal viscera in addition to the lung injury.

They are bringing him down,
He looks at me wanly.

The bandages are brown,
Brown with mud, red only —But how deep a red in the breast of the shirt,
Deepening red too, as each whistling breath
Is drawn with the suck of a slow filling squirt
While waxen cheeks waste to the pallor of death. From

Bullet wounds create a cavitating defect in the tissues that they pass through. The tissue damage may be very extensive with high-velocity missiles, and entry and exit wounds should be noted. Lung tissue is more compliant than the bone and muscles that comprise the limbs, and enthusiastic resection along the track can be avoided in most cases. Tetanus prophylaxis and high-dose antibiotics (to cover anaerobic organisms) should be given. Bullets lodged in the lung do not require removal if they are not causing any problems.

Penetrating wound of the heart

This is usually the result of a stabbing or shooting incident, but can also be iatrogenic from central line placement, cardiac catheterisation and endomyocardial biopsy. Cardiac tamponade may occur rapidly even with small amounts of blood in the pericardium and the condition is recognised by low blood pressure, tachycardia, a high central venous press-sure, pulsus paradoxus and faint heart sound (Fig. 47.7). Emergency treatment includes aspiration of the pericardium by advancing a wide-bore needle to the left of the xiphisternum towards the heart. This may hold the situation until surgical repair is performed. The heart is exposed via a median sternotomy with incision of the pericardium in the midline. For the more generally trained surgeon or those without the necessary equipment to saw the sternum, a left anterior thoracotomy may be preferred. The pericardial cavity is evacuated and the cardiac defect repaired using buttressed sutures. Bullets in cardiac chambers should be removed under cardiopulmonary bypass.

How to do a thoracotomy

All surgeons dealing with trauma victims should be able to perform a thoracotomy if required. The standard route into the thoracic cavity is
through a posterolateral thoracotomy. The incision is used for access to:

- the lung and major bronchi;
- the thoracic aorta (aneurysm resection, repair of transection, coarctation repair and ligation of patent ductus arteriosus);
- the oesophagus (resection and repair);
- the posterior mediastinum (for mediastinal mass resection).

Following induction of anaesthesia, a preoperative rigid bronchoscopy is performed, especially if a resection for cancer is contemplated. A double-lumen tube is used to control the lungs separately, if desired. Ventilation may be maintained by ventilating one lung while the other is collapsed to facilitate surgery. However, remember that they were devised to protect the underlying lung from pus and blood, and to stay under the anaesthetist’s control. The patient is turned on to the unaffected side in the lateral position (Fig. 47.8). The lower leg is flexed at the hip and the knee with a pillow between the legs. Table supports are used to maintain the position and additional strapping is used at the hips for stability. The upper arm is supported by a bracket in a position of 90° flexion. The lower arm is flexed and positioned by the head. It is important for the surgeon to be completely satisfied with the position of the patient at this stage.

The incision is made from 1 to 2 cm inferolateral to the nipple in men and the inframammary fold in women. The incision extends along 1—2 cm below the tip of the scapula and extends posteriorly and superiorly between the medial border of the scapula and the spine. The incision is deepened through the subcutaneous tissues until the latissimus dorsi is met. This muscle is divided with coagulating diathermy taking care over haemostasis. The line of division is the same as for the skin. A plane of dissection is developed by hand under the scapula and serratus anterior. The ribs can be counted down from the highest palpable rib (which is usually the second) and the sixth rib periosteum is scored with the diathermy near its upper border. A periosteal elevator is used to lift the periosteum off the superior border of the rib. This reveals the pleura which may be entered by blunt dissection. A rib spreader is inserted between the ribs and opened gently to prevent fracture. Exposure may be facilitated by dividing the rib at the costal angle or by dividing the costotransverse ligament. Routine resection of a rib is an uncommon practice. The anaesthetist is now able to deflate the affected lung to allow a better view of the intrathoracic structures. In an emergency thoracotomy for penetrating wounds of the heart, a more anterior approach is used and no specialised supporting equipment is required (Fig. 47.9).

Large-calibre (28—32 Fr) intercostal drains are usually inserted at the end of the procedure. It is common practice to site them through the seventh or eighth intercostal space anterior to the midaxillary line so that the patient does not lie on them. For chronic management, such as closed drainage of empyema, the drains are tunelled to come out more anteriorly for easier management. Traditionally, the more anteriorly sited drain goes to the apex and the posteriorly placed drain goes to the lung base. A rib approximator is used to realign the ribs and the stripped periosteum and intercostal muscle is sutured to the intercostal muscle below the stripped rib using a continuous absorbable suture. A nonabsorbable suture may be used to maintain the closure if healing is likely to be compromised. The fascia and muscle layer are closed in layers using an absorbable suture (Fig. 47.10). Skin closure is a matter of personal preference.

Analgesia is an important aspect of postoperative care and the process may be started intraoperatively by infiltrating the intercostal nerves in the region of the incision with a long-acting local anaesthetic. Various strategies have been developed to deliver analgesics postoperatively to facilitate a normal breathing pattern.

**Postoperative care**

Lung function is rarely assessed before urgent thoracotomy for trauma but it is a vital part of the patient’s preoperative work-up before elective thoracotomy. A description of lung function testing is given in Appendix 2 at the end of this chapter. These patients have limited respiratory reserve following lung resection, so infection and fluid overload are to be avoided. Chest drains placed at the time of surgery drain blood collections and cope with air leaks if present. Once the air leaks have settled and any remaining lung is re-expanded, the drains are removed. Mobilisation, breathing exercises and regular physiotherapy are begun as soon as the patient’s condition permits.

**Postoperative pain**

It is important to deal with post-thoracotomy pain effectively so that a normal breathing pattern and gas exchange are achieved in the early postoperative period. Patient-controlled analgesia is an important development but still requires regular nursing and anaesthetic supervision. Internally placed catheters delivering local anaesthetic into the wound and beneath the pleura may also be effective. Long-term post-thoracotomy pain can be avoided by careful attention to detail during the operation. Sources of avoidable chronic pain include rib fracture and entrapment of intercostal nerves during wound closure. Trauma accounts for most of the emergency workload of the thoracic surgeon but other situations are encountered that demand prompt investigation and treatment.
Airway obstruction

Tracheal obstruction may present acutely as a life-threatening emergency or insidiously with little in the way of symptoms until critical narrowing and stridor occur. The more common causes of airway narrowing are outlined in Table 47.1.

Treatment depends on the underlying cause. Tracheal resection is a very specialised problem but in expert hands up to 6 cm of trachea may be resected without undue tension on the anastomosis. Tracheostomy may be required to overcome the obstruction but there are few indications to do this as an emergency and, in this situation, a crico-thyroidotomy is probably preferable. Tracheal replacement with artificial substitutes has so far been unsuccessful. Sleeve resections of the major bronchi are also possible. Reversible airway obstruction (e.g. asthma) is the domain of respiratory physicians.

Inhaled foreign bodies

This is a regrettably common occurrence in small children and is often marked by a choking incident which then apparently passes. Surprisingly large objects can be inhaled and become lodged in the wider calibre and more vertically placed right main bronchus. If not removed, an obstructive emphysema may result but, if there is total occlusion of the bronchus, the air distally will be absorbed and the secretions may become infected. There are three possible presentations:

1. asymptomatic;
2. wheezing (from airway narrowing) with a persistent cough and signs of obstructive emphysema;
3. pyrexia with a productive cough from pulmonary suppuration.

A chest radiograph is vital as the object may be radio-opaque. Often it is not radio-opaque or is obscured by the cardiac shadow or the inflammatory response. Bronchoscopy is required by an experienced operator with an experienced anaesthetist to administer the anaesthetic. The procedure may be very difficult if there is a severe inflammatory reaction. The rigid bronchoscope is best for retrieving inhaled foreign bodies. Failure to remove the object may necessitate a bronchotomy through a formal thoracotomy. If the object has caused chronic lung damage it may be necessary to remove the affected lobe.

Haemoptysis

There is a variety of conditions giving rise to repeated haemoptysis, including carcinoma, bronchiectasis, carcinoid tumours and certain infections. Severe rheumatic mitral stenosis is a rare cause. All patients with haemoptysis should be investigated at the very least by chest radiography and bronchoscopy and those with normal findings carefully followed up. Haemoptysis following trauma may be from a lung contusion or injury to a major airway. Severe haemoptysis is unusual and the treatment depends on the underlying cause.
Pulmonary neoplasms

Carcinoma of the bronchus is the most common malignancy in men and the second most common (after carcinoma of the breast) in women. A number of neoplasms affects the airways and suspicion of carcinoma of the bronchus should prompt thorough investigation to make the diagnosis at an early and therefore treatable stage.

Benign tumours

Benign tumours of the lung are uncommon and account for less than 15 per cent of solitary lesions seen on chest radiographs. They are usually an incidental finding on a chest radiograph done for some other reason, but symptoms, when present, depend on the site of the lesion. A peripheral tumour may produce little in the way of symptoms, whereas a centrally placed tumour may present with haemoptysis and signs of bronchial obstruction at a relatively early stage. A tumour is likely to be benign if it has not increased in size on chest radiograph for more than 2 years or has some degree of calcification. However, a tissue diagnosis is advisable as a noncalcified solitary lesion may be a primary carcinoma.

Most benign nodules are granulomas (tuberculosis or histoplasmosis), which give the appearance of a high-density lesion on CT. Low-density appearances are suspicious and the nodule should be removed by excision biopsy. Less than 50 per cent of solitary nodules are benign, underlining the importance of accurate diagnosis.

The most common benign tumour is the pulmonary hamartoma which is really a developmental abnormality containing mesothelial and endothelial elements. They may be lobulated and, although unlikely to undergo malignant transformation, they may be multicentric. Diagnosis (and definitive treatment) is achieved by excising the lesion.

Epithelial tumours

Epithelial tumours of the airways are a particularly troublesome problem. The airways become infected with a papilloma virus at birth and small stalk-like papillomas develop, initially in the larynx and then down into the major airways. Regular endoscopic follow-up is required following bronchoscopic resection, because recurrence is common and malignant change may occur.

Fibroma

Fibroma is the most common mesodermal tumour and tends to occur in the bronchi rather than the trachea. Fibromas are often pedunculated and therefore easily removed at bronchoscopy.

Hamartoma

Hamartoma is a disorganised mass of tissue within the lung substance containing respiratory structures. It is the result of a developmental abnormality and malignant change is rare. Any of the mesodermal elements of the lung may form a mesodermal tumour (chondroma, lipoma, leiomyoma). Deposits of amyloid may give similar radiographic appearances of a nodule (pseudotumour).

Bronchial adenomas

Bronchial adenomas are mainly carcinoid tumours derived from the neuroendocrine cells of bronchial glands. Most (80 per cent) are found in the major bronchi and are characteristically slow growing and highly vascular. Occasionally these tumours secrete hormones adenocorticotrophic hormone (ACTH), melanocyte-stimulating hormone or insulin. This may be the first presentation but usually there are recurrent chest infections, persistent cough, haemoptysis and occasionally chest pain. Carcinoid tumours belong to a class of tumours that are benign at one end of the scale, to those that are locally aggressive and to the highly malignant oat cell tumour at the other end of the scale. Surgical excision is the most appropriate treatment and regular follow-up is advised.

Malignant tumours

Carcinoma of the bronchus, as stated earlier, is the most common malignancy in men and the second most common (after carcinoma of the breast), resulting in over 30000 deaths per year in the UK (Fig. 47.11). There is only a 20 per cent 1-year survival for all cases after diagnosis and surgery represents the best chance of prolonged survival.

Accurate diagnosis and staging of the tumour are vital if surgery is to be considered. The real incidence of carcinoma of the bronchus earlier in the twentieth century was probably masked by the presence of tuberculosis. Once a cure for tuberculosis became available, the importance of carcinoma of the lung became apparent. Cigarette smoking is undoubtedly one of the major risk factors for developing bronchial carcinoma. To a lesser extent, atmospheric pollution and certain occupations (radioactive ore and chromium mining) also contribute to the problem. In the UK, the mortality from lung cancer for individuals smoking more than 40 cigarettes per day is over 210/100 000. This compares to a mortality of less than 4/100 000 in nonsmokers. Regular smoking causes characteristic changes in the bronchial epithelium from hyperplasia through to proliferation and then to carcinoma in situ. These changes are to some extent reversible if smoking is stopped.

Histological types

Many bronchial and lung tumours have more than one cell type, and the behaviour and prognosis depend largely on the dominant cell type seen. There are several histological types which have an important bearing on prognosis and response to treatment.

Squamous cell carcinoma (SCC) accounts for the majority (over 60 per cent) of lung cancers. It is uncommon in non-smokers and tends to be centrally placed. There is a tendency to cavitate and metastasise outside the thoracic cavity.

Adenocarcinoma is less common than SCC (15 per cent) in the UK but the incidence can vary in different countries. It is more common in females and nonsmokers, and tends to be sited in the periphery of the lung. Adenocarcinoma often metastasise widely to the liver, brain and adrenals. The typical histological appearance is that of gland formation and the only worthwhile treatment, if feasible, is surgical excision (Fig. 47.12). It is important to exclude secondary adeno-carcinoma from other sites such as colon, breast and ovary.

Small cell carcinoma metastasises widely early in its course and is therefore rarely amenable to surgical resection. If discovered early then surgical removal has led to increased survival, but palliative chemotherapy and radiotherapy are the most appropriate treatment. These tumours are often associated with ectopic hormone production and paraneoplastic syndromes. The 5-year survival is less than 5 per cent, even with treatment.

Alveolar cell carcinoma arises in the distal airways. Resection of a solitary nodule is associated with a good prognosis but the occurrence of
a multicentric pneumonic type of alveolar cell carcinoma is associated with a poor prognosis.

**Clinical features**

Clinical features of lung carcinoma depend on:

- the site of the lesion;
- invasion of neighbouring structures;
- the extent of metastases.

Common symptoms include a persistent cough, weight loss, dyspnoea and nonspecific chest pain. Haemoptysis occurs in less than 50 per cent of patients presenting for the first time. Severe localised pain suggests chest wall invasion with the infiltration of an intercostal nerve. Invasion of the apical area may involve the brachial plexus leading to Pancoast's syndrome. Dyspnoea may come from loss of function of lung tissue, lymphatic invasion or the development of a large pleural effusion. Clubbing and hypertrophic pul-monary osteoarthropathy are sometimes seen, particularly with squamous cell lesions. These features may resolve with excision of the primary lesion. The presence of blood in a pleural effusion suggests that the pleura is invaded. Invasion of the mediastinum may result in hoarseness (due to recurrent laryngeal nerve involvement), dysphagia (due to involvement of, or extrinsic pressure on, the oesophagus) and superior vena caval obstruction. Hormonal secretion by a tumour will have predictable pathological and physiological effects depending on the nature of the hormone. Small cell carcinoma is associated with the development of myopathies including the Eaton—Lambert syndrome, which is similar to myaesthenia gravis although the weakness tends to improve with repeated movement.

**Diagnosis and staging**

There are three keys to diagnosis:

- detection of the primary lesion;
- tissue diagnosis;
- assessment of spread (Table 47.2).

Detection of the primary lesion. Chest radiography. The principal investigation in detecting pulmonary pathology is a good-quality posteroanterior chest radiograph with an additional lateral view. The radiographic appearance will vary according to the site of the lesion and its effects (pleural effusion, lobar collapse, raised hemidiaphragm) (Fig. 47.13).

**Computerised tomography (CT).** This is more sensitive and reproducible than tomography, and has become almost routine in the assessment of these patients. The questions that the surgeon wants answered are (1) is the lesion resectable and (2) are the mediastinal lymph nodes involved? These two questions determine the prognosis (Fig. 47.14). Unfortunately, CT cannot always provide the answers. Lymph nodes more than 2 cm in diameter are likely to be involved in the disease (70 per cent) but those smaller than this (1—2 cm) may or may not be involved. Mediastinal lymph nodes of less than 1 cm in the longest axis are very unlikely to be involved. Visualisation of the liver by CT is a useful means of excluding metastases. Involvement of the mediastinal lymph nodes is usually regarded as a contraindication to surgery, but this view is continually debated. Enthusiasts of resection still seek to cure lung cancer by more extensive resection in N2 disease. Resection is only justified in the presence of metastases if there is chronic debilitating sepsis from a cavitating tumour or uncontrolled haemoptysis.

Sputum cytology may reveal malignant cells but the false-negative rate is high, particularly in poorly differentiated lesions.

**Bronchoscopy** is used to visualise the bronchial tree and is useful in a number of ways (Table 47.3).

**Flexible bronchoscopy** may be performed with the patient awake and the oropharynx anaesthetised with topical ligno-caine (Fig. 47.15). The bronchoscope is passed into the nose and through the vocal folds under direct vision. As the scope is flexible its tip can be directed into the segmental bronchi with ease. Tissue and sputum samples may be obtained for diagnostic purposes. There is a greater range of movement with this instrument but the biopsies are relatively small and the suction facility may not be adequate. Nearly 40 per cent of biopsy diagnoses require modification following resection.

**Rigid bronchoscopy.** The rigid bronchoscope requires a general anaesthetic in most cases. However, it is ideal for therapeutic manoeuvres such as removal of foreign bodies, aspiration of blood and thick secretions, and intraluminal surgery (laser resection or stent placement). This instrument, introduced under general anaesthesia, allows visualisation and generous biopsy of the lesion (Fig. 47.19). The surgeon and the anaesthetist share control of the airway. The view is improved by using muscarinic premedication and paralysing agents. Continuous ECG and pulse oximetry monitoring are now mandatory. The operator stands behind the patient and lifts the maxilla by the upper teeth with the middle and forefinger of the left hand. The bronchoscope rests on the left thumb as it is introduced over the tongue in the midline. As the bronchoscope is passed under direct vision into the oropharynx, the neck is extended and the bronchoscope is lowered and advanced to visualise the larynx. Turning the instrument through 90 degrees will help to negotiate the vocal cords. Care must be taken not to trap the lips or tongue between the teeth and the bronchoscope and the fulcrum should be the left thumb and not the teeth. The tracheal rings and the carina should be easily seen. Advancing the bronchoscope into the main bronchus reveals the orifices of the more peripheral bronchi. Operability is determined by the proximity of a lesion to the carina and whether or not the carina is widened (indicating inoperability from subcarinal lymph node involvement). If the bronchoscopy is for diagnosis rather than preoperative assessment, a biopsy may be taken. This should be done when the anaesthetist is satisfied that the anaesthetic can be quickly reversed. The biopsy is taken and a check made for bleeding. The anaesthetic is reversed and the patient turned on the side. This will allow drainage and easy expectoration of any blood or secretions.

Biopsy is hazardous under the following conditions:

- bleeding disorders;
- systemic anticoagulation;
- pulmonary hypertension.

Complications are rare in experienced hands but include bleeding, pneumothorax, laryngospasm and arrhythmia.
Bronchoscopy may not visualise the lesion unless it is in the main airways, and is inadequate for staging operable disease. More invasive techniques of biopsy of intrathoracic lesions are often necessary to confirm diagnosis, stage disease and plan treatment. The options range from percutaneous needle biopsy under radiological control to open lung biopsy (see below).

**Needle biopsy.** A thin needle passed into a lesion through the chest wall under local anaesthesia gives a good yield of malignant cells. It is best reserved for large or peripheral lesions and is performed under radiological CT control. Pneumothoraces are common (30 per cent) but rarely require intercostal tube drainage. Seeding in the biopsy track and haemorrhage are also reported complications. This procedure is also used in the diagnosis of life-threatening pneumonia where other attempts to establish a diagnosis have failed. The contraindications are similar to those of bronchoscopy but include those with poor respiratory reserve in whom even a small pneumothorax would be fatal.

The more invasive techniques of thoracoscopy, mediastinoscopy, mediastinotomy and open lung biopsy, are aimed at establishing a tissue diagnosis and assessing the degree of spread (staging) which determines resectability. Mediastinoscopy or mediastinotomy is advisable on all patients who have enlarged lymph nodes (>1 cm) on CT of the mediastinum to avoid futile thoracotomy without hope of cure. Smaller nodes are not likely to be involved and thoracotomy may be done based on the benefit of doubt. Whatever staging procedure is used, there will inevitably be a small rate (<5 per cent) of nonresective thoracotomies.

**Mediastinoscopy.** This procedure is performed under general anaesthesia with the patient supine and the neck extended (Fig. 47.16). A transverse incision is made 2 cm above the sternal notch and deepened until the strap muscles are reached. These are retracted laterally and the thyroid isthmus superiorly to reveal the pretracheal fascia. Careful blunt dissection in this plane allows direct palpation of the paratracheal and subcarinal nodes. A mediastinoscope may be introduced for direct visualisation and biopsy. Care must be taken to avoid damage to the brachiocephalic vessels anteriorly.

**Mediastinotomy.** An incision is made through the second intercostal space to gain access to some of the mediastinal lymph nodes on the affected side (Figs 47.17 and 47.18). Damage to the internal mammary artery and great vessels must be avoided. Biopsy of the mediastinal lymph nodes is possible and the medial extension of tumour can be assessed, so this technique has important application in the staging of lung cancer.

Great caution should be used in the presence of superior vena caval obstruction and previous exploration is a relative contraindication. Complications include pneumothorax and haemorrhage. These techniques may also be used in the diagnosis of other mediastinal conditions, including:

- lymphoma;
- anterior mediastinal tumours;
- thymoma;
- sarcoid or any other cause of lymphadenopathy.

**Thoracoscopy.** A thoracoscope may be introduced through a small stab incision and a peripheral lesion biopsied. This requires general anaesthesia and double-lumen intubation. The technique has more application in the diagnosis of suspected metastatic disease and malignant pleural effusion (see Pleura).

**Open lung biopsy.** This requires a thoracotomy and is rarely performed to diagnose carcinoma. The site of the incision is dictated by the site of the lesion.

**Treatment of lung cancer**

Only 10 per cent of patients have potentially curable lesions on presentation, so careful investigation is required to determine which patients are operable and will benefit from a major thoracic resection. The internationally agreed staging system [tumour, node, metastasis (TNM)] gives some prognostic information on the natural history of the disease but it assumes that lung cancer behaves and spreads in a progressive manner by local invasion of the lymph nodes and then into the bloodstream. Tumours graded T2, N1, M0 or less have a better prognosis when treated surgically. This means that the tumour must be staged as accurately as possible before resection (Table 47.4). Unfortunately, most lung cancers are beyond curative treatment at the time of presentation. However, palliation is a skilled process from which patients may benefit in terms of quality of life and disease-free survival. If preoperative investigations suggest that a lesion is localised and resectable then surgery should be undertaken. A number of factors including general fitness of the patient and the lung function tests determines the nature of treatment. Many patients are smokers and elective physiotherapy before the operation may be worthwhile.

**Surgical management**

The principle of surgery is to remove all cancer (the primary and the regional lymph nodes) but to conserve as much lung as possible. This is usually done by lobectomy but there is evidence that small peripheral lesions have as good an outcome if subjected to segmentectomy or simple wedge excision. A double-lumen tube for separate control of the lungs is used to facilitate dissection. It should be remembered, however, that techniques of one-lung anaesthesia were developed by anaesthetists to protect the nonoperated lung and to retain their control (Fig. 47.19).

Following exploration of the fissure, the lobar artery is isolated and ligated. The vein is then divided and oversewn leaving the affected bronchus, which is divided so as not to leave a stump. The divided bronchus is oversewn or stapled according to preference (Fig. 47.20).

At the completion of the operation, the remaining lung is reinflated. Air leak is common and usually settles within a number of days. Intercostal drains are inserted to lie basally and apically. The patient is extubated in the recovery area once ventilation is deemed adequate.

Pneumonectomy is removal of the whole lung. This is a major undertaking and has a high mortality rate (5—10 per cent). The surgeon must be satisfied that the patient is fit enough to tolerate this procedure from the preoperative work-up. This procedure is reserved for either centrally placed tumours involving the main bronchus or those that straddle the fissure. At thoracotomy, an inspection of the lung and direct palpation of the mass will determine resectability and lymph node spread. Fixation of the tumour to the aorta, heart or oesophagus implies irresectability. Involvement of the mediastinal lymph chain is associated with a poor prognosis. In all, 5—10 per cent of thoracotomies are exploratory only with no resection. The objective is to keep this to a minimum but extensive conservation would deny the patient a chance of cure.

Pneumonectomy, if performed, involves isolation of the main pulmonary artery after the initial exploration. An occlusive clamp is placed across the artery and, if this is tolerated, the resection proceeds. The artery is divided and oversewn. The pulmonary veins are then isolated.
and clamped. They too are divided and oversewn. This leaves the main bronchus which is divided so that no blind stump remains (Fig. 47.21). The technique of stump closure is important if a bronchopleural fistula is to be avoided. The tissues are carefully handled and the stump is closed with good apposition of the sides. Topical antibiotics may be used to prevent infection. The chest cavity is irrigated with warm saline to remove any blood clots or debris. Some saline is left in the hemithorax to cover the bronchial stump. The anaesthetist manually ventilates after the clamp is removed from the tube serving the affected side. The inflation pressures are gradually increased until the surgeon is satisfied that there is no leak present (by the absence of bubbles in the saline). Haemostasis is vital because there is a large space left after pneumonectomy. Drainage is a matter of preference. Some prefer to insert drains and unclamp them for 1 minute every hour until the drainage ceases; others prefer not to drain. The critical point is that no suction should be applied as there is now a sealed space with the mobile mediastinum on one side of it. The air in the pneumonectomy space is gradually absorbed and the fluid level within the space rises (Fig. 47.22).

Thoracoscopic lung resection. Minimally invasive surgery has become fashionable in recent years in all forms of surgery. The thoracoscope has been used for many years but its use was limited mainly to performing biopsies. The instru-ment was a limited view and was uncomfortable to use for any length of time. All this has changed since the advent of video-assisted thoracoscopy (Fig. 47.23). The surgeon’s hands are freed because the camera is attached to the thoracoscope which can be operated by an assistant; and the image is displayed on a television screen. The surgeon is able to manipulate instruments with both hands to perform an impressive variety of procedures. Pneumonectomy, lobectomy and empyema drainage are all possible, but thoracoscopic procedures for common, more minor problems is the area providing clear justification for this technique. Lung biopsy and the treatment of recurrent pneumothorax are the most frequent indications for this technique of operation. The principal advantage is that a large incision is not required and therefore less postoperative pain and a more rapid recovery should result. The scope of thoracoscopic surgical procedures is increasing with the modern trend of less invasive surgery. Thoracoscopic lobectomy is now a feasible and reproducible procedure although the long-term results remain unproven. The thoracoscope is used in staging lung and oesophageal malignancy and in sympathectomy. Port access coronary artery surgery will be discussed in Chapter 48.

Complications of lung resection

Bleeding should be avoidable by use of careful surgical technique but may be very severe in the presence of dense adhesions.

Respiratory infection. Many of these patients are ex smokers so basal collapse and hypoxaemia are common post-operatively.

Persistent air leak. Chest drains placed at the time of surgery should deal with this problem, but occasionally the air leak becomes chronic and the remaining lung does not expand. Re thoracotomy may then be necessary to seal the leak.

Bronchopleural fistula. Following pneumonectomy, the space left behind is initially filled with air. This is slowly reabsorbed and the space fills with tissue fluid. The fluid level rises until the air is finally reabsorbed. Dehiscence of the bronchial stump leads to the development of a bronchopleural fistula and the tissue fluid (which is almost inevitably infected) is expectorated in large quantities. This is a catastrophic complication with high morbidity and mortality. The patient is laid flat with the affected side down (to prevent infected fluid from entering the remaining lung) while arrangements are made to site a pleural drain. Bronchopleural fistulas are unlikely to resolve with conservative treatment and therefore some operative strategy must be tried. There is a number of ways of sealing the fistula, from tissue glue down the rigid bronchoscope to thoracotomy and a muscle flap to cover the bronchial stump. Bronchoscopic sealing with tissue glue may be successful but is difficult. Resutting the bronchial stump may lead to healing and the thoracotomy will allow evacuation and thorough irrigation of the pneumonectomy space. Closure is more successful if viable tissue can be brought over the bronchial stump. This is achieved by dissecting a pedicle of intercostal muscle off the chest wall leaving its artery and vein intact and suturing it over the repair. Omentum is an alternative source of pedicled tissue. If closure is not possible or the patient will not tolerate closure, then a fenestration procedure may be performed to allow drainage of the fluid, usually including rib resection. Suturing the skin to the pleural surface to form a Clagett window provides chronic management in desperate circumstances.

Hypoxaemia. Poor oxygenation, as a result of pre-existing lung damage, pulmonary oedema from overenthusiastic crystalloid replacement, atelectasis and bronchopneumonia, may occur. Treatment is aimed at the underlying cause but great care must be taken in pneumonectomy patients who are very susceptible to hypoxaemia.

Survival

Carcinoma of the bronchus generally has a low survival rate after diagnosis (Table 47.5).

Important factors in determining prognosis are the histological type of tumour, the spread(stage) and the general condition of the patient. The 5-year survival rate is less than 2 per cent if no treatment is offered at the time of diagnosis and ipsilateral lymph nodes are involved. Those with mediastinal lymph nodes discovered and removed at thoracotomy have a better prognosis (15—30 per cent 5-year survival). Early detection and surgical resection offer the best hope for cure.
The mediastinum

Primary tumours of the mediastinum (Fig. 47.24)

Secondary, involvement from direct infiltration of an intrathoracic primary or metastatic disease from elsewhere occurs more frequently than primary mediastinal tumours. Thymoma, neurogenic tumours and lymphoma account for most primary tumours of the mediastinum. Rarer conditions such as germ cell tumours, mesenchymal and endocrine tumours account for the remainder.

Thymoma

This is the most common mediastinal tumour accounting for 25 per cent of the total. These are tumours of the thymic epithelial cells of Hassall’s corpuscles and are sited in the anterior and superior compartments. They generally occur after childhood and present as lobulated, occasionally calcified, masses in the anterior mediastinum (Fig. 47.25). They may appear encapsulated and are often associated with the autoimmune disease myasthenia gravis. The tumours vary in their behaviour from completely benign to aggressively invasive. The only reliable indicator of malignancy is capsular invasion. Diagnosis and treatment are best achieved by complete thymectomy, but radiotherapy may be the only treatment option if the lesion is advanced.

Eighty per cent of thymomas are benign and the prognosis is good. There is, however, a small risk of recurrence. A rarer type of thymoma has similar histological appearance to the benign thymoma, but it has capsular invasion and is occasionally aggressive with widespread metastases. Rarer still is the thymic carcinoma. This is not associated with myasthenia and resembles an SCC or an undifferentiated large cell tumour. The prognosis is generally poor in spite of combination treatment of excision, radiotherapy and cytotoxic therapy.

Germ cell tumour

Germ cell tumours account for 13 per cent of all mediastinal masses and cysts, and are usually found in the anterior mediastinum (Fig. 47.26). They tend to occur in young adults and 75 per cent are benign and cystic, although they may cause compression of neighbouring structures. They contain elements from all three cell types (mesoderm, endoderm and ectoderm) and are best treated by surgical excision in case malignant transformation should occur. Malignancy is suspected if elevated levels of serum alpha-fetoprotein, human chorionic gonadotrophin and carcinoembryonic antigen are detected.

Lymphoma

Lymphoma is a common cause of a mediastinal mass lesion, particularly the anterior mediastinum, leading to obstruction of the superior vena cava. Lymphomas arise from the thymic lymph tissue or the lymph nodes of the mediastinum. They can be classified into Hodgkin’s and non-Hodgkin’s types but details of the pathological differences and their implications are outside the scope of this chapter. Hodgkin’s lymphomas presenting in the thymus tend to be localised and usually have favourable histology and a favourable response to treatment. Non-Hodgkin’s lymphomas are usually high grade and are more common in young to middle-aged females. A tissue diagnosis is essential so that the appropriate treatment can be planned. The overall prognosis in non-Hodgkin’s lymphomas is poor.

Mesenchymal tumours

A small number of mesenchymal tumours occurs within the mediastinum and approximately half are malignant. Lipomas are common in the anterior mediastinum, whereas the malignant form, liposarcoma, tends to occur posteriorly. Fibrosarcoma and mesothelioma may also occur.

Thyroid

Ectopic thyroid tissue (and parathyroid) may be found in the anterior mediastinum. Neoplasia and hyperplasia may occur but these are uncommon. More often the tumour is merely a mediastinal extension of a thyroid lesion.

Neural tumours

These may derive from the sympathetic nervous system or the peripheral nerves and are more prevalent in the posterior mediastinum. They may be painful but are more often discovered accidentally on routine chest radiography (Fig. 47.27).

Tumours of the sympathetic nervous system are more common in young patients less than 10 years of age.

Neuroblastoma. This rare childhood tumour consists of poorly differentiated primitive neural cells. It metastasises widely and has a poor prognosis.

Ganglioneuroma. This is a mixture of mature ganglion cells and spindle cells which does not progress after puberty and generally has a good prognosis.

Ganglioneuroblastoma. This tumour has a mixed pattern of mature and immature cell types and has an intermediate prognosis.

Adults are more prone to develop Schwannomas and neurofibromas. The histological appearances are similar to those found in conventional sires and they present as a mass lesion with pressure effects or as asymptomatic radiographic findings.

Tumours of the nerve sheath and fibres (neurofibromas and Schwannomas) have a wide range of presentations and behaviours. Multiple neurofibromas may be part of a familial syndrome (von Recklinghausen’s disease, neurofibromatosis). Tumours in the paravertebral gutter may have a component within the intervertebral canal (a so-called ‘dumb-bell’ tumour).

Phaeochromocytomas. These arise from the sympathetic chain and produce the characteristic endocrine syndrome.

The mediastinum may be involved by metastatic tumour mimicking a primary mediastinal lesion. In elderly people, this is the most common cause of mediastinal lymphadenopathy.

Symptoms of mediastinal masses

Most asymptomatic mediastinal masses discovered by routine chest radiography will be benign. In contrast, masses presenting with symptoms, in particular pain, are much more likely to be malignant.
Symptoms are generally secondary to compression or invasion of a structure within the mediastinum.

**Superior vena caval obstruction**

Tumours located behind the sternum have little space in which to grow and consequently the low-pressure superior vena cava is the first to be compressed. Venous engorgement of the upper extremities and face occurs and persists even when the patient sits upright. The most common cause of this syndrome is carcinoma of the bronchus and radiotherapy usually provides good symptomatic relief.

**Tracheal and oesophageal compression**

This may be extrinsic or from mural invasion; symptoms include dysphagia, dyspnoea and occasionally stridor. Radiotherapy or intraluminal stenting may provide some relief.

**Neural invasion**

A left-sided hilar lesion may infiltrate the recurrent laryngeal nerve and paralyse the vocal cords leading to hoarseness and a bovine cough. Paralysis of the phrenic nerve causes a raised hemidiaphragm on the affected side and indicates irresectability if bronchial carcinoma is present. Homer’s syndrome is a result of invasion of the sympathetic chain superiorly.

**Pericardial invasion**

Direct invasion may cause changes similar to pericarditis with arrhythmias and ECG changes. Chronic tamponade may occur from the slow accumulation of fluid in the pericardium.

**Neural tumours**

Invasion of the spinal cord may lead to progressive paraplegia.

**Investigation and treatment**

Investigation of a mediastinal lesion follows the same pattern as investigation for pulmonary lesions with more emphasis on radiology, and mediastinotomy and mediastinoscopy. If a resection is planned, the best approach to the anterior and superior mediastinum is through a median sternotomy. The posterior mediastinum can be reached through a postero-lateral thoracotomy at the appropriate level. Any operation must be carefully planned because the pitfalls are numerous and may be difficult or impossible to counter.
Pleural conditions

Normal pleural physiology (Fig. 47.28)

There is a potential space between the parietal and visceral pleura that contains only about 5 ml of pleural fluid at any one time. The amount of pleural fluid is governed by the factors producing and absorbing it (capillary hydrostatic pressure, capillary permeability, lymphatic drainage and colloid osmotic pressure). The turnover of fluid in the human pleural space is about 1 litre in 24 hours. Protein-depleted fluid is filtered into the pleural space from the capillaries in the parietal pleura. The fluid is then mostly absorbed into the pulmonary capillaries, with only about 10 per cent being absorbed by the pleural lymphatics.

Any disturbance of the equilibrium will lead to the development of a pleural effusion. There are two described types depending on the protein content of the fluid, although the distinction is not always clear.

Accumulation of protein in the pleural space results if the lymphatic drainage is deranged. This alters the osmotic pressure within the space and leads to the formation of an effusion. There is usually in excess of 30 g of protein per litre and this is termed an effusion. The underlying pathological mechanisms are:

- increased capillary permeability — capillary damage or inflammation;
- lymphatic obstruction;
- venous obstruction.

The most common pathologies associated with exudative effusions are:

- malignancy;
- infection;
- connective tissue disease;
- pulmonary infarction.

A transudate has less than 30 g/litre of protein and is the result of low colloid osmotic pressure from liver cirrhosis or high hydrostatic pressure from cardiac failure or a combination of both.

Presentation

The clinical signs depend on the rate of effusion growth. Rapidly developing effusions may cause severe dyspnoea, whereas slowly developing ones may be very large but asymptomatic. On clinical examination there are reduced breath sounds on the affected side with tracheal deviation to the opposite side. The chest is stony dull to percussion. A pleural effusion may be the initial presentation of a systemic malignancy in up to 30 per cent of cases.

Investigation

Radiology

A chest radiograph will determine the size of the effusion and may give a clue as to the aetiology (coexistent tuberculosis, hilar shadow, etc.). Further information about the lung may be obtained by CT if the lung is the primary pathology. Pleural thickening is best distinguished from fluid by ultrasonography.

Aspiration

Pleurocentesis (Fig. 47.29) is performed under local anaesthesia using aseptic precautions. The needle is introduced just above a rib (to avoid the neurovascular bundle) at the point of maximal dullness. Fluid is drawn for diagnosis (cytology and biochemistry) and symptomatic relief. It is important not to remove too much fluid because pulmonary oedema may ensue. Biochemistry will determine whether the fluid is an exudate. If it is then diagnostic efforts must be directed at finding the cause.

Cytology

Histological examination of the aspirated fluid may be useful but the absence of malignant cells does not rule out malignancy. The yield may be increased by pleural biopsy (using an Abram’s needle) taken at the same time.

Thoracoscopy

This is a more invasive technique performed under general anaesthesia. The patient is positioned and draped as for a thoracotomy. A small incision is made over an intercostal space down to the pleura. The pleura is opened and the effusion drained by suction. The thoracoscope is introduced and the parietal pleural and lung are inspected thoroughly. Any suspicious nodules or plaques may be biopsied and in the case of a recurrent malignant pleural effusion, definitive pleurodesis may be done.

Treatment

The prognosis for malignant pleural effusion is very poor and therefore the treatment should be simple and effective if the patient is to enjoy a reasonable quality of life. Simple aspiration is a temporary solution in the symptomatic patient, because the effusion usually re accumulates and repeated aspiration merely results in loculation of the fluid. Treatment of the underlying malignancy may lead to resolution of the effusion but the distressing dyspnoea will be prolonged. A much better method of palliation is aspiration of the effusion and pleurodesis.

Three requirements must be met for successful pleurodesis:

The pleura must be aspirated to dryness, the pleural surfaces must be kept apposed and the fluid must not be allowed to re accumulate. This can be achieved by tube drainage with underwater seal and 5 mmHg of suction pressure, and the introduction of a sclerosing agent. There is a variety of sclerosing agents, including tetracycline, bleomycin and iodised talc. Pleurodesis may be carried out on the ward but the success rate
is higher if the procedure is performed under general anaesthesia with talc insufflation and thoracoscopic inspection to ensure that the pleural surface is completely covered. At the end of the procedure, basal and apical drains are inserted and left on suction to ensure that the pleural surfaces are apposed. Theme is an intense inflammatory reaction which is very uncomfortable for the patient. Adequate analgesia (avoiding nonsteroidal anti-inflammatory drugs) is therefore essential while the drains are in place. The success rate is over 75 per cent for this form of treatment and failures usually result from failure of the underlying lung to expand, lung metastases or lymphangitis. Pleurectomy is hard to justify because it is a major procedure in a patient with a very limited life expectancy.

**Tumours of the pleura**

The pleura is often secondarily involved as a result of direct or transcoelomic spread of lung or breast malignancy resulting in a malignant pleural effusion. However, there is one malignant tumour of the pleura that deserves mention.

**Mesothelioma**

Fibrous plaques overlying the pleura are often seen at thoracotomy and are benign in most cases. The most important malignant tumour affecting the pleura is a mesothelioma. This is an aggressive tumour that grows in diffuse layers, encapsulating and compressing the lung substance. It is associated with asbestos exposure and is a notifiable condition because sufferers may be eligible for compensation. There are several different cell types seen within the tumour (adenomatous, squamous or sarcomatous), although there is usually a predominance of one cell type.

**Clinical features.** The patients often present with large unilateral pleural effusions and dyspnoea and occasionally chest pain. Advanced disease is heralded by weight loss, pyrexia and night sweats.

**Investigation.** Chest radiography suggests the diagnosis but CT will show marked pleural thickening with compression of the lung. Pleural aspiration may reveal atypical cells but the diagnosis is more certain if thoracoscopic biopsy is performed. This also allows pleurodesis at the same time. Treatment. The disease follows a progressive course over 12—24 months. Cure is rarely possible because the tumour is unresponsive to radiotherapy or chemotherapy, and palliation is difficult. Pain relief and appropriate supportive measures are best arranged at an early stage.

**Pneumothorax**

Pneumothorax is the presence of air in the thoracic space, outside the lung, that is, between the visceral and parietal layers of pleura which are normally only separated by a thin film of fluid. The lung is collapsed to the extent that it is displaced by the pneumothorax.

**Classification of pneumothorax**

- **Spontaneous — primary.** The only abnormality is superficial blebs at the apex of one or more lobes, typically the upper lobes, which either leak spontaneously or are triggered by an otherwise unremarkable event such as exertion. It is more common in males, occurs predominantly in the ‘teens or twenties, may be bilateral and may be familial.

- **Spontaneous — secondary.** Any lung disease that breaches the pleura may cause a pneumothorax so probably every possible lung disease will, at one time or another, cause a pneumothorax. The most common causes are obstructive airways disease in any form and bullous emphysema.

- **Traumatic.** See Thoracic trauma section.

- **Iatrogenic.** This is commonly seen in general hospital practice as a result of insertion of central lines for central venous pressure monitoring, intravenous feeding or cardiac pacing.

- **Open.** The air may come from a penetrating injury (stabbing or shooting) and passes in and out of the chest wall with each breath, but no effective ventilation occurs (see Thoracic trauma section).

- **Closed.** Rib fracture — see Thoracic trauma section.

When air in the pleura is under pressure the situation is called ‘tension pneumothorax’ and is a medical emergency. This depends on the non return valve-like mechanism, which is inherent in the structure of the lung. Positive pressure, generated within the airways with coughing or groaning in pain, forces air out which then cannot return through the collapsible peripheral alveoli (Fig. 47.30).

**Diagnosis**

The first thing is to suspect a pneumothorax and look for it deliberately in patients at risk:

- following needling of central veins;
- sudden deterioration in a ventilated patient;
- any trauma case;
- patients with obstructive airways disease.

**On examination** the affected side is more resonant and the breath sounds, listened for laterally in the axilla, are markedly different and reduced on the affected side. Shifts of the cardiac apex and trachea require severe distortion and are unreliable signs.

**Chest radiography** should be diagnostic but beware the supine film. Standard films are taken in inspiration. A small pneumothorax is exaggerated by expiration because the pneumothorax occupies proportionally more of the chest cavity.

**Management**

Tension pneumothorax is relieved by insertion of a large-bore intravenous cannula in a convenient intercostal space (with the usual precaution — see Chest drains) and then the situation can be managed as for a simple pneumothorax.

Spontaneous pneumothorax in a fit individual may cause little in the way of symptoms but in someone with poor respiratory reserve (chronic
obstructive airway disease) it may be life threatening.

The natural elastic recoil of the lung is balanced by the negative pressure within the pleural space. Disruption of this equilibrium by air in the pleural space results in collapse of the lung to some extent. If the chest wall remains intact but the lung is punctured by a fractured rib then the situation is termed a 'closed pneumothorax'. The danger is that, if this injury is part of a multiple injury, then positive pressure ventilation may lead to the development of a tension pneumothorax. If the chest wall is breached then this is termed an 'open pneumothorax', with the result that air moves in and out of the chest through the wound with each breath and there is no gas exchange across the alveolar surface.

Spontaneous pneumothorax may occur in any individual but is more common in young, slim men. The condition is often associated with apical blebs and there is a 30 per cent chance of recurrence.

Iatrogenic pneumothorax occurs when the lung parenchyma is breached by a medical procedure such as thoracocentesis, lung biopsy, liver biopsy or central venous cannulation.

**Treatment**

The initial treatment depends on the nature and severity of the pneumothorax; small pneumothoraces causing little disability may be observed with serial radiographs or may be aspirated. Large symptomatic or traumatic pneumothoraces require the insertion of a chest drain. Repeated spontaneous pneumothoraxes are an indication for definitive treatment to prevent recurrence. This depends on the age of the patient, their general condition and the underlying aetiology of the pneumothorax. In older patients, talc pleurodesis has a good chance of success (>60 per cent) but many feel uncomfortable about this procedure in the young. Procedures such as thoracoscopic abrasion and partial pleurectomy or thoracotomy and pleurectomy (often with stapling of bullae) have a higher success rate. Older patients with severe obstructive airway disease (who may be receiving steroid therapy) present a major management problem.

**Pleurectomy.** Pleurectomy is the definitive treatment for recurrent pneumothorax. A small posterolateral thoracotomy is performed and as much of the parietal pleura as possible is stripped off the chest wall, particularly at the apex of the hemithorax. There are often apical bullae that may require stapling or over sewing. The parietal surface is abraded with a swab to induce an inflammatory reaction. Large calibre suction drains are inserted to drain the apex and diaphragmatic surfaces of the lung. It is essential that suction is maintained long enough for the lung surface to become firmly adherent to the chest wall (usually 2—3 days). The thoracoscopic method of pleurodesis is becoming commonplace, with comparable results to open pleurodesis.
The chest wall

Tumours of the chest wall

These can be tumours of any component of the chest wall, i.e. bone, cartilage and soft tissue. They are treated similarly to those that occur in other sites and only require specialist input if major resection and chest wall reconstruction are contemplated. The most common tumour is that of the rib (chondroma or osteoma) and presentation is as a hard swelling over the rib. Malignant tumours are painful and destructive and require wide resection. Even so, there is a tendency for tumours to recur and histological classification is difficult. Tumours of the sternum are usually malignant. Lung and pleural tumours may involve ribs and destroy them.

Most lesions may be seen on a chest radiograph but occasionally CT or isotope bone scanning is required. Excision biopsy is often the best way to deal with a rib neoplasm because the differentiation between benign and malignant growths may be difficult. This avoids the risk of ‘spillage’ and tumour seeding in the wound of an incision biopsy. If a major resection is to be planned, it may be preferable to know the nature of the lesion before surgery. The principle of surgery is to remove the rib along with the rib immediately above and below, and a length well past the margins of the tumour. Reconstruction is possible using a prosthetic material Marlex or acrylic plates) to provide some stability to the chest wall. Myocutaneous flaps are occasionally employed to cover extensive tissue defects and therefore prior discussion with a plastic and reconstructive surgeon may be useful.

For lesions that are not amenable to resection, chemotherapy or radiotherapy, although unlikely to be curative, may provide symptomatic relief.

Other diseases of the chest wall

Congenital abnormalities are often incidental findings on chest radiography (bifid rib) but there are some important exceptions.

Cervical rib

This rib is usually represented by a fibrous band originating from the seventh cervical vertebra and inserting on to the first thoracic rib. It may be asymptomatic but because the axillary artery and brachial plexus course over it a variety of symptoms may occur. The lower trunk of the plexus (mainly T1) is compressed, leading to wasting of the interossei and altered sensation in the T1 distribution. Compression of the axillary artery may result in a post stenotic dilatation with thrombus and embolus formation. Treatment is by division or removal of the rib by a supraclavicular or an axillary approach.

Pectus excavatum

The sternum is depressed, with a dish-shaped deformity of the anterior portions of the ribs on one or both sides. It is probably never a cause of respiratory problems but may coexist with asthma, which is a common condition of children and young people. It may come to light during the growth spurt at adolescence when, of course, the teenager is particularly sensitive about appearance. Most patients are asymptomatic and the only justification for treatment is on cosmetic grounds. Some surgeons, and their referring doctors, make a very good case for this but the risk of morbidity and of a less than perfect result must be clearly spelt out to the patients and their parents.

The operation involves mobilising the sternum with the costal cartilages and holding this central panel anteriorly with a steel bar. Surgery is best left until the late ‘teens when further growth of the chest wall is unlikely. It is worth recommending some body-building exercises because muscle development not only masks the skeletal deformity but boosts confidence.

Pectus carinatum (pigeon chest)

In this condition the sternum is elevated above the level of the ribs and treatment is offered for cosmetic reasons. The sternum is mobilised and allowed to fall back into place.

Pulmonary sepsis

Infections of the chest wall

These are unusual but may occur following osteomyelitis of the underlying rib. An empyema of the underlying thoracic cavity may discharge through the chest wall (empyema necessitans) leaving a chronic sinus. Sterile pus should alert the clinician that tuberculosis is present.

Treatment of the chest wall infection depends on adequate treatment of the underlying condition.

Empyema

This is the end point of a number of conditions that result in the presence of pus in the pleural space, pleural thickening surrounding the walled-off infection and finally restricted lung movement on the affected side as a result of fibrosis. The presence of white cells and organisms is not sufficient to make the diagnosis of empyema.

The classic aetiology and still probably the most common is postpneumonic. A ‘syn-pneumonic effusion’ becomes colonised by bacteria and, at this stage, there is turbid but thin fluid, minimal pleural thickening and a mobile underlying lung. This is not properly called an empyema, an important point because the old-fashioned methods of rib resection would be fatal if applied to this condition and simpler treatments are effective. Untreated, this infected effusion develops into an empyema with thick pus in the pleural space surrounded by inflamed pleura thickened by deposition of fibrin. Finally, the cortex organisers to form dense scar tissue or a ‘fibrothorax’. Any cause of fluid collection, once contaminated, can evolve to reach this same end point (Table 47.6). Once established, any contaminated collection in the chest can result in empyema.

Symptoms. There are symptoms of pus at any site, namely swinging pyrexia with general malaise. Finger clubbing and weight loss are signs of chronicity. Progressive dyspnoea occurs as the hemithorax becomes more rigid. There may also be signs and symptoms of various predisposing conditions (see above). Pus may discharge into the overlying skin (empyema necessitans). Since the introduction of antibiotics, chronic empyema is not often seen but it is still a serious problem when it occurs.

Treatment. The management depends on the stage of the empyema.

Early empyema (thin pus, mobile lung and thin pleura). At this stage a brief period of pleural drainage, with underwater seal and adequate dosage of appropriate antibiotics, should result in resolution but inadequate treatment or no treatment will lead to a chronic empyema — a much more serious problem. Complete drainage and re-expansion of the lung should be achieved before the drains are removed. This need
not take more than 2—3 days. Pus should be sent for microscopy and culture before antibiotic therapy.

**Established empyema** (adherent lung caused by inflamed and thickened pleura with thick pus in the empyema space). At this stage the old treatment of rib resection with open drainage is safe in that the lung is tethered. However, it is inelegant, protracted and incomplete in its results. It is better to insert drains, through a small thoracotomy (with resection of rib) if practical. This is best done under a general anaesthetic, except in desperate circumstances, and all the loculi are broken down, ensuring free drainage and the siring of one or two carefully situated tubes. The drains should span the cavity, have the last side hole just within the ribs, and be tracked to lie anterior to the midaxillary line so that they are comfortable and do not kink as the patient lies back.

Video-assisted thoracoscopic placement of drains is an increasingly appropriate alternative approach. Suction drainage is employed on chest closure and this is continued until the patient is ready for mobilisation. Provided there is no air leak (and there is usually none) portable vacuum drains, which the patient is able to manage at home, are inserted. Appropriate antibiotics are also given. A daily record of the amount drained is kept by the patient and, once the drainage is less than 25—5 0 ml/24 hours of serous fluid (it never becomes zero), the drain is removed.

**Chronic empyema.** If progression to a chronic fibrothorax has occurred, aspiration or drainage of pus will not lead to expansion of the lung because there is considerable fibrosis constricting the lung parenchyma.

**Thoracotomy and decortication.** A formal thoracotomy is performed and the thickened parietal pleura and the fibrin peel overlying the lung are painstakingly removed, piecemeal if necessary. This allows the lung to expand but there is often considerable blood loss from the raw surfaces. Wide bore drains are inserted and connected to an underwater drainage system. Protracted air leak is common. When the leak has stopped (often up to 10 days later), the drains are removed. Antibiotics are given to cover organisms grown from the pus.

**Postpneumonectomy empyema**

This is discussed in the section concerning lung resections.

**Lung abscess**

Abscesses in the lung do not occur unless the underlying infection has caused thrombosis of the segmental artery and vein leading to infection with tissue necrosis. The most common causes are secondary to a chronic upper respiratory tract infection (sinusitis, dental abscess) or following bronchial obstruction from a neoplasm (*Table 47.7*).

**Diagnosis and treatment.** The chest radiograph usually demonstrates a cavitating shadow which is similar in appearance to a necrotic bronchial carcinoma or less commonly a fungal infection. The diagnosis is confirmed with a combination of sputum culture, bronchoscopy and radiography. Most acute abscesses resolve with appropriate antibiotic therapy and postural drainage. The course of antibiotics is usually the highest permitted dose for a protracted period. The virulent organism may change with such a prolonged antibiotic assault and the sputum must therefore be regularly monitored. Surgery is not usually part of the treatment. It is better for a lung abscess to drain via the bronchus and the contents are coughed up. Inserting a percutaneous drain creates a particularly difficult form of bronchopleural fistula.
Other thoracic disorders

The lungs

**Lung cysts**

*Developmental.* These may develop from the primitive lung buds near the trachea or main bronchi. There are no communications with the bronchi even though they are lined with respiratory epithelium and have a tendency to become infected. Removal is advised for this very reason.

*Acquired.* Lung cysts may contain air or fluid and may be single or multiple. The most common cause of multiple lung cysts is pulmonary hydatid disease, although this is unusual except in endemic areas. Air cysts (bullae) may be spontaneous but may be secondary to emphysematous degeneration (Fig. 47.31). In either case the cysts may become infected or compress functioning lung tissue and therefore some form of treatment is required.

**Pulmonary sequestration**

This describes a section of lung supplied by the aorta and draining into the systemic circulation. There is no communication with the remainder of the lung and the segment becomes multicystic and infected, therefore compromising the surrounding healthy lung tissue. An interlobar sequestration occurs within the lung substance and commonly presents in younger patients.

Many cases are discovered on routine chest radiography but others may present with recurrent chest infections and occasionally bloodstained sputum. The chest radiograph normally shows a rounded opacity and the lesion cannot be seen at bronchoscopy (Fig. 47.32). Arteriography demonstrates the abnormal communication from the aorta and treatment involves removing the affected lobe, taking care to divide the abnormal artery (which usually runs in the inferior pulmonary ligament) as the first stage in the resection.

**Bronchiectasis**

This is defined as chronic irreversible dilatation of the medium-sized bronchi. There are several causes but there are two basic mechanisms that account for this dilatation:

1. a weakening of the bronchial walls;
2. outward tension on the lung substance.

These may occur following a suppurative pneumonia or bronchial obstruction. The process often starts in childhood following a respiratory infection and slowly progresses during adult life. It is rarely confined to one lobe or even one lung, which precludes surgery in many cases. The incidence of severe bronchiectasis is falling thanks to the reduction in cases of whooping cough, measles and tuberculosis, and the improved management of infantile bronchiolitis. Inhalation of foreign bodies remains a potential cause of bronchiectasis and this possibility should be borne in mind.

**Presentation.** Some patients remain asymptomatic and the problem is discovered by chance on chest radiograph or postmortem. Usually there is a history of frequent chest infections from infancy with the production of copious volumes of sputum. In advanced cases foul-smelling sputum is produced with pain over the affected area, and there is weight loss and cachexia. Physical examination may be normal but often there is finger clubbing (in advanced disease), wheezing and consolidation over the affected lobe. Chronic nasal sinusitis may be a presentation and, in severe cases, amyloidosis may occur.

**Investigation.** A good posteroanterior chest radiograph will often show crowding of the lung markings on the affected side. A series of chest radiographs taken over two to three exacerbations may show persistent collapse or recurrent consolidation affecting the same area of lung. CT is now the investigation of choice.

**Bronchography.** This is rarely necessary to define which lobe(s) are affected; most surgeons would be satisfied with a CT scan. This investigation may need to be preceded by intensive physiotherapy and postural drainage to obtain adequate images.

**Treatment.** Removal of the bronchiectatic part of the lung is indicated when the disease is localised, and the respiratory function is adequate to cope, with a reduced lung volume. Conservative surgery to preserve functioning lung tissue should be employed at all times.

**Tuberculosis**

This infection remains a major health problem in less developed countries but is increasing in frequency in Western countries as a result of immigration and immunosuppression [human immunodeficiency virus (HIV) and chemotherapy]. It commonly presents in the lungs and, if untreated or inadequately treated, can lead to serious complications. There is commonly a chronic cough with haemoptysis, weight loss and night sweats. The diagnosis should be firmly established by Ziehl—Neelsen staining of bacteria in the sputum or culture in Lowenstein—Jensen medium before starting antituberculous chemotherapy. Characteristic chest radiographic changes in symptomatic patients may be diagnostic if cultures are persistently negative; as a very last resort chemotherapy may be tried for 2 weeks. An improvement in symptoms indicates that tuberculosis is the problem.

The mainstay of treatment is antituberculous chemotherapy for the individual and bacille Calmette—Guérin (BCG) immunisation for contacts, attention to hygiene and housing in the community. Combination chemotherapy is usually successful in treating the infection. Inadequate treatment or noncompliance leads to the development of resistant organisms. The course of treatment is often over 6 months and in some less developed countries this can result in noncompliance. Surgery is rarely indicated for tuberculosis in developed countries but, when it is, it must be combined with adequate antituberculous chemotherapy or the benefit of surgery will be lost.

**Indications for surgery.** Indications are:

- suspicious lesion on chest radiograph in which neoplasia cannot be excluded;
- chronic tuberculous abscess, resistant to chemotherapy;
- aspergilloma within a tuberculous cavity;
Diagnosis. Surgical procedures may be necessary to establish the diagnosis if the disease is suspected clinically, but sputum or pus cultures are persistently negative.

Bronchoscopy. This has a higher diagnostic yield than expectorated sputum.

Open lung biopsy. Tissues from intrathoracic lymph nodes, lung and pleura may be found to contain tuberculous material.

Pulmonary vascular disease

A detailed discussion of all the diseases of pulmonary vasculature is beyond the scope of this book. However, pulmonary embolus is a major cause of morbidity and mortality and is discussed here, as is lung and heart—lung transplantation, which is indicated for end-stage pulmonary vascular disease.

Pulmonary embolus. This occurs following dislodgement of venous thrombi, generally from the femoral and iliac veins, and their subsequent impaction in the pulmonary vasculature. More unusual causes are fat embolus from multiple trauma, tumour embolus (renal carcinoma) and amniotic fluid. Pulmonary embolism accounts for over 20,000 deaths per year in the UK. Strategies aimed at preventing the development of thrombi in those at high risk (postsurgical patients, postmyocardial infarction and those who have previously had pulmonary embolus) include early mobilisation, low dose subcutaneous heparin and compression stockings. The presentation can vary according to the size, number and timing of embolic episodes.

Small emboli may pass unnoticed, giving rise to minor pleuritic chest pain. Pulmonary vascular hypertension may develop with repeated episodes. Larger emboli may give rise to pleurisy and haemoptysis with signs of pleural rub and crackles on auscultation. Massive emboli lead to haemodynamic collapse if the outflow to the right ventricle is obstructed. There is severe chest pain and acute shortness of breath. The clinical signs are of right heart failure with raised central venous pressure and tachycardia, and there may be some changes on the ECG. A chest radiograph is often not helpful in the early stages but a ventilation—perfusion scan may show a mismatch, thereby confirming the diagnosis. A contrast-enhanced CT scan is the most accurate diagnostic technique.

Treatment: acute minor pulmonary embolus. Small emboli do not require specific treatment but preventive measures are needed to prevent further episodes. These rake the form of systemic heparinisation in the first instance and then oral anticoagulation with warfarin or its derivatives. Recurrent emboli, even with adequate anticoagulation, may require treatment with an inferior vena caval filter.

Treatment: acute massive embolus. This occurs when a large embolus obstructs the pulmonary vasculature and results in haemodynamic disturbance. There is often a history of one or more minor emboli before the current episode. The haemodynamic problems dominate the clinical picture of acute might heart failure with corresponding low cardiac output and acute ventilation—perfusion mismatch. Theme is peripheral vasoconstriction, tachycardia with a small volume pulse and tachypnoea. Blood gas analysis usually reveals a low P02 from the ventilation—perfusion mismatch and a low Pco2 from the associated hyperventilation. The patient will usually be more comfortable lying flat, in contrast to the patient with myocardial infarction who prefers to sit upright. Once the diagnosis has been made, treatment with thrombolytic agents (streptokinase and tissue plasminogen activator) is started. The emboli are seen as filling defects in the pulmonary artery (Figs. 47.33). The immediate priority is to resuscitate the patient by administering intravenous fluids to increase the right ventricular filling pressure and to avoid venodilators. Oxygen is administered via a face mask (100 per cent) and intravenous heparin is administered to prevent any further propagation of thrombi. Thrombolytic agents may be given directly into the pulmonary artery to ensure high concentrations at the appropriate site. Occasionally pulmonary embolectomy may be required. This may be done without cardiopulmonary bypass using caval inflow occlusion and extracting the embolus through a pulmonary arteriogram. Better results are likely if the patient is fit enough for cardiopulmonary bypass to be established.

Lung transplantation. Lung transplantation is becoming an established therapy for those with end-stage parenchymal or pulmonary vascular disease. The indications for lung transplantation are varied and may involve the use of one donor lung, two donor lungs or the heart—lung block. Cystic fibrosis and irreversible pulmonary hypertension with right ventricular failure are the main indications for heart—lung transplantation but there is now a trend towards single and sequential bilateral lung transplantation, leaving the native heart in situ. This reduces the risk of airway dehiscence which is common with a tracheal anastomosis. Pulmonary fibrosis and obstructive airway disease in young people are indications for single lung transplantation. Donor selection is much the same as for cardiac transplantation except that there must be good respiratory function and no evidence of pulmonary oedema, contusion or infection at the time of harvesting. Matching of donor and recipient and cytomegaloviral (CMV) status is more important than in heart transplantation in trying to avoid the development of CMV pneumonitis.

The recipient operation depends on the nature of the transplant. Heart—lung transplantation requires a median sternotomy and cardiopulmonary bypass. The recipient heart (in the absence of right heart failure) may be suitable for transplantation into another recipient. Single lung transplantation is performed through a thoracotomy with cardio-pulmonary bypass if required. Vigorous physiotherapy and judicious antibiotic use are important in the early postoperative period. Opportunist infections may develop secondary to the immunosuppressive drugs and carry a high mortality unless treated aggressively. One-year survival following heart—lung, double lung and single lung transplantations stands at between 60 and 70 per cent.

There is a current shortage of suitable donors for organ transplantation, therefore alternative treatments for end-stage disease are being explored. One recent development in the field of thoracic surgery is lung volume reduction. This involves excising areas of lung in emphysematous patients with often surprising degrees of subjective and objective improvement. It is unsure whether this procedure restores the mechanics of breathing by altering the chest wall dimensions or improves respiratory function by minimising ventilation—perfusion mismatching. • life-threatening haemoptysis.

Surgery is indicated for certain situations and is always used in conjunction with chemotherapy. With effective treatment and earlier diagnosis, the role of surgery is gradually decreasing in the management of this condition.

Pulmonary embolus accounts for over 20,000 deaths per year in the UK. Strategies aimed at preventing the development of thrombi in those at high risk (postsurgical patients, postmyocardial infarction and those who have previously had pulmonary embolus) include early mobilisation, low dose subcutaneous heparin and compression stockings. The presentation can vary according to the size, number and timing of embolic episodes.

Small emboli may pass unnoticed, giving rise to minor pleuritic chest pain. Pulmonary vascular hypertension may develop with repeated episodes. Larger emboli may give rise to pleurisy and haemoptysis with signs of pleural rub and crackles on auscultation. Massive emboli lead to haemodynamic collapse if the outflow to the right ventricle is obstructed. There is severe chest pain and acute shortness of breath. The clinical signs are of right heart failure with raised central venous pressure and tachycardia, and there may be some changes on the ECG. A chest radiograph is often not helpful in the early stages but a ventilation—perfusion scan may show a mismatch, thereby confirming the diagnosis. A contrast-enhanced CT scan is the most accurate diagnostic technique.

Treatment: acute minor pulmonary embolus. Small emboli do not require specific treatment but preventive measures are needed to prevent further episodes. These rake the form of systemic heparinisation in the first instance and then oral anticoagulation with warfarin or its derivatives. Recurrent emboli, even with adequate anticoagulation, may require treatment with an inferior vena caval filter.

Treatment: acute massive embolus. This occurs when a large embolus obstructs the pulmonary vasculature and results in haemodynamic disturbance. There is often a history of one or more minor emboli before the current episode. The haemodynamic problems dominate the clinical picture of acute might heart failure with corresponding low cardiac output and acute ventilation—perfusion mismatch. Theme is peripheral vasoconstriction, tachycardia with a small volume pulse and tachypnoea. Blood gas analysis usually reveals a low P02 from the ventilation—perfusion mismatch and a low Pco2 from the associated hyperventilation. The patient will usually be more comfortable lying flat, in contrast to the patient with myocardial infarction who prefers to sit upright. Once the diagnosis has been made, treatment with thrombolytic agents (streptokinase and tissue plasminogen activator) is started. The emboli are seen as filling defects in the pulmonary artery (Figs. 47.33). The immediate priority is to resuscitate the patient by administering intravenous fluids to increase the right ventricular filling pressure and to avoid venodilators. Oxygen is administered via a face mask (100 per cent) and intravenous heparin is administered to prevent any further propagation of thrombi. Thrombolytic agents may be given directly into the pulmonary artery to ensure high concentrations at the appropriate site. Occasionally pulmonary embolectomy may be required. This may be done without cardiopulmonary bypass using caval inflow occlusion and extracting the embolus through a pulmonary arteriogram. Better results are likely if the patient is fit enough for cardiopulmonary bypass to be established.

Lung transplantation. Lung transplantation is becoming an established therapy for those with end-stage parenchymal or pulmonary vascular disease. The indications for lung trans-plantation are varied and may involve the use of one donor lung, two donor lungs or the heart—lung block. Cystic fibrosis and irreversible pulmonary hypertension with right ventricular failure are the main indications for heart—lung transplantation but there is now a trend towards single and sequential bilateral lung transplantation, leaving the native heart in situ. This reduces the risk of airway dehiscence which is common with a tracheal anastomosis. Pulmonary fibrosis and obstructive airway disease in young people are indications for single lung transplantation. Donor selection is much the same as for cardiac transplantation except that there must be good respiratory function and no evidence of pulmonary oedema, contusion or infection at the time of harvesting. Matching of donor and recipient and cytomegaloviral (CMV) status is more important than in heart transplantation in trying to avoid the development of CMV pneumonitis.

The recipient operation depends on the nature of the transplant. Heart—lung transplantation requires a median sternotomy and cardiopulmonary bypass. The recipient heart (in the absence of right heart failure) may be suitable for transplantation into another recipient. Single lung transplantation is performed through a thoracotomy with cardio-pulmonary bypass if required. Vigorous physiotherapy and judicious antibiotic use are important in the early postoperative period. Opportunist infections may develop secondary to the immunosuppressive drugs and carry a high mortality unless treated aggressively. One-year survival following heart—lung, double lung and single lung transplantations stands at between 60 and 70 per cent.

There is a current shortage of suitable donors for organ transplantation, therefore alternative treatments for end-stage disease are being explored. One recent development in the field of thoracic surgery is lung volume reduction. This involves excising areas of lung in emphysematous patients with often surprising degrees of subjective and objective improvement. It is unsure whether this procedure restores the mechanics of breathing by altering the chest wall dimensions or improves respiratory function by minimising ventilation—perfusion mismatching.
The diaphragm

The diaphragm is the fibromuscular structure separating the thorax from the abdomen (Fig. 47.34). There are two well-recognised congenital sites where abdominal viscera can herniate into the chest. Traumatic rupture of the diaphragm may also lead to herniation. Congenital hernia tend to be apparent shortly after birth, with over 80 per cent presenting on the left side (Fig. 47.35). There is respiratory distress, apparent dextrocardia, a scaphoid abdomen and radiological appearances of bowel in the hemithorax. Treatment involves urgent nasogastric suction (to prevent distension of the bowel and further compression of the lung) and general resuscitation before surgical repair. Hernias manifesting later in life present with vague dyspeptic symptoms or a feeling of fullness in the chest.

Repair is advised and is undertaken through a left upper transverse abdominal approach or by thoracotomy through the seventh intercostal space with nonabsorbable sutures to repair the defect once the hernia has been reduced.

Oesophageal hiatus hernia is a common problem and is dealt with in Chapter 50.

Hernia through the foramen of Morgagni

This is an anteriorly placed hernia with the defect between the sternal and costal attachments of the diaphragm. The most commonly involved viscus is the transverse colon.

Hernia through the foramen of Bochdalek

This is really the persistence of the pleuroperitoneal canal and the opening is in the dome of the diaphragm posteriorly. It is the most common diaphragmatic hernia in children and presents with severe respiratory distress. There is a classic triad of respiratory distress, apparent dextrocardia and a scaphoid abdomen.

Eventration of the diaphragm

This is an abnormally elevated position of one or both hemi-diaphragms from paralysis or atrophy of the muscle fibres. There may be some spontaneous improvement if the condition occurs in the perinatal period but long-standing cases with paradoxical respiration may benefit from operation.

The aim of surgery is to fix the diaphragm in inspiration so that paradoxical movement and mediastinal shift are minimised. This is achieved by plication of the redundant diaphragm, raking care not to damage the branches of the phrenic nerve.
Appendix 1: Anatomy and development of the lungs (Fig. 47.36)

During the fourth week of intrauterine growth the lung bud develops from the ventral surface of the primitive foregut. This becomes a bibbed structure, the ends of which ultimately become the lungs. The trachea and bronchi derive their blood supply from the bronchial arteries coming from the aorta. Although development is initially symmetrical in each lung bud, the typical lobar arrangement is defined early in foetal life. Congenital abnormalities may occur during development, the most important ones being agenesis (nonformation) or accessory lobes.

The primitive lungs drain into the cardinal veins which ultimately become the pulmonary veins draining into the left atrium. Abnormalities of venous drainage may occur at this stage of development (compare anomalous venous drainage).

Surgical anatomy of the lungs

There are three lobes to the right lung and two to the left, although the two sides are basically very similar (Fig. 47.37). Each lobe is composed of segments (see above) with its own discrete blood supply of pulmonary artery and pulmonary vein: an important point when resecting individual segments. No bronchi or arteries cross the intersegmental plains.

The right main bronchus is shorter, wider and nearly vertical compared with the left. As a consequence, inhaled foreign bodies are more likely to enter the right main bronchus than the left. The bronchi are supplied with blood from the bronchial arteries which arise directly from the aorta. They drain into both the systemic and pulmonary circulations (Figs 47.38 and 47.39).

Lymphatic drainage tends to follow the bronchi and certain collections of lymph nodes are recognised around the hila and trachea (Fig. 47.40).

These are important as their presence or absence is useful in staging malignant disease (noninvasively by radiography or invasively by needle biopsy, mediastinotomy or mediastinoscopy). They are also important in determining prognosis following resection of a lung neoplasm.
Appendix 2: Investigation of the respiratory system

Any patient undergoing general anaesthesia requires some assessment of respiratory function. This is especially important in patients who are undergoing thoracotomy and lung resection, and in patients with limited pulmonary reserve undergoing any surgery.

There is a range of lung function tests available to provide objective evidence of pulmonary disease. These tests are useful in determining the functional capacity of the patient and the severity of the disease, and in predicting the response to various treatment options. The tests range from those that are simple and can be done at the bedside to those that are only available in specialist centres.

The simpler tests are the following (Table 47.8).

**Peak expiratory flow rate (PEFR)**
This is measured by a Wright peak flowmeter or a peak flow gauge. This is a reliable and reproducible test, but has the disadvantage of being effort dependent and therefore it may be affected by abdominal or thoracic wound pain.

**Forced expiratory volume in 1 second (FEV₁)**
This is the amount of air forcibly expired in 1 second. It is low in obstructive lung disease and may be normal in restrictive lung disease.

**Forced vital capacity (FVC)**
This is the volume of air forcibly displaced following maximal inspiration to maximal expiration. The FEV₁ and the FVC can be measured using a Vitallograph and a ratio (FEV₁/FVC) can be calculated (Fig. 47.41). A low ratio indicates obstruction and the test should be repeated after bronchodilators. A normal ratio (FVC and FEV₁ reduced to the same extent) indicates a restrictive pathology.

**Blood gases**
A simple noninvasive probe will measure the oxygen saturation of haemoglobin but it should be borne in mind that the oxygen content of blood may fall precipitously at saturations of less than 90 per cent (as an effect of the oxygen dissociation curve). Arterial blood gases give a great deal of information; this is summarised in Table 47.9. Changing trends in the data provided by blood gas analysis are as important as the absolute values.

The risks and benefits of lung surgery should be discussed with the patients in the light of these tests. There are no absolute guidelines but, in general, a patient with the following values should tolerate a major lung resection:

- FEV₁ >1 litre;
- FVC >2 litres;
- normal carbon dioxide tension (Pco₂);
- age <70 years.

Heart surgery

Congenital, valvular and coronary heart disease all have a largely mechanical component and lend themselves particularly well to surgical correction. This was predicted in 1925 by Henry Souttar of the London Hospital, Whitechapel, who wrote in the British Medical Journal, in the introduction to his report of the first mitral commissurotomy, that the heart should be as amenable to surgery as any other organ and that many of the problems in heart disease were to a large extent mechanical. He saw the main problem as being maintenance of blood flow, particularly to the brain, while surgery was being performed. The first real steps in surgery in and around the heart came in the late 1940s and early 1950s, driven by surgeons who had gained confidence and experience under the pressures and opportunities provided by war. Further progress had to wait until the development of cardiopulmonary bypass in the mid 1950s. Now the number, range and technical complexity of heart operations are remarkable; with the pump restored to good working order, the well-being and lifespan of patients with congenital, valvular and degenerative heart disease can be very much improved.

In this chapter those cardiac diseases that can be helped by surgery are included. The surgical management of heart disease is particularly appropriate to illustrate some principles in the logic of surgical decision making.

The purpose of an operation should be to relieve symptoms, to improve prognosis or both. As far as symptoms are concerned the surgeon should help the patient towards an informed appraisal of the risks and benefits applicable to the particular case, as with any other operation. For prognosis, the matter is one in which the surgeon should provide the patients with advice based on the best available knowledge. Ideally, three numerical pieces of information are required:

1. the outlook if the condition remains unoperated on;
2. the risk of the operation itself, including failure to deal with the disease;
3. the outlook following successful surgery.

The approach is illustrated diagrammatically (Fig. 48.1).

Cardiopulmonary bypass

Cardiopulmonary bypass allows the surgeon to manage the circulation while operating on a still heart in a bloodless field. Valve surgery under direct vision would not have been possible had it not been for the introduction of cardiopulmonary bypass in the 1950s by Gibbon. Before this, valve surgery was performed using closed techniques (mostly commissurotomies or valvotomies performed with dilators). There is still a role for these procedures, but now most valve procedures are performed on a still heart with the aid of cardiopulmonary bypass, which has undergone many modifications since its first development (Figs 48.2 - 48.4).

Today it is a very safe way to manage the circulation during surgery, although there are still some associated problems that cause morbidity. For most operations, the heart is approached by a median sternotomy. An incision is made from the jugular notch to the lower end of the xiphisternum. The sternum is divided and retracted to expose the pericardium. The patient is fully heparinised and the pericardium is opened, taking care not to damage the brachiocephalic vein. The great vessels are exposed and a purse string is inserted into the adventitia of the ascending aorta proximal to the brachiocephalic artery. A second purse-string suture is inserted into the right atrium by the appendage. A 1-cm cannula is inserted into the ascending aorta and held in place by the purse-string suture. Air is excluded and the cannula is connected to the bypass circuit. Venous drainage is established from a cannula placed in the right atrium. Alternatively, the superior and inferior caval veins may be cannulated separately to gain better control over the venous return and to facilitate surgery within the right atrium. Once the circuit is connected, the cardiopulmonary bypass machine (the pump) takes over the circulation and ventilation can be discontinued. The core temperature may be lowered to reduce the metabolic demands of the tissues, and the surgeon can now isolate the heart from the rest of the circulation.

At the end of the procedure air must be meticulously excluded from the cardiac chambers. Once perfusion is restored to the coronary arteries, the heart may beat spontaneously or, if ventricular fibrillation is present, it may require a shock by a direct current (DC). Epicardial pacing wires may be placed to treat postoperative bradycardia or heart block. The patient is rewarmed, acidosis or hypokalaemia is corrected, ventilation is restarted and venous blood is allowed to fill the right atrium by clamping the venous line of the bypass machine. The heart gradually takes over the circulation while the arterial flow from the cardiopulmonary bypass machine is reduced. When the blood pressure is acceptable and the surgeon is confident that the heart function is adequate, cardiopulmonary bypass is discontinued and the venous cannula removed. Blood from the bypass reservoir may be given through the arterial cannula while protamine is given to reverse the effects of heparinisation.

Femorofemoral bypass

This is a form of cardiopulmonary bypass that is used when it is difficult or impossible to enter the chest until bypass has been established. Venous drainage may be from the femoral vein or the right atrium. Arterial return is via the femoral artery which has to be surgically exposed.

Vascular shunts

Heparin-bonded shunts are used to bypass a section of aorta requiring resection or repair. They are particularly useful for aortic transection repair following a high-speed deceleration injury when cardiopulmonary bypass would be inadvisable. The shunt perfuses the aorta distal to the site of injury and therefore protects against paraplegia (Fig. 48.5).
Valvular heart disease

The normal functioning of the atroventricular valves depends on the integrity of the valve annulus, the leaflets, the chordae tendineae and the papillary muscles. Malfunction of one or more components will adversely affect the performance of the valve. The semilunar valves allow blood to leave the ventricle during systole and prevent its regurgitation during diastole. The intrinsic shape of the valve allows this and disruption of the leaflets or the annulus can affect valve function. In the normal state a heart valve presents no resistance to forward flow but prevents regurgitation into the chamber proximal to it (Figs 48.6 and 48.7).

Mitrail valve disease

Mitrail stenosis

Apart from rare congenital anomalies which present in infancy, mitral stenosis is a consequence of rheumatic fever (Figs 48.8 and 48.9). During the healing phase of acute rheumatic fever, the valve leaflets become adherent to each other at their free border so that the commissures become obliterated. This narrows the valve orifice and further obstruction ensues when the cusps become thickened and stiff. There may be a degree of regurgitation if the valve is unable to close during systole. This is the most common inflammatory disease affecting the heart valves world-wide, but the incidence has fallen over the last few decades probably as a result of the combination of improved living standard and better treatment of streptococcal infections with antibiotics. The incidence affects all parts of the heart but the major residual haemodynamic effects are the result of involvement of the valves. The mitral valve is most frequently involved with the aortic, tricuspid and pulmonary valves affected less often. The characteristic pathological finding in chronic rheumatic valve disease is thickened valve cusps with fused leaflets and fused chordae.

Haemodynamics. The passage of blood is obstructed from the left atrium to the left ventricle and the pressure in the left atrium rises. The pressure in the pulmonary veins and capillaries rises and, if it exceeds the oncotic pressure, there is acute pulmonary oedema. The lungs are protected against pulmonary oedema by contraction of proximal pulmonary arterioles, but this leads to an increased demand on the right ventricle which ultimately fails. Raised systemic venous pressure leads to peripheral oedema.

A serious complication of mitral stenosis is the development of atrial fibrillation. This may herald the onset of symptoms and the enlargement of the left atrium may predispose to the formation of thrombus. Infective endocarditis is a further hazard (Fig. 48.10).

Clinical features. There may be signs of right heart failure and the pulse may be irregular if atrial fibrillation has occurred. The heart sounds may reveal an opening snap if the valve is still pliable and in pure mitral stenosis, a low rumbling diastolic murmur will be heard. The presence of the second heart sound may be loud depending on the severity of the pulmonary hypertension.

Investigation. Chest radiography. There is a small aortie outline and a prominent pulmonary artery. The left atrium enlarges (sometimes to an enormous degree) and the right ventricle also appears enlarged. The left ventricle is spared if there is no aortic valve disease and is of normal size or small (Figs 48.11 and 48.12).

Electrocardiography (ECG). The right ventricular hypertrophy results in tall QRS complexes in the right ventricular leads (combined height of Q and R>30 mm in leads V1-V3). There may also be a characteristic notched P wave (P mitrale) if sinus rhythm is present. In standing long-term mitral stenosis there is usually atrial fibrillation and no P waves are seen.

Indications for surgery. Surgery is indicated for severe symptoms which are usually present if the pressure difference across the valve (during diastole) is 10 mmHg or more. Surgery is also indicated to protect the patient's future under certain circumstances, even if the patient is uncomplaining. Prognosis is determined by the severity of the stenosis, the size of the atrium, the onset of atrial fibrillation, rising pulmonary artery pressure and the unpredictable risk of embolism from a large fibrillating atrium. The operation carries a low risk, particularly if the valve can be conserved rather than replaced; there is a high prospect of success and improved prognosis thereafter.

Surgery is best avoided during pregnancy but may be necessary if the heart cannot meet the extra demands placed on it. Other valves may be affected and their relative importance to the patient's condition must be assessed. Age is not a contraindication but the risks from surgery increase with age. A pliant, mobile valve may benefit from balloon valvotomy but restenosis is likely. Stiff, calcified valves require replacement.

Mitrail regurgitation

Any pathology affecting the integrity of the valve apparatus (annulus, leaflets, chordae tendineae and papillary muscles) will lead to mitral regurgitation. There are many causes of regurgitation but they can be broadly classified into four headings:

1. degenerative (flabby valve - myxomatous degeneration of the leaflets);
2. ischaemic (papillary muscle rupture);
3. rheumatic (stiffened leaflets unable to coapt);
4. endocarditis (leaflet destruction by the infective process).

Mild degrees of regurgitation are well tolerated and even severe regurgitation which has slowly progressed may cause little disability (Fig. 48.13). The ventricle ejects into a large compliant left atrium and the pulmonary capillary pressure may be little affected. There is a pansystolic murmur over the apex, but there may be no other clinical signs if the process has progressed slowly and the left ventricle has adapted to the volume load placed on it. In contrast, acute mitral regurgitation is not well tolerated because the atrium is small and it may be associated with left ventricular ischaemia (for example, with papillary muscle rupture). There may then be clinical and radiological evidence of acute pulmonary oedema.

Investigations. Electrocardiography. This does not really contribute to the diagnosis although there may be left ventricular hypertrophy (Fig. 48.14).

Chest radiography. There may be cardiomegaly and plethoric lung fields (Fig. 48.15).

Echocardiography. This will confirm the diagnosis and assess the degree of regurgitation.

Indications for operation. Patients with similar haemodynamics may have very different symptoms. Definite indications include severe symptoms, increasing pulmonary hypertension and uncontrolled endocarditis. Even in an asymptomatic patient it may be important to operate to protect the future if the left ventricle is beginning to dilate. The aim is to conserve the valve but, if it cannot be made competent by surgical valvuloplasty, replacement is necessary.

Mitrail valve operations

Closed mitral valvotomy

This procedure was the first commonly performed valve operation which effectively and reproducibly relieved the obstruction of mitral stenosis. The heart is approached through a left thoracotomy, and purse-string sutures are placed at the apex of the left ventricle and in the left atrial appendage. A finger is introduced into the left atrial appendage and the mitral valve is assessed by direct palpation. A speculum (Tubbs) is inserted through the left ventricular apex and across the mitral valve (Fig. 48.16). The dilator is opened and the fused commissures are split. Some regurgitation may occur and the process may have to be repeated after 10-15 years. For the best results, the valve should be pliant, judged clinically by its loud first sound and opening snap; the characteristics of the valve are now ascertained by two-dimensional echocardiography. In experienced hands, the mortality rate is less than 1 per cent. It is uncommonly performed at present as similar results can be achieved with percutaneous balloon valvotomy (Fig. 48.17).

Open repair

The current preference is to perform an open valvotomy with cardiopulmonary bypass under direct vision. This allows more accurate division of the commissures. In
regurgitation, the valve can be repaired with a variety of techniques depending on the underlying pathology. Annular dilatation may be corrected by the use of an annuloplasty ring (Fig. 48.16). Leaflet destruction can be repaired with autologous pericardium and redundant tissue can be excised with direct repair to ensure leaflet apposition. Chordae can also be reconstructed. There is a trend to try and preserve the patient’s native valve but if the valve is irreparable then it requires replacement.

**Valve replacement**

Valve replacement has undergone many modifications since it was introduced in the 1950s. There are two basic categories of replacement valve: biological and mechanical.

**Biological valves.** The most commonly used valve is the glutaraldehyde-preserved porcine valve, mounted on a sewing ring and frame (Carpenter). It has very similar haemodynamics to a human valve but it degenerates with time. Its main advantage is that it is not thrombogenic and therefore anticoagulants are not required. Its limited lifespan and nonthrombogenicity make it suitable for elderly patients. Other indications include women of child-bearing age and those in whom warfarin is contraindicated; however, a further valve replacement will become necessary within 10-15 years. Human valves (homograft) may be used particularly in the aortic position in young patients. There is an increasing trend to remove the native pulmonary valve and place it in the aortic position, using a homograft to replace the pulmonary valve (Ross). This operation is technically difficult and involves two valve operations (aortic and pulmonary) but the results are impressive with a low valve degeneration rate.

**Mechanical valves.** There are three commonly used designs: the cage and ball, the tilting disc and the bileaflet (Fig. 48.19). They are composed of a sewing ring and moving component(s) and have the advantage of durability. The main disadvantage is that the components of the valve are thrombogenic and therefore the patient requires systemic anti-coagulation, usually with warfarin. This subjects the patients to a lifetime of blood tests, medication and the constant threat of haemorrhagic complications (intracerebral, epistaxis, gastrointestinal bleed). All patients with prosthetic valves are at risk of developing endocarditis.

**Results of treatment**

The operative mortality rate for elective mitral valve replacement is around 5 per cent (Fig. 48.20). This depends largely on the state of the myocardium and the general condition (including age) of the patient. Any associated pathology such as endocarditis or ischaemic heart disease increases the risk.

The aortic valve

**Aortic valve disease**

The normal aortic valve has three cusps corresponding to the sinuses of Valsalva, and named according to the relationships of the coronary orifices - right, left and noncoronary. Its surgical anatomy is challenging as it sits in the middle of the heart surrounded by the neighbouring three cardiac chambers: the right atrium (RA) and right ventricular (RV) outflow and the left atrium. The anterior leaflet of the mitral with the conducting tissue lies in continuity with the aortic valve annulus.

**Stenosis**

In young patients, stenosis is almost always congenital. In middle age, pathology is usually extensive calcification in a congenitally bicuspid valve. Severe stenosis is a result of thickening and calcification of the valve cusps but with no commissural fusion (unlike the appearances in rheumatic stenosis (Figs 48.21-48.23). The left ventricle hypertrophies to overcome the stenosis but eventually the ventricular muscle fails. Patients are often asymptomatic until decompensation occurs. Dyspnoea, angina and exercise syncope are common complaints. There is an ejection systolic murmur over the aortic area radiating to the carotids. The pulse is slow rising in character and the apex beat may be displaced.

**Investigations.**

**Chest radiography.** There is cardiomegaly in the advanced case and poststenotic dilatation of the aorta (Fig. 48.23).

**Electrocardiography.** There is left ventricular hypertrophy with tall R waves in the lateral leads and sometimes a strain pattern’ (ST depression in the lateral leads).

**Echocardiography.** This confirms the diagnosis and estimates the gradient.

**Coronary angiography** is often undertaken to exclude concurrent coronary artery disease and a direct measurement of the pressure gradient (the peak systolic difference between the left ventricle and the aorta) across the valve may be obtained.

**Indications for operation.** Operation is indicated for symptoms. In asymptomatic patients the stenosis should be relieved before irretrievable left ventricular failure occurs. The natural history is poor with a median survival of less than 2 years once symptoms occur. The patient is at risk of sudden death related to the severity of the stenosis. An estimated or actual gradient of over 60 mmHg is sufficient indication for replacement, but it should be remembered that, as the left ventricular function deteriorates, the stroke volume falls and the measurable gradient becomes less.

**Aortic regurgitation**

This may be caused by a number of conditions which disrupt the integrity of the aortic valve by affecting the cusps or their ability to coapt (Figs 48.23 and 48.26). Marfan's syndrome causes dilatation of the aortic root thus preventing closure of the valve. Other causes include rheumatic fever, connective tissue disorders, aortic dissection, tertiary syphilis and endocarditis. The increased stroke volume results in left ventricular dilatation. The pulse is large volume and collapsing in character. Slowly progressive regurgitation may be well tolerated for years but the patient may complain of progressive dyspnoea on exertion and angina. Up to 70 per cent of the ejection fraction may return to the left ventricle in aortic regurgitation.

**Investigations.**

**Chest radiography.** The disease may be severe without overall increase in the cardiac dimensions and increasing size is an indication that the left ventricle is dilating.

**Electrocardiography.** There are enlarged R waves in the lateral chest leads denoting left ventricular hypertrophy and a strain’ pattern (ST depression) but the rhythm is normally regular.

**Echocardiography** with a Doppler probe will confirm the regurgitation.

**Coronary angiography** may be required if coexistent ischaemic heart disease is suspected.

**Indications for operation.** Minor degrees of aortic regurgitation are well tolerated but if the ventricle deteriorates and dilates it may be too late to retrieve the situation. The end- systolic dimension, as measured by echocardiography, is often the best serial measure of worsening left ventricular dilatation and a figure of over 5.5 cmHg indicates severe pathology warranting valve replacement. Patients with severe symptoms or worsening left ventricular dilatation are candidates for surgery.

**Aortic valve surgery**

Unlike mitral valve surgery, there are few occasions where the aortic valve can be repaired and usually the valve requires replacement. This is performed through a median sternotomy on cardiopulmonary bypass. The aorta is cross-clamped and opened proximally to reveal the diseased valve. Cardioplegic solution is infused into the coronary arteries to arrest the heart in diastole. The valve is then excised leaving the annulus in situ but removing as much calcific debris as possible. The replacement valve is then sutured into position at the level of the native annulus and the aortotomy is closed. The heart is de- aired and the cross-clamp released, thus reperfusing the myocardium.

**Results of treatment**

The operative mortality rate for elective aortic valve surgery is less than 5 per cent, but emergency surgery, surgery for endocarditis or surgery in older patients results in a higher operative mortality rate (Fig. 48.27).
Tricuspid valve

**Tricuspid valve disease**

This valve is rarely involved in isolation by a disease process (Fig. 48.28). In rheumatic fever, the aortic and mitral valves are usually affected as well, with stenosis more common than regurgitation. The carcinoid syndrome may produce isolated stenosis.

Isolated tricuspid regurgitation is almost exclusively caused by endocarditis in drug addicts who inject intravenously. There is characteristic venous pulsation in the neck and systolic pulsation of the liver, leading to abdominal pain and ascites.

It may be possible to perform a valvotomy for stenosis but this usually leads to severe incompetence. In these cases it is necessary to replace the valve. For regurgitation there are numerous ways to perform valvuloplasty, all of which seem to produce reasonable results. The mortality from tricuspid valve surgery is high, largely as a result of the associated pathology from other valve lesions.

**Pulmonary valvular disease**

Acquired pulmonary valve disease is rare and usually results from the carcinoid syndrome or rheumatic fever. In both diseases, other valve lesions usually dominate the clinical picture. Pulmonary valvotomy is usually feasible for stenosis. Replacement is almost never performed.

Prosthetic valve

**Prosthetic valve disease**

There is now a large cohort of patients who are long-term survivors after prosthetic valve surgery and a number of problems and complications can occur. Some of these problems may be technical and related to the valve itself and others are the result of valve replacement in general (Fig. 48.29).

**Valve failure.** From about 7 years after implantation, cases begin to come back for reoperation with increasing frequency. The deterioration results in stenosis, incompetence or both. This usually progresses slowly, allowing planned replacement in most cases (Fig. 48.30).

Failure of a mechanical prosthesis can be sudden and catastrophic, resulting in a rapid demise.

**Thromboembolism.** This is always a risk with foreign material in the circulation (Fig. 48.31). The risk is low with the biological valves and anticoagulation is unnecessary. This makes this type of valve suitable for elderly patients. Anticoagulation is mandatory for mechanical valves and this results in frequent blood tests and the associated bleeding problems.

**Paravalvular leak.** This is usually a technical problem resulting in a leak between the valve ring and the native annulus (Fig. 48.32). It may also be the result of infection. The leak can cause haemolytic anaemia or haemodynamic compromise and the valve may need replacement.

**Endocarditis** is a serious complication. All patients must be made aware of this potential complication and must have prophylactic antibiotics for any type of surgical or dental procedure. There are marked systemic symptoms and the infective process may progress rapidly to destroy the native valve annulus, leading to abscess formation.

The mortality rate from this condition is very high (>50 per cent) even with antibiotics, and early surgery to remove the infected prosthesis is recommended. Aggressive surgical therapy using a homograft wherever possible has reduced the mortality rate to less than 20 per cent. Management should be a joint approach with involvement of the surgeon, physician and microbiologist.

**Infective endocarditis**

Endocarditis of a heart valve occurs when a suitable organism is exposed to a vulnerable intracardiac site. Most commonly, this is the patient's own abnormal valve or a valve replacement. Rarely it can occur in an intracardiac shunt (ventricular septal defect or patent ductus arteriosus). The bloodstream is often exposed to transient bacteraemias, particularly during dental treatment, but any microorganism, except viruses, can lead to endocarditis.

The most common organisms are:

- Streptococcus viridians;
- staphylococci;
- enterococci.

Endocarditis seems to become established in regions of turbulent flow in the heart. Fibrinous deposits containing platelets and the organisms develop to form characteristic vegetations. These may invade the surrounding tissue and destroy it, leading to valve incompetence and abscess formation (Fig. 48.33). Embolic debris may become lodged in the peripheries causing a variety of clinical features.

Presentation. There is often an influenza-type illness with generalised pain. The symptoms may fluctuate over several weeks, but once the endocarditis begins to destroy tissue then the patient's condition may markedly worsen. An important part of the history is the presence of an underlying congenital or valvular anomaly. Anaemia may be present together with splinter haemorrhages and tender nodules (Osler's nodes) in the finger pulps. A detailed examination of the cardiovascular system should note any murmurs or change of murmur from those heard previously. Splenomegaly may occur and retinal emboli should be specifically excluded. Daily examination is mandatory to detect any deterioration in the patient's condition.

Blood cultures are taken from up to six different sites before antibiotics are given. Once an organism is grown, the antibiotics can be tailored to the organism isolated. About 80 per cent of blood cultures will grow an organism in this condition. The chest radiograph is often normal but the cardiac outline may enlarge if valve regurgitation is present and metastatic lung abscesses may occur. The EGG may show a lengthened P-R interval or degrees of heart block if an aortic root abscess has formed. Echocardiography is an important investigation because it will demonstrate the motion of the heart, the state of the valves and any vegetations present. Serial echocardiograms will monitor response to treatment.

In spite of the introduction of antibiotics, the 1-year mortality rate of this condition is 25-30 per cent. Cure is often possible if a sensitive organism is present and treatment started early. A delay in the diagnosis, inadequate treatment, prosthetic valve endocarditis and resistant organisms all reduce the likelihood of cure. Urgent surgery may be necessary if the haemodynamic state deteriorates while infection is still present. If the patient is haemodynamically stable, he or she needs 6 weeks of intravenous antibiotics. Indications for surgical intervention are:

- an important mechanical lesion that can be corrected (regurgitant valve or acquired shunt);
- development of an abscess resulting in heart block;
- uncontrolled infection in spite of seemingly adequate antibiotic regimens.
Congenital heart disease Development of the heart

The primitive vascular tube is apparent by the third week of foetal life and over the next weeks it folds in on itself, becomes septated and begins to beat (Fig. 48.34). By 12 weeks it has fully developed. Abnormalities may arise from the persistence of normal foetal channels (patent ductus arteriosus, patent foramen ovale), failure of seption (atrial septal defect (ASD), ventricular septal defect, tetralogy of Fallot), stenosis (intracardiac - supravalvular, valvular, infravalvular; or extracardiac - coarctation of the aorta), atresia or abnormal connections (transposition of the great arteries, total anomalous venous drainage). Echocardiography is now sufficiently sensitive to detect intracardiac lesions in the second trimester.

The incidence of congenital heart disease is about 1 per cent for live births. There is often no obvious aetiology but well-recognised associations include:

- Maternal illness:
  - systemic lupus,
  - diabetes,
  - rubella,
  - alcohol abuse,
  - certain drugs (warfarin, phenytoin);
- chromosomal anomalies:
  - trisomy 21 (atrial septal defect - primum type, atrioventricular septal and atrioventricular canal defects),
  - trisomy 13 and 18,
  - Turner’s syndrome (coarctation).

If the haemodynamic abnormality is tolerated, elective definitive operation is planned at an appropriate time in childhood but in some cases the infant is very ill and requires surgery in the neonatal period. Close co-operation between the paediatric cardiologist and the cardiothoracic surgeon is essential to define the anatomy of the defect, the degree of compromise and the necessary treatment.

Investigation of a child suspected of having a congenital defect begins with an accurate history from the parents and specific questions about maternal health and drug intake during pregnancy. A detailed family history is important because some defects are familial. Clinical examination may reveal a murmur, evidence of heart failure, failure to thrive and cyanosis. Investigation is much the same as for the adult patient and, with echocardiography available, catheterisation is now avoided whenever possible.

Classification

Congenital heart disease is broadly classified into cyanotic and acyanotic, although the distinction is not often clear cut. Only the more commonly encountered anomalies will be described.

There are three groups of cyanotic congenital heart disease and a representative example from each group will be described in detail.

1. A right-to-left shunt (compare Fallot's tetralogy): desaturated blood enters the systemic circulation before it passes through the lungs.
2. Parallel systemic and pulmonary blood flows (transposition of the great vessels): some mixing must occur or this situation would be incompatible with life.
3. Defects in the connections of the heart where there is mixing of the systemic and pulmonary blood flows [total anomalous pulmonary venous drainage (TAPVD)].

Tetralogy of Fallot

This is a range of conditions in which there is a ventriculoapertal defect with an overriding aorta, pulmonary artery stenosis and right ventricular hypertrophy making up the tetralogy (Fig. 48.35).

It is a relatively common condition accounting for about 10 per cent of all congenital heart defects. The large ventriculoapertal defect results in equal pressures within both ventricles. As a result of the pulmonary stenosis, more blood is discharged into the aorta but this blood is only partially saturated and cyanosis results. The lungs are only partially perfused and the total oxygenation is poor. The right ventricle is the dominant chamber in the circulation. One clinical feature of Fallot's tetralogy is squatting. This increases systemic vascular resistance and consequently blood is diverted into the pulmonary circulation with increased oxygenation. Lethargy and tiredness are common presenting symptoms but cyanosis is the most obvious clinical feature.

There is usually polycythaemia and the chest radiograph reveals a boot-shaped heart with poorly developed lung vasculature. The diagnosis is confirmed by echocardiography and cardiac catheterisation.

Indications for operation. These include severe cyanosis, dyspnoea on exertion and syncopal attacks. The choice of operation depends on anatomical considerations and the age and general condition of the patient.

There are two approaches to the operative treatment of Fallot's tetralogy (Fig. 48.36). Palliative procedures to divert systemic blood into the pulmonary circulation may be used to improve oxygenation. These include right subclavian to pulmonary artery anastomosis (Blalock-Taussig) or a modification in which an interposition graft is used or an aortopulmonary artery anastomosis (Potts). Definitive repair may be performed as the first procedure, or some years after a palliative shunt.

Total correction is via a median sternotomy and can include dealing with a previously constructed shunt. The correction is performed using cardiopulmonary bypass and the ventricular septal defect is closed (often with autologous pericardium), the stenotic infundibulum or pulmonary valve is dealt with and the right ventricular outflow tract is widened using a pericardial or a synthetic patch. Repair is often undertaken in the third year and ideally before the child reaches school age.

Transposition of the great vessels

In this condition the aorta arises from the right ventricle and the pulmonary artery from the left ventricle (Fig. 48.37). Oxygenated blood from the lungs is returned to the lungs and desaturated blood is pumped around the systemic circulation. Obviously, if the pulmonary and systemic circulations are separate, the situation is compatible with life. Mixing of blood must occur via an atrial or ventricular septal defect or patent ductus arteriosus. The condition was first described by Morgagni. Palliation was achieved by initially creating an ASD (Blalock) but both Senning and Mustard devised operations to redirect atrial blood into the appropriate ventricle so that oxygenated blood reaches the systemic circulation and deoxygenated blood goes into the pulmonary circulation.

The most obvious presentation is severe cyanosis in the neonatal period, but there is little in the way of respiratory symptoms. Cardiac catheterisation and echocardiography confirm the diagnosis and delineate the anatomy.

Treatment. The initial treatment for this condition is balloon septostomy (Rashkind). A balloon-tipped catheter is advanced from a large vein and manipulated across the atrial septum. The balloon is inflated and forcibly retracted thus producing a large tear in the intra-atrial septum. This allows adequate mixing of the two circulations and provides excellent palliation until a corrective procedure can be performed. Total anatomical correction has become popular and can be carried out even in the neonatal period. This involves disconnecting the pulmonary artery from the left ventricular outflow and the aorta from the right ventricular outflow. The coronary arteries are reimplanted into the aorta which now arises from the left ventricle (as it should). The mortality rate is 10 per cent but the long-term results for those who survive are good.

Total anomalous pulmonary venous drainage

This condition accounts for only 1-2 per cent of congenital heart disease. In this condition the pulmonary venous drainage has become disconnected from the left atrium and drains into the systemic venous circulation at some point (inferior vena cava, superior vena cava, coronary sinus or right atrium). There is mixing of the systemic and pulmonary circulations through a patent foramen ovale.

Diagnosis. There is cyanosis on exertion, often with failure to thrive and feeding difficulties. The chest radiographic appearances depend on the anatomy but may be
normal. There is right axis deviation and right ventricular hypertrophy on the ECG. Echocardiography and cardiac angiography are necessary to confirm the diagnosis and establish the location of the anomalous drainage.

Indications for surgery. Prognosis without operation is poor and the exact operative technique depends on the anatomy. The surgical principle is to re-establish the pulmonary venous drainage into the left atrium. Operative mortality is higher in younger patients and in those with complex lesions. The long-term results for survivors of the operation are generally good.

**Eisenmenger's syndrome**

This occurs following the reversal of a left-to-right shunt. There is a number of conditions resulting in a left-to-right shunt (atrial and ventricular septal defects, patent ductus arteriosus, etc.), but eventually the right ventricle hypertrophies and the pressure in the pulmonary artery increases as a result of the increased flow. Increasing pulmonary hypertension leads to equalisation of pressures either side of the shunt but, at some point, the right-sided pressures will exceed those on the left side and desaturated blood enters the left side of the circulation. Cyanosis and dyspnoea are the most common clinical features. This state of affairs is termed Eisenmenger's syndrome and is irreversible. Closure of the shunt is contraindicated if pulmonary hypertension is irreversible because the right-to-left shunt now serves to decompress the pulmonary circulation.

**Acyanotic congenital heart disease**

**Persistent ductus arteriosus**

This anomaly accounts for 5-10 per cent of congenital heart disease. Following birth, the ductus arteriosus, which facilitates the transfer of oxygenated blood in the foetal circulation from the pulmonary artery to the aorta, begins to close. The trigger for this is poorly understood but the drop in the resistance of the pulmonary circulation as the lungs expand may contribute. The mechanism of ductus closure involves prostaglandins and prostaglandin analogues may be used therapeutically to keep the ductus open in the first few weeks of life. There may be occasions when a patent ductus is necessary for survival as in some forms of congenital heart defects (such as coarctation of the aorta), where the ductus provides the only means of oxygenated blood reaching the systemic circulation. The ductus may be closed during the first few weeks of life by administering indomethacin. In the isolated case of patent ductus, there is a left-to-right shunt of blood resulting in a high pulmonary blood flow. This may lead to respiratory difficulties in the preterm child in addition to heart failure. If medical treatment to close the ductus is unsuccessful, the lesion may be treated by intervention. Cardio in the ductus arteriosus should be considered because of the risk of endocarditis.

**Coarctation of the aorta**

This accounts for 5 per cent of congenital heart disease. In this condition the arch of the aorta around the area of the ductus arteriosus is narrowed (Fig. 48.39 and 48.40). The coarctation puts a pressure load on the left ventricle which can ultimately fail. The upper body is well perfused but the lower body, including the kidneys, is poorly perfused leading to fluid overload, excess renin secretion and acidosis. There is often radiofemoral delay when examining the pulses. The child often appears well in the first few days of life because the coarctation is bypassed by the ductus arteriosus and oxygenated blood reaches the entire systemic circulation.

As the ductus closes, the child becomes progressively more unwell. Emergency treatment includes the administration of prostaglandin analogues to keep the ductus open and general resuscitation before corrective treatment, which includes balloon dilatation or open operation via a stenotic thoracotomy.

Operative options include resection of the coarctation and end-to-end anastomosis or the use of the left subclavian artery as an onlay flap. In older children, there is upper body hypertension with development of enormous collateral vessels which may cause rib notching and flow murmurs over the scapula. Treatment is advised because of the risk of endocarditis and heart failure, but the preoperative hypertension may not resolve. In the older patient, the subclavian flap operation is not feasible and resection with end-to-end anastomosis, interposition graft or a jump graft are the surgical options.

**Vascular rings**

Abnormalities of the great vessels can constrict the structures in the mediastinum, namely the trachea and the oesophagus. Many vascular rings can be explained by the persistence or failure to regress of parts of the aortic arch system during embryonic development. Investigations include a barium swallow, bronchoscopy or angiography. Treatment is indicated for the relief of symptoms and is usually directed at dividing the nondominant vascular component of the ring.

**Congenital valvular abnormalities**

Among the obstructive lesions are aortic, mitral and pulmonary valve stenoses, as well as supravalvular and infravalvular obstructions.

Pulmonary stenosis. There is an incomplete obstruction in this condition to the flow from the right ventricle. This accounts for about 10 per cent of all congenital heart disease. The obstruction is often at valve level and there may be an associated ASD.

The right ventricle hypertrophies in an effort to overcome the obstruction and pulmonary artery pressures may exceed systemic pressure (Fig. 48.41). The defect is often asymptomatic and a murmur is detected at preschool screening. On chest radiographs the lung fields will be oligaemic and there is often poststenotic dilatation of the pulmonary artery. Treatment is directed at relieving the obstruction and this may be done under direct vision or by balloon dilatation.

Congenital aortic stenosis. This may be valvular, subvalvular or supravalvular but in all cases there is a pressure load on the left ventricle leading to hypertrophy (Fig. 48.42). The most common defect is a bicuspid valve where one of the cusps has not developed; however, this is rarely a problem until adulthood. There may be a lot of calcification by the time initial symptoms present. There may be a regurgitant element to the problem. Echocardiography demonstrates the size of obstruction.

Indications for operation. Unfortunately the condition is well advanced once symptoms occur and therefore treatment may be indicated to safeguard the patient's future. The operation relieves the obstruction by repairing the cusps, excising obstructing hypertrophic myocardium or replacing the valve. Infravalvular obstruction is dealt with by excising the obstructing membrane and supravalvular obstruction is repaired using a patch graft. There is a high mortality for emergency procedures, but in the elective situation the mortality rate should be less than 5 per cent.

**Atrial septal defect**

The development of the atrial septum is complex and abnormalities of development lead to three commonly recognised ASDs.

**Fossa ovalis defect** (syn. ostium secundum ASD)

This is the most common type of ASD and is a defect in the floor of the fossa ovalis. Symptoms develop insidiously and may be no more than a tendency to chest infections. Rarely it presents early as a result of a paradoxical embolus from the venous circulation traversing the patient foramen ovale and reaching the systemic circulation. Symptoms appear when pulmonary hypertension develops, usually in the fourth decade, but may appear earlier under conditions of increased cardiac output (i.e. pregnancy).

Should the shunt reverse (i.e. become right to left) because of the pulmonary hypertension, then closure of the ASD is contraindicated. The development of a reversed shunt is termed Eisenmenger's syndrome.

**Atrioventricular septal defect** (syn. primum defects)

When abnormalities of this type are confined to the atrial septum they are commonly called ostium primum ASD. Failure of the development of the septum primum is uncommon, but when it occurs it is associated with abnormalities of the mitral valve. A more extreme version may lead to an atrioventricular canal defect. There is a
relatively high incidence of this abnormality in those born with trisomy 21 (Down's syndrome).

**Sinus venosus**

This is a rare defect and is the result of failure of partition of the pulmonary and systemic venous circulations. It is associated with anomalous pulmonary venous drainage (Fig. 48.43).

**Treatment of atrial septal defect**

Echocardiography will define the anatomy and any other abnormalities including the direction of the shunt. Pressure measurements may be required if pulmonary hypertension is suspected. Treatment is aimed at closing the defect. This may be from simple closure or patch graft in the primum type to an extensive closure and reconstruction of the mitral valve in the secundum type.

**Ventricular septal defect (VSD)**

This accounts for 15-20 per cent of congenital heart disease and affects 2 in 10 000 live births (Fig. 48.44). There is a high spontaneous closure rate and only 25 per cent persist. There is communication between the ventricles and this may occur in isolation or as part of a more complex set of cardiac abnormalities. Blood ejected from the heart tends to go into the pulmonary circulation where the resistance to flow is lower. If no compensation occurs, severe pulmonary oedema results. The pulmonary circulation may adapt by increasing the resistance to flow but this may lead to irreversible pulmonary oedema if the defect is not corrected. Small defects may close or cause little systemic disturbance (maladie de Roger).

In the case of larger defects the infant may have frank pulmonary oedema, failure to thrive and recurrent chest infections. In older children, pulmonary hypertension may be the predominant clinical feature with cyanosis present if the left-to-right shunt reverses (Eisenmenger's syndrome).

Echocardiography confirms the diagnosis and can estimate the degree of shunting across the defect. Catheterisation is recommended to quantify the various pressures within the cardiac chambers.

Most VSDs will close spontaneously within the first year of life, but some will lead to death or irreversible pulmonary hypertension if not treated quickly. If the infant is severely symptomatic, the defect should be closed urgently otherwise elective repair is advised between 1 and 3 years of age. Very sick infants can be tided over by banding the pulmonary artery. This protects the lungs from pulmonary hypertension and diverts the blood into the aorta. Elective surgery can then be carried out at a later stage when the child has grown.
Ischaemic heart disease

Ischaemic heart disease is a major cause of morbidity and mortality in developed countries. The underlying pathology is usually atherosclerosis of the coronary arteries. The coronary anatomy is such that each of the three major arteries (the right, the left anterior descending and the circumflex) supplies a similar proportion of the myocardium (Fig. 48.45). Triple-vessel disease refers to significant stenosis in these three vessels.

Presentation.

Coronary artery disease may be (1) asymptomatic until it presents as sudden death or an acute myocardial infarction as the first manifestation, or (2) symptomatic with angina, typically on exertion and relieved by rest.

Pathophysiology

The starting point in atherosclerosis is believed to be endothelial injury. This may be mechanical or biochemical and the result is platelet aggregation at the site of injury. There is consequent migration of smooth muscle cells into the intima. The risk factors are the following:

- hypercholesterolaemia;
- hypertension;
- cigarette smoking;
- diabetes mellitus;
- advancing age;
- family history of ischaemic heart disease.

An elevated plaque forms within the lumen and, with time, progressive thickening with ulceration, plaque rupture, thrombus formation or calcium deposition will further narrow the lumen. With a narrowing of over 70 per cent, the lumen is critically stenosed (Fig. 48.45).

Slow progression of this process encourages the formation of collateral vessels whereas sudden occlusion results in myocardial infarction. The rate of progression is highly variable and the distribution patchy, but to have only one vessel involved is unusual. Plaques tend to form in the proximal areas of the artery or branches.

Symptomatic patients with ischaemic heart disease can usually be helped by medical treatment in the first instance. Attention is paid to the elimination of risk factors wherever possible.

Pharmacological agents that relieve angina include nitrates, calcium antagonists and ß-blockers. These agents reduce the vascular tone and therefore reduce preload and/or afterload of the left ventricular muscle, reduce the work of the heart and therefore reduce the metabolic demand.

Surgical involvement occurs when the symptoms are severe and not adequately controlled on a reasonable trial of medication or when the prognosis is adversely affected by continuing medical treatment.

Investigations

Clinical examination is typically normal (although stigmata of diabetes or hypercholesterolaemia may be evident) and objective evidence of myocardial ischaemia must be sought.

Electrocardiography

The simplest test to demonstrate ischaemia is an exercise ECG. The patient is asked to undergo an increasing amount of exercise on a treadmill according to a carefully described protocol. Every 2 minutes the work rate increases. Full resuscitative equipment is available and the patient is continually monitored by ECG. The test is stopped if the patient experiences chest pain or arrhythmias or becomes dyspnoeic. If there is evidence of ischaemia on the ECG (>2 mm ST depression) then the test is positive.

Radionuclide studies including thallium scanning also provide objective evidence of reversible ischaemia but the equipment is not always available.

Coronary angiography

This is an invasive test performed under radiographic screening. The arterial circulation is entered via the femoral or brachial artery and a catheter is advanced into the aorta to the coronary sinuses. The coronary ostia are located and iodine-containing dye is infused to outline the coronary anatomy. At least two views of the coronary anatomy are filmed in different planes to give a three-dimensional impression of the arterial system. A left ventriculogram is performed to estimate the ejection fraction, and a measurement of the left ventricular end-diastolic pressure is taken. This test only outlines the coronary anatomy and does not demonstrate ischaemia.

Indications for surgery

Many patients can be managed medically and there is an increasing trend for cardiologists and interventional radiologists to palliate the symptoms of angina by the technique of coronary angioplasty. This involves passing a small balloon-tipped catheter into the femoral or radial artery and feeding it retrogradely into the aortic root. Soluble dye is injected into the coronary ostia to delineate the coronary anatomy; the catheter is then passed across the stenosis and inflated so as to crush the atheromatous plaque with a 90 per cent initial success rate. If successful, this procedure provides symptomatic relief but restenosis occurs in 30 per cent within 3-6 months. The long-term benefits are unclear and the process may have to be repeated with up to 40 per cent of patients coming to definitive coronary artery bypass grafting within 2-5 years. Coronary artery stenting following angioplasty has improved the medium-term patency rate but the long-term benefits remain unclear. Several trials (RITA, BARI and CABRI) show that the early morbidity for angioplasty is less than that for coronary artery bypass graft (CABG) but the patients in the angioplasty groups are more likely to have more interventions and require more medication in the short term. A detailed discussion of these points is outside the scope of this chapter.

Angina can be relieved by surgical revascularisation in most patients and symptomatic improvement can be expected for over 10 years. Patients with lesions in one or two vessels may benefit from balloon angioplasty, but triple-vessel disease or left main stem stenosis is an indication for surgery.

Data from prospective, randomised trials demonstrate that patients with angina and left main stem stenosis or triple-vessel disease have a poor natural history which is significantly improved by surgery. Survival in patients with single-vessel disease is equally good when medical and surgical treatment are compared. Survival is further increased if an internal mammary artery is used to bypass a proximal stenosis of the left anterior descending (LAD) artery. Acute unstable angina usually settles with continuing medical treatment but continuing pain in spite of adequate therapy is an indication for surgery. Surgery should be considered for chronic stable angina when a reasonable trial of medication has failed to control symptoms.

The history of surgical revascularisation

The earliest surgical proposal for the relief of angina was in 1899 by Franck when he suggested cervical sympathectomy to divide the cardiac afferents and cause coronary vasodilatation. It was not until the 1930s that augmentation of coronary blood flow was suggested as a treatment for angina.

Various attempts to provide additional blood to the myocardium were tried (omentotomy and induced pericardial adhesions) but were of little benefit. Vineberg pioneered an operation in which the internal mammary artery was dissected from its bed and the distal end implanted in the myocardium. This procedure was...
successful in some cases but gave inconsistent results and it is no longer performed. Cardiopulmonary bypass meant that it was possible to operate directly on the coronary arteries. The development of coronary angiography by Mason Sones led to the first CABG performed by Favaron at the Cleveland Clinic in 1967. This was found to be an effective and reliable way to revascularise the myocardium. The long saphenous vein is the most commonly used conduit, but the internal mammary artery is now used for the left anterior descending graft in over 60 per cent of cases.

Vessels with 70 per cent stenosis or more require bypassing. Stenoses of less than 50 per cent may not progress and there is no evidence that grafting is beneficial. The usual procedure is three to four grafts.

**Choice of conduit**

The patient's own saphenous vein and internal mammary artery are the conduits of choice but there is a small trend towards using other arterial conduits such as the gastroepiploic artery and the inferior epigastric artery. Other conduits such as human umbilical vein, bovine internal mammary artery and prosthetic grafts (Dacron and polytetrafluoroethylene) have disappointing patency rates of less than 50 per cent at 1 year.

**The long saphenous vein graft** ([Fig. 48.47](#))

Although this graft has been used for over 25 years, there is a significant occlusion rate of 10-15 per cent at 1 year. Thereafter there is an occlusion rate of 2-3 per cent per annum. Low-dose aspirin from the time of operation reduces the graft occlusion rate.

**The internal mammary graft** ([Fig. 48.48](#))

This graft has been accepted as the conduit of choice in terms of reliability, low occlusion rate and long-term patency. It can be adapted to the demands placed on it and provides excellent symptomatic relief.

The operation is usually performed with cardiopulmonary bypass ([Fig. 48.49](#)). The distal anastomosis is performed beyond the narrowing in the coronary vessel. Application of the aortic cross-clamp facilitates this by preventing blood flow down the coronary arteries. This renders the myocardium ischaemic but there are ways of minimising this which are discussed in the Myocardial protection section. Once the final distal anastomosis is completed, the cross-clamp is removed and the heart is reperfused with oxygenated blood. Rewarming is commenced and the final proximal anastomosis is completed. The patient is returned to the intensive care unit at the completion of the operation. There is a trend to try and avoid cardiopulmonary bypass in coronary artery surgery altogether. Coronary anastomoses are possible on the beating heart with the aid of appropriate stabilising devices. The advantage is that the patient avoids the potential damaging effects of cardiopulmonary bypass and therefore has a shortened hospital stay. There is concern that the quality of the anastomosis may not be as good as those done on a completely still heart in a bloodless field. An extension of this principle is the development of port access surgery, where the operation is carried out through a small incision. The early results appear encouraging but the techniques have yet to gain widespread acceptance.

Postoperative complications are not uncommon following cardiac surgery. Many patients are ex-smokers or diabetic so respiratory infections and basal collapse are common after surgery, and should be treated aggressively with antibiotics and physiotherapy. Minor wound infections may need little attention, but major wound infections leading to sternal dehiscence and mediastinitis may be very difficult to treat. The risk of serious sternal infection increases in elderly and diabetic patients and in those undergoing bilateral internal mammary artery grafting.

**Results of treatment**

Relief of symptoms and functional capacity are significantly improved following surgery when compared with medical therapy alone. Patients with impaired left ventricular function have a poor natural history, and it is this group that benefits most from surgical revascularisation. The hospital mortality rate has increased slightly to 3-4 per cent as a result of operating on older patients and those with impaired ventricular function. There is no doubt that the internal mammary artery improves patient survival and has a superior long-term patency over other conduits.

Up to 80 per cent of patients have complete relief of symptoms and require no further medication. Unfortunately, angina may return as a result of the following:

- graft thrombosis;
- anastomotic stenosis;
- conduit atherosclerosis;
- progression of native disease.

Attention is paid to secondary prevention of progressive disease and return of symptoms requires careful evaluation. There is clear evidence that cholesterol lowering (even in those who have a normal cholesterol) significantly reduces the progression of atherosclerosis in saphenous vein grafts. Developments in cardiology and therapeutics mean that patients have a wide range of options before reoperation is considered. Many patients respond to medical treatment but some require redo surgery. This is associated with an increased operative mortality and is only recommended for patients with severe symptoms. It is hoped that the use of arterial conduits will reduce the need for redo surgery, although this remains to be seen.

**Surgery for the complications of myocardial infarction**

Myocardial infarction leads to myocyte necrosis which may heal to form scar tissue or rupture if the ventricular wall gives way. Free rupture of the ventricle is usually fatal in spite of treatment, but intramyocardial rupture gives rise to a number of mechanical problems that have a very high mortality without surgery. The myocardial rupture rate is less than 2 per cent with the distribution in proportion to the relative risk. Free wall rupture is the most common, followed by ventricular septal rupture and then papillary muscle rupture.

**Ventricular septal rupture** ([Fig. 48.50](#))

This occurs following an anterior or inferior infarct affecting the ventricular septum. The patient typically presents with an infarction and 3-7 days later develops pulmonary oedema with a pansystolic murmur and hypotension. The prognosis is dismal without surgery but operation carries a mortality rate of up to 40 per cent. The diagnosis is confirmed by transoesophageal echocardiography or Swan-Ganz catheterisation (the degree of left-to-right shunting can be calculated using this technique). The patient requires stabilisation and myocardial support (inotropes, renal dopamine and intraaortic balloon pump counterpulsation) before surgical repair if this is indicated. The repair is undertaken with the aid of cardiopulmonary bypass and a pericardial patch or an artificial graft may be used to facilitate repair.

**Papillary muscle necrosis** ([Fig. 48.51](#))

This occurs with full-thickness myocardial papillary muscle necrosis. The patient develops a pansystolic murmur and pulmonary oedema. Unlike chronic mitral regurgitation, where the left ventricle has time to adapt to the increased volume load, the left ventricle is acutely overloaded and failure results. Diagnosis is made by echocardiography and right heart catheterisation (showing large V waves). Mitral valve replacement is usually necessary, but the mortality is higher than in valve replacement for rheumatic heart disease as a result of the associated coronary artery disease.

**Ventricular aneurysm** ([Fig. 48.52](#))

Partial-thickness necrosis of the ventricular wall may result in the development of a ventricular aneurysm if the free wall is replaced by noncontractile fibrous tissue. Left ventricular function is affected because the fibrous wall balloons out during systole and reduces the actual stroke volume. Repair is undertaken using cardiopulmonary bypass.
bypass and CABG is undertaken at the same time if necessary.

Some patients develop refractory cardiac failure from a variety of causes that are not amenable to surgery because of poor left ventricular function. These patients should be considered for heart transplantation.
The pericardium

This is a fibrous envelope covering the heart and separating the heart from the mediastinal structures. It is a fibrous structure with a parietal layer and it allows the heart to move with each beat. It is not essential for life because it can be left wide open after cardiac surgery without any ill effects. There is, however, a number of conditions affecting the pericardium which may present to the surgeon.

Pericardial effusion

There is a continuous production and resorption of pericardial fluid. This is a balanced system and only a few millilitres of fluid are present at any one time. A disease process that disturbs this balance by increasing production or interfering with resorption will lead to a build-up of fluid in the pericardium. If the pressure exceeds the pressure in the atria, compression will occur, venous return will fail and the circulation is compromised. This state of affairs is called tamponade. A gradual build-up of fluid (e.g. malignant infiltration) may be well tolerated for a long period before tamponade occurs, and the pericardial cavity may contain 2 litres of fluid. Acute tamponade (penetrating wounds or postoperatively) may occur in minutes with small volumes of blood. The clinical features are low blood pressure with a raised jugular venous pressure (JVP) and pulsus paradox. Kussmaul's sign is a characteristic pattern when the JVP rises with inspiration as a result of the impaired venous return to the heart.

Emergency treatment of pericardial tamponade is aspiration of the pericardial space and therefore relief of the compression on the cardiac chambers. A wide-bore needle is inserted under local anaesthesia to the left of the xiphisternum between the angle of the xiphisternum and the ribcage (Fig. 48.58). The needle is advanced towards the tip of the scapula into the pericardial space. An EGG electrode attached to the needle will indicate when the heart has been touched.

This will hold the situation temporarily until the cause of the tamponade is established. It is occasionally possible to drain the pericardium with a percutaneous drainage system. To prevent recurrence of a chronic tamponade, it is sometimes necessary to fashion a pericardial window between the pericardial space and the pleural or peritoneal space. This may be done through a subxiphoid incision, anterolateral thoracotomy, either thoracoscopically or percutaneously. Penetrating wounds of the heart usually require exploration through a median sternotomy. Emergency room thoracotomy is rarely required.

Causes of acute tamponade

The causes include:

- trauma;
- aortic dissection;
- penetrating cardiac injury (usually of the atria as ventricular and aortic wounds tend to be fatal);
- iatrogenic: penetration of the right ventricle following central venous cannulation, endomyocardial biopsy, etc.;
- postoperative: blocked drains or inability of the drains to cope with excessive blood loss.

Chronic tamponade is usually a result of malignant infiltration of the pericardium (usually secondary carcinoma from breast or bronchus) or very occasionally uraemia or connective tissue diseases.

Pericarditis

Infection and inflammation may also affect the pericardium. Acute pericarditis usually occurs following a viral illness. There is a sensation of heaviness in the chest which may be positional. Treatment is with nonsteroidal anti-inflammatory drugs and bed rest (as in case there is an underlying myocarditis). Acute purulent pericarditis is uncommon but requires urgent drainage and intravenous antibiotics with attention to the underlying cause.

Chronic pericarditis is an uncommon condition in which the pericardium becomes thickened and noncompliant. The heart cannot move freely and the stroke volume is reduced by the constrictive process. The central venous pressure is raised and the liver becomes congested. Peripheral oedema and ascites are also a feature. Establishing the diagnosis may not be easy because the chest radiograph and echocardiograph may be normal. Cardiac catheterisation demonstrates a reversed square root sign. Treatment is aimed at relieving the constriction. The heart is approached through a median sternotomy and the pericardium is carefully stripped off the left ventricle, followed by the right ventricle. Cardiopulmonary bypass may be required if haemodynamic instability occurs.
Heart transplantation

Much of the pioneering work into human heart transplantation was done by Shumway and Lower in the early 1960s but the first successful human heart transplantation was performed by Barnard in 1967. The early results were very poor and, in spite of the initial optimism for the technique, the number of centres declined to only a few. Better patient and donor selection, together with the introduction of cyclosporin A, has led to a revival of the technique and it is now established as a treatment for end-stage cardiac failure in certain groups.

The main indication for heart transplantation is advanced terminal cardiac disease classified as New York Heart Association (NYHA) 4, with no alternative conventional medical or surgical treatment, and with a mortality rate higher than 90 per cent per year if transplantation is not carried out. Indeed, death commonly occurs while on the waiting list. Most cases referred for transplantation have either an ischaemic or a dilated cardiomyopathy. Rarer causes include postviral and hypertrophic cardiomyopathy. The patient needs careful preoperative assessment to determine the suitability for transplantation and counselling to prepare for the demands of life after transplantation. Younger patients tend to benefit most but the indications for transplantation have broadened since it was first introduced. Unfortunately, the limiting factor on the number of transplantations performed per year is the availability of donor hearts.

Absolute contraindications to transplantation include:
- active infection (or human immunodeficiency virus (HIV) positive);
- irreversible pulmonary hypertension;
- malignancy;
- another life-threatening illness.

Relative contraindications include:
- age >60 years;
- active duodenal ulceration;
- significant pulmonary vascular disease;
- creatinine clearance <30 mmol/litre;
- drug or alcohol abuse;
- psychiatric illness.

Donor selection is critically important if early postoperative problems are to be avoided. Potential donors will be certified as brain dead if two separate brain-stem function tests show no activity. Most donors have had head injuries or an intracerebral haemorrhage. Injuries to other organs may be present, but if the heart shows no evidence of injury then it may be used. Haemodynamic instability can occur at any time in these patients, and skilled intervention with judicious use of inotropes, ventilation and diuretics may be required to keep the patient stable until the organs are harvested. Ideal criteria for the donor include the following:
- age (~45 years for males; ~50 years for females) - the incidence of coronary artery disease rises after these ages;
- weight (within 25 per cent of the recipient);
- ABO compatibility;
- no evidence of cardiac injury (normal EGG, normal chest radiograph);
- no increased requirements for inotropes;
- no evidence of active infection (HIV, hepatitis B or bacterial);
- no palpable coronary artery disease.

The donor operation is usually performed in conjunction with other transplant teams. If the liver and kidneys are to be used, they require some preliminary dissection before removal of the heart. The heart is exposed by a median sternotomy and the cavae are dissected from the pericardial reflections to expose more of their length. Heparin is given and the aorta cannulated with a perfusion catheter. The aorta is clamped and the inferior vena cava divided to allow venous blood to escape into the chest. Cold cardioplegic solution is infused under pressure into the aortic root and the heart arrests in diastole. A pulmonary vein is then divided to allow blood in the left atrium to escape. Once the cardioplegic solution is infused, the pulmonary veins are divided followed by the pulmonary artery. The aorta is then divided just below the cross-clamp, leaving only the superior vena cava to be divided. This is divided as high as possible to avoid damage to the sinoatrial node. Care should be taken that all central venous cannulae are withdrawn to avoid possible embolism in the donor heart. The heart is then stored in cardioplegic solution and transported in ice to the recipient hospital.

The recipient operation

Once it is clear that the donor heart is satisfactory then the recipient operation is started. The heart is approached through a median sternotomy and heparin is given intravenously. The cavae are cannulated separately and the aorta is cannulated just proximal to the innominate artery. Cardiopulmonary bypass is not started until the donor heart is in the operating room. The recipient heart is excised leaving a generous cuff of atria and interatrial septum. The donor heart is trimmed appropriately and sutured in place. The heart is then de-aired and the cross-clamp released. Ventricular activity usually starts spontaneously but occasionally temporary pacing is required. The heart is allowed to beat on bypass until rewarming is complete and haemostasis is achieved. Ventilation is commenced and cardiopulmonary bypass is slowly weaned until the donor heart is supporting the circulation.

Postoperative care

In common with all forms of allotogenic transplantation, the normal host response is to mount an immune response to the donor organ. To combat this problem, regimens of immunosuppressive therapy have been developed. Intravenous methylprednisolone and azathioprine are given at the time of operation and these are converted to the oral forms once the patient is able to tolerate oral or nasogastric fluids. Cyclosporin A is added if the renal function is satisfactory. Cyclosporin A is nephrotoxic and regular trough levels are required to avoid excessive toxicity. Treatment with azathioprine can result in liver dyscrasias and neutropenia. The incidence of rejection is greatest in the first year post-transplantation. The only reliable way of monitoring the presence or absence of rejection is by endomyocardial biopsy. This is an invasive procedure requiring cannulation of a major vein and taking small biopsies of the ventricular septum from the right ventricle. The presence of a lymphocytic infiltrate suggests rejection and myocyte necrosis implies severe rejection. A pulse of intravenous steroids is usually given as first-line treatment but other therapies include antilymphocyte globulin and the monoclonal antibody preparation OKT3. Most rejection episodes resolve with treatment but occasionally the rejection is refractory to treatment and the allograft fails.

Another important cause of morbidity and mortality in these patients is infection. Immunosuppression lowers the host's resistance to infection and opportunistic infections in addition to common infections may occur. The most common site for infection is the chest. Antibiotics should not be commenced until a full infection screen (throat swabs, midstream urine, sputum and venous blood cultures) has been taken. Viral, protozoal and fungal infections may also occur. Late complications include accelerated graft vascular disease and systemic malignancy.

Alternatives to transplantation are being explored. Novel operations such as skeletal myoplasty, left ventricular reduction surgery and implantable ventricular assist devices have had some notable success but these procedures have yet to gain widespread acceptance.

Results

The perioperative mortality rate is about 10 per cent but patients surviving to leave hospital may have a 90 per cent 1- year survival. This falls to 70 per cent at 5 years and 60 per cent at 10 years. Patients surviving more than 1 year usually have a good exercise capacity and are able to return to work (Fig. 48.59).

Future prospects

Heart transplantation is limited by donor availability. Increasing the donor pool by widening donor criteria and increasing public awareness have helped, but demand exceeds supply. The use of xenografts is one possibility but ethical, logistic and rejection problems mean that this prospect is a long way off. Artificial hearts have a role to play in supporting the circulation until a heart becomes available for transplantation but they do not seem practical for long- term use.
Appendix A: Myocardial management during aortic occlusion

The ideal situation for the surgeon operating on the heart is to have a still heart in a bloodless field. To render the heart bloodless, the aorta must be cross-clamped to prevent coronary perfusion. The heart is then rendered ischaemic and there are two ways of coping with this ischaemia without causing lasting myocardial damage.

Cardioplegic arrest

There are various cardioplegic solutions which arrest the heart in diastole and preserve adenosine triphosphate (ATP) levels. They all have high potassium levels and may be crystalloid or contain blood. Blood cardioplegia has become popular because it can act as a buffer with a high oncotic pressure and because it can also supply oxygen to the ischaemic myocardium at a rate sufficient to meet its metabolic demands. With the patient on full cardiopulmonary bypass, the core temperature is reduced to 26-28°C and the aorta is cross-clamped. Cardioplegic solution is infused into the aortic root and topical cooling with iced slush may also be employed to increase myocardial protection. The heart can be kept arrested for up to 2 hours with this technique.

There are many permutations with the type of cardioplegia, the temperature of cardioplegia, its route of delivery and whether it is given continuously or intermittently. There is no consensus agreement and the reader should refer to a specialist text for more information.

Ventricular fibrillation and intermittent aortic occlusion

This is a technique where ventricular fibrillation is induced by a small electrical charge. The heart does not eject and is relatively still but not bloodless. To perform an operative procedure (e.g. CABG) the aorta is cross-clamped to render the heart ischaemic. The heart can tolerate short periods of intermittent ischaemia providing the heart is reperfused and allowed to beat in-between. For CABG the choice between this technique and cardioplegia depends on the surgeon's preference.

Total circulatory arrest

Cardiopulmonary bypass is instituted and the core temperature reduced to 12-18°C. The metabolic rate of all the organs of the body is so low that periods of up to 30 minutes of total circulatory arrest with the pump switched off are tolerated. This technique has its main role in paediatric surgery and surgery of the ascending aorta.
Appendix B: Investigations in cardiac surgery

ECG

A resting EGG may provide valuable information but a cardiological textbook should be consulted for EGG changes associated with all of the conditions discussed in the text.

Chest radiography

Many patients with ischaemic heart disease are ex-smokers so pulmonary lesions may be noted in addition to the aortic and cardiac dimensions, although the chest radiograph is usually normal. Chamber hypertrophy, valve calcification and abnormalities of the great vessels may point to congenital or valvular heart disease but the chest radiograph may again be normal (Fig. 48.60).

Exercise ECG

To obtain objective evidence of myocardial ischaemia, an exercise EGG may be performed in patients with suspected ischaemic heart disease. Under carefully controlled conditions with full resuscitation equipment available, the patient is asked to perform a graded series of treadmill exercises. The work rate is increased every 2 minutes and continuous EGG recording is performed. The test is terminated when the patient complains of pain or dyspnoea, or there are significant ST segment changes or arrhythmia on the EGG. This test is potentially dangerous in patients with valvular lesions and other tests (e.g. isotope scanning) may be required to demonstrate ischaemic myocardium in these patients.

Isotope scanning

The radioisotope thallium is taken up by perfused myocardium and therefore ischaemic myocardium is shown up as a cold spot. A myocardial uptake gated acquisition (MUGA) scan uses labelled erythrocytes to demonstrate left ventricular function and the ejection fraction (Fig. 48.61).

Coronary angiography (Fig. 48.62)

This is an invasive test performed under radiographic screening. The arterial circulation is entered via the femoral or brachial artery, and a catheter is advanced into the aorta to the coronary sinuses. The coronary ostia are located and iodine-containing dye is infused to outline the coronary anatomy. At least two views of the coronary anatomy are filmed in different planes to give a three-dimensional impression of the arterial system. A left ventriculogram is performed to estimate the ejection fraction and a measurement of the left ventricular end-diastolic pressure is taken. Direct pressure measurements of all of the cardiac chambers may be taken during this investigation.

Cardiac catheterisation

Cardiac catheterisation involves the introduction of a balloon flotation catheter (Swann-Ganz) into the right atrium, across the tricuspid valve and into the pulmonary artery. The pressure changes as the catheter passes through the cardiac chambers are characteristic. An estimate of the left atrial pressure can be obtained by wedging the balloon in a peripheral pulmonary artery. The cardiac output and other parameters can be calculated using a thermodilution technique.

Echocardiography

This is an extremely valuable examination because it can demonstrate valve thickness, calcification and motion, in addition to ventricular wall thickness, motion and chamber dilatation. Ultrasonic waves are transmitted through the heart until they reach an interface. They are reflected back to a probe and an image of the cardiac chambers, wall movement and valve motion can be made. The gradient across the stenotic valve can be estimated by a Doppler probe and regurgitation may also be demonstrated. Coronary angiography is used in patients suspected of having coexistent ischaemic heart disease and the actual gradient across the aortic valve may be shown during this procedure.

Other investigations

CT and MRI are not widely used for myocardial investigations but are useful in visualising the great vessels (aneurysms and dissection) and for demonstrating mediastinal and thoracic pathology.
Appendix C: Postoperative complications in cardiac surgery

Postoperative problems common to all patients occur following cardiac surgery (chest infection, wound infection, etc.) but some are characteristically seen in cardiac patients.

Neurological sequelae

For most patients, cardiopulmonary bypass leaves no obvious neurological deficit but, on detailed psychological testing, subtle abnormalities may be detected that often persist for up to 1 year. There is a risk of permanent stroke in the order of 1-2 per cent depending on age and carotid disease. This fact should be mentioned to all patients undergoing any cardiac surgery.

Poor cardiac output

There are several mechanisms for this complication in the early postoperative period, namely:

- poor myocardial function;
- tamponade or bleeding;
- intravascular volume depletion.

The diagnosis is usually simple as the patient is peripherally cold, with a low blood pressure and poor urine output.

Treatment

In the absence of tamponade, any underfilling should be corrected. Rhythm disturbances are treated and, if the low output state persists, the heart may require pharmacological or mechanical support.

Pharmacological support. Inotropic drugs act in a variety of ways to alter the systemic vascular resistance, increase the heart rate and increase the force of myocardial contraction. Commonly used inotropes include isoprenaline, dopamine, dobutamine, adrenaline and noradrenaline; they are commonly used in conjunction with vasodilating agents which decrease the afterload.

Dobutamine is a 3-agonist with chronotropic and inotropic properties and limited vasodilatation. The dose is titrated to the haemodynamic response and the usual range is 5-15 mg/kg per minute. Dopamine at low doses (<5 mg/kg per minute) has the beneficial effect of augmenting renal blood flow. At higher doses it constricts the renal arteries and has an inotropic effect (Table 48.1).

Judicious use of inotropes and vasodilators, with the use of physiological measures (heart rate, blood pressure, central venous pressure and Swan-Ganz measurements), help to optimise the cardiac output.

Rhythm disturbances. Atrial arrhythmias are common after cardiac surgery and must be treated if persistent or causing haemodynamic compromise. The most common arrhythmia is atrial fibrillation which occurs in 20-30 per cent of postoperative patients. Digoxin is a common treatment but calcium channel blockers or membrane stabilisers may be used. DC shock is only used if urgent control is necessary. Bradycardia is seldom seen, but temporary followed by permanent pacing may be required. Any arrhythmias may occur and the surgeon must be familiar with their cause, pattern, treatment and prevention.

Cardiac support. There is a number of ways to support the failing heart in the anticipation that it will (1) recover some or all of its function or (2) maintain the circulation long enough for cardiac transplantation.

There are circumstances when conventional cardiopulmonary bypass (from right atrium to aorta) is either not feasible, as in aortic dissection, or not advisable (multiple injury), and other means of supporting the circulation are employed.

Left and right heart bypass. This employs a similar technique to cardiopulmonary bypass except oxygenation is not employed and the returning blood is channelled into the same side of the circulation. In right ventricular dysfunction, blood is drained from the venous system, passed through the pump and returned to the pulmonary artery, thereby bypassing the right ventricle. It is useful when temporary dysfunction of a ventricle occurs and full recovery is expected. It has also been used on occasions to support the heart until transplantation.

Mechanical support (Fig. 48.63). If low cardiac output persists in spite of inotropic support, the heart may require mechanical support while it recovers its function. The intraaortic balloon pump is a device that is inserted, either percutaneously or under direct vision, into the common femoral artery. It is threaded into the aorta until its tip lies just distal to the arch vessels. The balloon is triggered by the EGG to deflate in ventricular systole (thus reducing afterload) and inflate in diastole (displacing blood which perfuses the coronary arteries retrogradely). When the heart has recovered sufficiently, the balloon is removed. Complications include damage to the femoral artery, leg ischaemia and haemolysis.

Other means of augmenting ventricular performance

Intra-aortic balloon counterpulsation may not be sufficient to support the failing ventricle and is only suitable for the left-sided circulation. The ventricle (right or left or both) may be bypassed by draining blood from the proximal atrium, passing it through a centrifugal pump and returning it to the distal great vessel thereby bypassing the affected ventricle altogether. As the ventricle recovers, the flow in the pump is gradually reduced so that the ventricle slowly takes over the circulation. Once weaning is complete, the assist device is removed. Bi-ventricular support is possible as a bridge to transplantation.

Artificial hearts

It has proved impossible to find a perfect mechanical substitute for the native heart. The totally artificial heart is limited by thrombosis and infection, although survival of over 3 months has been documented. The energy supply to drive the implanted heart often weighs more than the patient and therefore mobility is restricted. The Jarvik total artificial heart has had limited success in temporarily supporting the circulation while heart transplantation is awaited. Further research is required before the expense of this technology can be justified for routine use.
Appendix D: Cardiopulmonary resuscitation

Cardiopulmonary resuscitation begins with basic life support before more advanced techniques can be employed. A logical approach to resuscitation has been produced in detail by the European Resuscitation Council in the British Medical Journal (Vol. 306, 1993, pp. 1587-1593). An outline of the steps involved using algorithms and flow charts in basic and advanced resuscitation (currently under review) are taken from this article (reproduced with permission) (Fig. 48.64).

Cardiac arrest is the cessation of cardiac mechanical activity, confirmed by the absence of a detectable pulse; unresponsiveness and apnoea (or agonal respirations). In adults the most common cause is primary ischaemic heart disease. Cardiac arrest may be associated with any of four heart rhythms: ventricular fibrillation, pulseless ventricular tachycardia, asystole or electromechanical dissociation.

Management of ventricular fibrillation or pulseless ventricular tachycardia - see Fig. 48.65.

Management of asystole - see Fig. 48.66.

Management of electromechanical dissociation - see Fig. 48.67.

Airway management
Tracheal intubation is the preferred technique for airway control during cardiopulmonary resuscitation. Advantages include isolation of the airway, prevention of aspiration and avoidance of gastric dilatation, facilitation of mechanical ventilation and the delivery of high oxygen concentrations. Suction of the trachea and major bronchi and delivery of drugs via the endobronchial route are also possible.

Drug delivery routes
The venous route is recommended for drug delivery during cardiac arrest. Peripheral venous cannulation is rapid, safe and does not interfere with cardiopulmonary resuscitation. Cannulation of an antecubital vein is the site of choice, although the external jugular vein is an alternative.

Open cardiac massage
Open chest massage is only rarely indicated in advanced cardiac life support for a patient with a medical cardiac arrest, although emergency thoracotomy in cases of trauma is a well-validated procedure for which clear indications exist.

Background

The experience of bowel surgery until the latter part of the nineteenth century was limited to dealing with protruding intestine following abdominal injury usually sustained during wars. If a laceration of the bowel was encountered attempts were made to repair it using the jaws of ants (described by Sushruta and Albucasis) or by suturing (Celsus). Probably the first surgeon to describe a suture made from animal gut was Albucasis. In Salerno, Italy, between the twelfth and thirteenth centuries, it was advised that if a piece of bowel had to be repaired it should be done over a stent of elder wood or animal trachea. Alternatives for dealing with injured intestine were to suture it to the abdominal wall to create a fistula or do nothing and let nature take its course. The latter management was frequently considered safer.

For centuries, no attempt was made to define the process of healing of the gastrointestinal tract. However, in 1812, Travers reported that intestinal wounds healed as a result of 'adhesive inflammation' binding down the peritoneal ('serosal') coat. Fourteen years later Lembert described a suturing technique in which serosa apposition was obtained.

As a consequence of the adoption of the Listerian principles of wound care and antiseptic surgery (Chapter 1) (together with general anaesthesia) surgeons in the second half of the nineteenth century began to perform laparotomies with the express purpose of resecting a piece of intestine and subsequently restoring continuity. Gastrointestinal surgery expanded rapidly and with it various methods of suturing the bowel together. All were modifications of Lembert’s basic principles and were reviewed by Senn in 1893. A year earlier Murphy introduced his button but an adverse report appeared in the surgical literature citing colocolic anastomotic stricture which resulted in the patient’s death.

In 1893, Senn advised two-layer interrupted anastomoses. His suture was of fine aseptic silk applied with ordinary sewing needles. Halsted favoured a one-layer anastomosis without penetration of the lumen. In contrast, Connell in 1903 strongly recommended a single layer of interrupted sutures which passed through all coats of the bowel and with the knots ligated intraluminally. Kocher also suggested an all-coats suture technique in two layers using catgut and silk. In 1907 Kerr and Parker used a temporary suture to close the bowel whilst the permanent sutures were inserted; once the anastomosis was completed these preliminary sutures were removed. Shoemaker and Remkin (1928) performed end-to-end anastomoses over narrow crushing clamps.

In 1922 Halsted described a closed colorectal technique in which the bowel was crushed, ligated and divided at the resection margins. Next submucosal buttress sutures joined the two ends of the bowel and finally an instrument with a knife blade was passed per rectum through the anastomotic diaphragm to divide the two Sutures which had closed the lumen: the forerunner of our contemporary stapling devices. Stapling techniques have been ‘reinvented’ recently.

The closed method of anastomosis has been replaced by the open method for four major reasons (Table 49.1):

- the introduction of antibiotics;
- improved preoperative bowel cleaning;
- the use of atraumatic sutures;
- better on-table control of suture-line bleeding.

Alexis Carrel was a recognised revolutionist in vascular surgery. In 1902 he described a suture technique that he had developed that created a perfect end-to-end anastomosis of blood vessels. His method employed three retaining sutures which, when drawn taut, pulled the edges into an equilateral triangle which could then be easily sutured. This technique preserved the full patency of the lumen, and gave a smooth interior surface to reduce platelet and fibrin deposition.
Factors influencing anastomoses

Anastomotic healing is influenced by many factors and it is difficult to assess the influence of any single factor especially in the clinical situation. Healing depends on fibroblastic response and on the formation of plentiful collagen in the submucosa round the anastomosis. The general, specific and local factors influencing anastomotic healing are listed in Table 49.2.

The surgeon should be aware of good techniques relating to the main sites of anastomoses (Table 49.3).
Techniques for the commoner anastomoses

Gastrointestinal anastomoses

Certain important generalisations can be made as follows.

Exposure

Any anastomosis becomes difficult if the surgical access and exposure are poor. This may be caused by inadequate anaesthesia and muscle relaxation, poor assistance, a badly placed and/or too short incision, and less than perfect illumination. Poor access may also result from inadequate mobilisation of the viscera and this is more likely to occur in oesophageal, colonic and rectal anastomoses as these parts of the gastro-intestinal tract are anatomically fixed and deeply situated.

Blood supply

The only absolute criterion of an adequate blood supply prior to anastomosis is free bleeding from the cut edges of the bowel. The blood supply can be compromised by undue tension on the suture line, devascularisation of the bowel during mobilisation, stranulation of the tissues by tightly knotted sutures and the excessive use of diathermy.

Suture technique

Experimental work and clinical trials have shown that invert-ed suture lines are superior to everted ones, although this principle has been challenged by Ravitch. The vast majority of surgeons uses an open method of intestinal anastomosis. One aspect which remains a controversy is the use of one or two layers. The latter was devised by Czerny and is probably still the most popular technique today. It is alleged that a single layer results in less ischaemia and tissue necrosis, and less narrowing of the lumen. Studies in both experimental animals and humans have shown no great difference between the techniques. Anastomoses involving the extraperitoneal portion of the rectum and also the oesophagus are better performed using a single-layer, full-thickness technique, as this preserves the blood supply and full lumen width better than a two-layer technique. Gastrointestinal anastomoses can be performed end-to-end, end-to-side or side-to-side and can be either ‘open’ or ‘closed’. Generally the method used in any one operation is standard. In the UK the majority of surgeons employs the open method, removing the clamps following the placement of the outer, posterior, serosal layer of sutures. The techniques used for uniting parts of the gastrointestinal tract are as follows.

The open, end-to-end, two-layer technique (Fig. 49.1). The divided ends of the bowel are held in crushing clamps and light occlusion clamps are applied across the bowel, avoiding the mesentery. The outer posterior layer of sutures is usually placed in a continuous manner (Fig. 49.1a) but interrupted sutures can also be used. The crushing clamps are then cut away.

The inner layers of sutures are then inserted commencing at the antimesenteric border with the knot on the serosal surface. A continuous over-and-over technique is used, care being taken to include all coats of the bowel wall and avoiding grasping the mucosa with forceps.

The mesenteric corner of the anastomosis is securely invaginated using a Connell suture (Fig. 49.1b) and the anterior aspect closed using a continuous Connell technique (Fig. 49.1c) or a simple over-and-over technique. The suture is then tied to its other end. The anastomosis is completed by an anterior row of serosal sutures either continuous from the posterior layer or interrupted (Fig. 49.1d). The mesentery of the small intestine must be closed in every case and the anastomosis checked for patency (Fig. 49.1e).

An alternative to the above procedure is to place the inner all-coats first and then the outer layer, rotating the anastomosis to complete the posterior aspect. This is not recommended when the mesentery is very fat laden.

If there is disparity of the bowel ends, the smaller lumen orifice can be widened by cutting along its antimesenteric border (Cheatle’s manoeuvre).

The open, end-to-end, one layer technique (Fig. 49.2). This method is increasingly favoured for end-to-end anastomoses in areas of the gastrointestinal tract where the blood supply is poor, where there is no serosal coat or the lumen is small. In infants, a one-layer technique is the rule. Most surgeons favour the use of a one-layer open technique for the oesophagus and lower rectum.

After preliminary corner stitches are inserted to steady and approximate the posterior wall of the anastomosis (Fig. 49.2a), a series of interrupted deep ‘all-coats’ sutures of absorbable material (Dexon, Vicryl or PDS) is inserted 5 mm apart. After the corners have been reached, the suturing is continued along the anterior walls as interrupted Lembert stitches with a wide margin of muscle coat as shown (Fig. 49.2b): some surgeons use interrupted Connell sutures, but these are less haemostatic and move in more tissue than the technique illustrated. The different single-row suture techniques are demonstrated in Fig. 49.3a–h.

The closed, end-to-end, single-layer technique (Fig. 49.4). The single-layer, inverting, closed anastomosis with interrupted nonabsorbable sutures was first advised by Halsted. The technique has been modified to incorporate the submucosa so that only the mucosa is excluded. It is commenced by inserting two angle stitches which are held untied. Posterior sutures are then placed longitudinally approximately 5 mm apart. Once finished, the anterior layer is inserted in a similar fashion. When this layer is in place the clamps are slipped out, the angle sutures tied and lastly the anterior ones. Patency must always be checked with finger and thumb (Fig. 49.4e).

End-to-end anastomosis (Fig. 49.5). This technique is used particularly in surgery of the oesophagus and stomach, and when there is significant disparity between two ends of intestine.

One end of the bowel must be closed and this is usually performed with a two-layer technique or alternatively by a row of staples. The anastomosis is performed as for an end-to-end one (Fig. 49.1).

Side-to-side anastomosis. This is usually performed to bypass an obstruction. Both ends are closed before the side-to-side anastomosis is carried out.

Stapling techniques (Figs 49.6 and 49.7).

1. Preliminary closure of the bowel ends can be performed using linear staples (Fig. 49.6) which can be cut away once the purse-string suture is in place.

2. End-to-end anastomosis is performed using circular stapling devices [Premium CEEA (Autosuture) and ILS (Ethicon)]. Purse-string sutures
must be carefully placed and for this the Furness clamp can be utilised (Fig. 49.6a). Circular staples are very useful for oesophageal and rectal anastomoses. A rectal anastomosis is illustrated in Fig. 49.6.

3. The double-stapling technique. The availability of an adjustable-angle linear stapler, the Roticator (Auto-suture), has added a new dimension to stapling techniques, further facilitating low rectal anastomoses. Together with the Premium CEEA (Auto-suture) a low rectal anastomosis is technically easier and safer. The anastomosis of colon to rectum is effected using the Premium CEEA circular stapler through the rectal Roticator linear staple line (see also Chapter 60).

4. Side-to-side anastomoses can be performed using the GIA stapler and this is useful for small-bowel and ileocolic anastomoses (Fig. 49.7).

Special sites (Table 49.3)

Oesophageal anastomoses

When suturing the oesophagus, horizontal mattress sutures can be used as they have less tendency to cut through the oesophageal muscle than vertical mattress sutures. The cervical oesophagus can be anastomosed to stomach, colon or jejunum. Providing there is no tension and the blood supply to the intestine brought up to the neck is adequate, these anastomoses heal well.

The stomach is the simplest method of reconstruction but reflux can be a problem. The sutures are placed as horizontal or vertical mattress sutures in one layer. The author uses PDS for all intestinal anastomoses. The thoracic oesophagus is usually anastomosed to stomach (the Ivor Lewis operation) or jejunum. The technique is the same although the circular stapling device can also be used. The abdominal oesophagus is almost always anastomosed to jejunum either as a Roux-en-Y or to a loop and the circular stapling device is increasingly used in this situation.

Gastric anastomoses

Following partial gastrectomy continuity is restored either to duodenum (Billroth I partial gastrectomy) or to jejunum (Polya partial gastrectomy) (Fig. 49.8). The latter can be antecolic or retrocolic and should be performed by joining lesser curve to afferent loop, the latter being kept as short as possible. Because of the excellent blood supply absorbable sutures can be used and placed in a continuous manner. If the operation has been for carcinoma, e.g. a radical subtotal gastrectomy, it is advisable to make the anastomosis antecolic in case of recurrence and to use nonabsorbable sutures or PDS for the outer layer. Closure of the duodenum or stomach can be performed using a linear stapling device.

Small-intestinal anastomoses

Jejunomejunal, jejunoileal, ileoileal, ileocolic and ileorectal anastomoses are all performed following resections for different disease processes. Like the stomach, the small intestine has an excellent blood supply and therefore continuous sutures can be used, although following right hemicolecotomy and total colectomy the ileocolic and ileorectal anastomoses are best performed with an outer layer of interrupted sutures. It is always advisable to slant the clamps so that less antimesenteric border is left. The GIA stapling device can be used for any of these anastomoses.

Colocolic and colorectal anastomoses

Because (a) the vascular supply is less good, (b) distension from gas occurs and (c) the contents are faecal, large intestinal anastomoses may not heal well. Prior to resection, tapes are placed round the bowel and tied to ensure that no exfoliated malignant cells are reimplanted. Two layers of interrupted sutures may be used although most surgeons use only one layer. It is the author’s practice to use one layer only for extraperitoneal anastomoses following anterior resection but for very low rectal anastomoses the circular stapling device is usually used (Fig. 49.6). No anastomosis should be performed if the colon has been poorly prepared as a low rectal anastomosis will be placed in jeopardy. The advent of ‘on-table’ lavage popularised at St Mary’s Hospital, London (Dudley), is employed by the author, which ensures an empty colon above the subsequent anastomosis. A self-retaining catheter is inserted into the caecum usually via the base of the appendix following antecolic or retrocolic anastomosis, or via the terminal ileum, and scavenger tubing tied in place over the cut colon (Fig. 49.9). Hartmann’s solution is then passed via the catheter until all faecal matter has been expelled from the colon via the scavenger tubing and the effluent is clear.

In the emergency situation, the catheter can be retained as a tube caecostomy which acts as a gas vent. The terminal portion of the colon tied round the scavenger tubing is resected prior to anastomosis. The rectal stump is also lavaged from above and the effluent collected via a procto-scope in the anus. It is usual practice in cancer cases to employ a cytotoxic fluid (mercuric perchloride, Noxythiolin and Povidone iodine are all used).

Biliary and pancreatic anastomoses

Either cholecystojejunostomy or choledochojejunostomy is used to bypass unresectable carcinoma of the head of the pancreas. Following cholecystojejunostomy a jejunoojbunalostomy distal to it is often performed. If there is danger of duodenal occlusion a gastrojejunostomy is also performed.

For benign strictures of the common bile duct, excision and primary anastomosis may be possible. Otherwise a Roux-en-Y loop is used as for some malignant strictures. Surgeons split these anastomoses bringing the stent out well away from the anastomosis through the Roux loop on to the abdominal wall. This Roux loop should be sutured to the peritoneum and the place marked for subsequent radiological identification so as to provide access if necessary. Alternatively an access loop can be constructed and this sutured to the skin marking the site with a ring.

Pancreatic duct anastomosis to jejunum is performed in a single layer and for all these anastomoses PDS is advocated. A nonabsorbable suture in the biliary tree can lead to stone formation.

Urological

Most anastomoses are ureterovesical but ureteroureteric and ureterocolic (Fig. 49.10) are also performed. Ureterocolic anastomoses are performed less commonly as an ileal bladder is preferable. The ureter should always be spatulated to increase the size of the anastomosis and so as to provide access if necessary. Alternatively an access loop can be constructed and this sutured to the skin marking the site with a ring.

Vascular

Except rarely (e.g. following trauma, when a severed vessel can be repaired primarily) most anastomoses are made to autografts or to veins (Fig. 49.11). The suture material used must be nonabsorbable and continuous, although occasionally with small vessels (e.g. fistula formation for haemodialysis) interrupted sutures are used. When placed end to end, the graft or vein should be stretched to increase the orifice size.
Microvascular anastomoses are always done with interrupted sutures. If a vascular anastomosis is close to a joint, e.g. to the hip joint in the groin, excessive movements at that joint should be avoided until the anastomosis is healed (see also Chapter 15). Small clips/staples have been developed for vascular anastomoses which are proving very quick and useful especially for small vessels and for fistula formation.

New techniques

Biofragmental anastomosis rings have been proven to be safe anastomotic devices in elective surgery. These can be used throughout the intestine but it must be pointed out the cost is substantially higher than for a hand-sewn anastomosis.

Suture less laser anastomoses have been performed experimentally using the neodymium: yttrium-aluminium-garnet (Nd:YAG) laser to create tissue welding. Tissue glue has also been used experimentally to anastomose small intestines.

Protecting an anastomosis

All anastomoses should be made without tension in an area of good blood supply. Colonic anastomoses can be protected from the faecal stream by a proximal colostomy or ileostomy. If drains are used they should lie alongside and not on the suture line. Gastrointestinal movement can be delayed or reduced by a policy of gastric suction, intravenous feeding and antispasmodic drugs (Buscopan). Oesophageal and rectal anastomoses should be checked by water-soluble contrast examination. Drains can be a source of sepsis and should be removed immediately they have ceased to drain significant quantities of fluid (or until a track has formed — usually after 7 or 8 days). If adverse healing factors are present (Table 49.3) precautions should be taken against breakdown, e.g. a diverting colostomy/ileostomy.
Minimal access knotting and suturing

The performance of knotting and suturing during laparoscopic and thoracoscopic surgery is difficult because as well as working in a three-dimensional cavity looking at a two-dimensional screen, one is working with a needle and suture at some distance from one’s fingers. Large needles cannot be introduced into the peritoneal cavity through a small port and long sutures become difficult to control whilst the instruments are less perfect than those used conventionally.

Endoloop ligation

Endoloop ligatures can be used to ligate tissue pedicles and vessels during laparoscopic and thoracoscopic procedures. They can also be used to close defects in structures, e.g. gall bladders and ovariess, thus preventing spillage of contents. The placement of an endoloop is a two-handed procedure. Pretied commercial ligatures are available in plain and chromic catgut, Vicryl and PDS; however they are expensive and they can be easily made out of the same ligatures utilising a Roeder or similar knot (Fig. 49.12).

Procedure

The endoloop ligature is ‘back-loaded’ into the introducer and the loop is completely retracted to protect the knot (Fig. 49.13). This introducer is then inserted via a 5-mm port and the endoloop advanced until the loop is exposed, resting it directly on the tissue with the pedicle centred in the loop. This pedicle is then held with a second grasper through the loop utilising it to pull the tissue upwards. The plastic shaft should be perpendicular to the knot, which helps to prevent suture breakage and ensures knot security. The endoloop is tightened by first snapping off the top end of the plastic shaft if a commercial endoloop is used and then pulling back on the small end piece whilst sliding the shaft forwards (Fig. 49.14a—c).

This movement allows the knot to slide forwards closing the loop. Once the knot has been moved down, the ligated tissue is released from the grasper. The knot is locked down securely, the plastic shaft withdrawn from the knot and the suture then cut at the required length. Alternatively, the small plastic end can be cut off by dividing the ligature at this point, the plastic pusher then removed and scissors introduced through the same port alongside the suture which is then cut and removed (Fig. 49.14d).

Extra-corpooreal knotting

This technique differs from intracorporeal knot-tying in one basic respect: once the needle/suture has been passed through the tissue, the suture is then brought outside the body and the knot is tied. The completed knot is then reintroduced into the abdominal cavity and then secured into position. Extra-corpooreal knot-tying can be used to ligate vessels, reconstruct organs, approximate opposing tissue surfaces and suture anastomoses.

Procedure

The needle/suture is loaded into the jaws of the needle holder by lightly grasping the needle below the swage point so that the needle will collapse into the introducer. The loaded introducer is then inserted through a 5-mm port (Fig. 49.15a, b). Once the needle appears in the peritoneal cavity it is passed to a grasper introduced from another port. The needle is steadied and then it is regrasped in the desired position by the needle holder. The suture and needle are then passed through the tissue and the tip of the needle is then regrasped with the needle holder. The suture will not be pulled out of the tissue if it is controlled with the second grasper; additional suture length is pulled into the peritoneal cavity. One must be careful not to bring the whole suture intraperitoneally as one needs the end of the suture outside the port for knotting. The needle is then released and once again regrasped below the swage point with the needle holder so that it can then be withdrawn through the port removing the excess suture with it.

An assistant then covers the introducer channel with a finger to prevent loss of pneumoperitoneum. With both suture ends outside the body, the needle is cut off and a single throw knot made with the two suture ends (Fig. 49.16). The knot is held securely with the thumb and third finger of one hand (Fig. 49.17) whilst with the other a Roeder or Melzer knot (Fig. 49.18a—b) is completed. The suture tail is then cut off and a pusher used to slide the knot down as with the endoloop knot. An alternative is to make the first throw of the knot as described and then pass the suture ends through the jaws of a knot pusher which is introduced through the 5-mm port and the knot slid down on to the tissues. The knot pusher is then removed and a second conventional part of the knot. fashioned, the ends of the sutures again being passed through the knot pusher. This second throw is then pushed down in a like manner to the first and the third knot can also be fashioned and slid down in a like manner. The suture is then cut using the scissors through the same port.

Intracorporeal suturing

Straight needle technique

A commercially available ski needle is available with different suture materials. The ski needle is a straight needle with a slight bend at its point. The suture should be cut to its desired length prior to introducing it into the peritoneal cavity. The suture/needle is held in the needle holder as previously described, holding it below the swage and then introducing the needle into an introducer. The needle and suture are manipulated in the same manner as for extracorporeal suturing, being careful to keep the swage point of the needle orientated towards the needle holder. Once the needle has been passed through the tissue to be sutured, two loops of suture are wrapped around the needle shaft utilising the second grasper. This is most easily performed by depressing the 5-mm grasper down around the tip of the needle holder and back up around its shaft. This motion is repeated to make the second loop (Fig. 49.18). After completing the two loops, one must be sure to keep the swage point of the needle orientated towards the needle holder.

The suture should be cut to its desired length prior to introducing it into the peritoneal cavity. The suture/needle is held in the needle holder as previously described, holding it below the swage and then introducing the needle into an introducer. The needle and suture are manipulated in the same manner as for extracorporeal suturing, being careful to keep the swage point of the needle orientated towards the needle holder. Once the needle has been passed through the tissue to be sutured, two loops of suture are wrapped around the needle shaft utilising the second grasper. This is most easily performed by depressing the 5-mm grasper down around the tip of the needle holder and back up around its shaft. This motion is repeated to make the second loop (Fig. 49.18). After completing the two loops, one must be sure to keep the swage point of the needle orientated towards the needle holder.

The tail of the suture is then pulled through the two loops creating a knot which is slid down. Whilst holding the needle in a 5-mm grasper, two additional loops in the opposite direction are made by bringing the grasper around the needle holder shaft and then down around the needle holder tip.

Once again the tail of the suture is grasped and pulled through the loops to tighten the knot. The suture is then cut at the desired length and the needle removed through the port.

Intracorporeal suturing using a curved needle

Endoscopic suturing with a curved needle offers the surgeon many of the same benefits experienced when suturing at laparotomy: precise needle placement and control in confined areas, rotational needle passage through tissue and a wide variety of needles and different suture materials from which to choose.

Technique. A needle holder is passed through an introducer and the end of the suture grasped. The entire length of the suture is then pulled...
back through the introducer leaving the needle free at its distal end. The tail of the suture is released and the needle holder then advanced again down the length of the introducer taking care not to crimp or damage the suture. The needle/suture is then grasped at the swage point keeping the needle curve parallel to the needle holder and introducer. The needle is then pulled into the distal end of the introducer (Fig. 49.20a—b). Excess suture is excised. A loaded needle holder and introducer is then introduced through a 10-mm port and it lies in the same fashion as for a straight needle. A different type of intracorporeal knot can be performed using the Topel or twist knot (Fig. 49.21). If the needle is too large for the port, then the cannula is removed and the needle passed through the incision and reintroduced through the port (Figs 49.20 and 49.21). Autosuture has developed a disposable straight needle ‘endo-stitch’ that uses a short straight needle which passes from jaw to jaw (Fig. 49.22). Knotting with this method is very easy.

**Stapling**

*Linear stapling*

An endo-GIA can be introduced through a 12-mm port and used thoracoscopically and laparoscopically. It is a haemo-static staple giving three rows of staples on either side of the tissue which is divided. Thoracoscopically it is used to divide the azygos vein and to staple off the lung. Intraperitoneally, it can be used on vascular pedicles and across the intestine. It is produced with different sizes of staples and in both 3-cm and 6-cm lengths. Further cartridges can be applied so that multiple uses of a disposable instrument can be effected during one operation. The resulting stapled ends are exactly the same as fashioned with the conventional GIA stapler.

It can also be used to anastomose two organs or loops of intestine together in the same manner as it is used conventionally at open operation. The defects left for the introduction of each jaw of the stapler then have to be closed either using a further stapler or closing it with a running suture.

The circular stapling devices are used at laparoscopic ante-rior resection and it is possible to place purse-string sutures across the divided colon and rectum. The anvil of the stapling device can be inserted through the rectum with its spike attached and then the purse string tightened. However, most surgeons performing laparoscopic colorectal surgery have moved towards laparoscopic-assisted colectomies and anterior resection so that the specimen would be brought out through a small iliac fossa or Pfannensiel incision, which makes the placement of a purse-string suture in the proximal end of the colon and insertion of the anvil very much easier and quicker. The rectum can either be closed using a stapler or oversewn. At laparoscopic-assisted right hemicolecotomy, the specimen is removed through a right hypochondrial or right iliac fossa incision and the anastomosis is most easily performed extracorporeally.

**New innovations**

Anastomosis can be performed using single staples and the peritoneum after a transabdominal preperitoneal hernia repair is usually closed with these staples, loaded in a multifire instrument. Absorbable staples a] being manufactured.

Another innovation is to have a stopper applied to the end of a suture so that a knot is not required.
Suture materials

The different types and ideal properties of sutures are described in Tables 49.5 and 49.6.

A suture can be chosen with different properties in mind as follows.

Absorbable

Catgut is the oldest suture material known and is made from the submucosa of sheep intestines. It can be chromic or plain and is still the most frequently used suture material for intestinal anastomoses.

Suture material is absorbed in one of two ways. The first applies to catgut and collagen where the absorption mechanism is by enzymatic digestion. The other method is one of preliminary hydrolysis which is the effect of water on the suture material and does not require the same cellular involvement as does catgut with its proteolytic digestive enzymes. Hydrolysis is increased with rise in temperature or pH changes. Figure 49.23a demonstrates in general terms the comparative absorption times for catgut, Dexon (homo-polymer of glycolide), Vicryl (copolymer of glycolide and lactide) and PDS (polydioxanone). Once a suture has been broken up by hydrolysis, polymorphonuclear cells and other macrophages (e.g. giant cells) can digest even so-called unabsorbable material. As the material absorbs it loses its tensile strength (Fig. 49.23b).

Delayed or nonabsorbable

Very few sutures are truly completely nonabsorbable. Silk is derived from the cocoon of the silkworm larva. The suture is braided round a core and coated with wax to reduce capillary action. Tissue reaction is greater than to the synthetic nonabsorbables because silk is a foreign protein. For this reason silk is not now used in anastomoses, and most surgeons prefer to use a monofilament synthetic suture if a nonabsorbable suture is deemed necessary. Wire sutures are ideal for qualities of inertness and permanence but working with them is difficult and they are virtually absolute.

Staples

Circular, linear and linear-cutting stapling devices are used to form anastomoses. The devices carrying these staples can be disposable or reusable. Until 1986 the staples were always nonabsorbable, being made of stainless steel. However, absorbable staples have now been developed. The circular stapling device is used for oesophageal and rectal anastomoses. Their use is not a short cut to the joining of two pieces of intestine. The preparation of the bowel ends and the placement of the purse-string sutures must be carefully executed. They do, however, help in situations where the placement of sutures can be difficult, e.g. a low colorectal or anal anastomosis in a patient with a narrow pelvis (Fig. 49.6).

Linear stapling for anastomoses may leave awkward edges and ends (Fig. 49.6). Linear-cutting staplers can save time if very long closures or multiple anastomoses are necessary but have little benefit over hand-sutured anastomoses.

It is necessary to choose suture material that has the best characteristics for carrying out an anastomosis in a particular site. Vascular anastomoses require fine suture materials with minimal tissue reaction — strength is a secondary consideration — and Prolene is commonly used. Gut anastomoses require sutures with good handling qualities with secure knotting; pliancy is also important, as is strength when the intestine begins to contract. Plain catgut is unsuitable for intestinal anastomoses, but chromic catgut can be used for gastric and small intestinal unions. Rectal and oesophageal anastomoses should employ unabsorbable, or long-delayed absorbable sutures (e.g. PDS), because these areas combine many adverse factors with the requirement to withstand powerful contractile activity.
Complications

There are four main complications, as follows (Table 49.7).

Haemorrhage

This can occur at the suture line or from the mesentery. The Connell suture is non-haemostatic and therefore should not be used if the cut intestine has a profuse blood supply, e.g. the stomach.

Haemorrhage can be immediate (reactionary) or late (secondary), although this is rare. If the bleeding causes systemic effects, a laparotomy must be performed and the anastomosis resected and refashioned.

Leakage

Oesophageal and colonic anastomoses are most prone to leak. The outcome depends on the size of the leak and its anatomical site. As already stated, the healing of anastomoses depends on good blood supply and no tension. With colonic anastomoses a clean bowel is also necessary.

Stenosis

Stenosis can be caused by excessive inversion especially with two-layer anastomoses. An inadequate stoma in the first place or ischaemia can also lead to subsequent stenosis. Circular staples, especially double rows, are prone to cause narrowing due to rigidity.

Diverticular formation

Caused by either a weakness of the wall or from a poor blood supply, a 'blow-out' occurs which is contained, i.e. perfora-tion does not occur.

Although anastomoses depend on the many factors men-tioned, a good technique is probably the most important one.

Gentle handling of the tissues will ensure better healing. Anastomoses should never be rushed or performed if the above conditions cannot be fulfilled. A few extra minutes spent pays handsome dividends and may save the patient’s life. An insecure anastomosis is an unacceptable iatrogenic hazard.

Background

Surgical anatomy

The oesophagus is a muscular tube approximately 25 cm long occupying the posterior mediastinum and extending from if criopharyngeal sphincter to the cardia of the stomach; 2 cm of this tube lies below the diaphragm. The musculature of if upper 5 per cent, including the upper oesophageal sphincter is striated; the middle 40 per cent has mixed striated an smooth muscle with the proportion of smooth muscle increasing distally; the distal 55 per cent is entirely smooth muscle It is lined by squamous epithelium. The parasympathetic nerve supply is mediated by the vagus which has synaptic connections to the myenteric (Auerbach's) plexus. Meissner submucous plexus is very sparse in the oesophagus.

There is an upper and a lower oesophageal sphincter. The upper sphincter is powerful striated muscle, while the lower sphincter is much more subtle, but the elegant studies Liebermann-Meffert have shown that there is an anatomic sphincter at the gastro-oesophageal junction. The arch of the aorta makes a definite impression on the oesophagus that can be seen on a radiograph (Fig. 50.1) or during endoscopy. It is helpful to remember the distances 15, 25 and 40 for anato-mical location during endoscopy (Fig. 50.3).

Physiology

The main function of the oesophagus is to transfer food from the mouth to the stomach in a co-ordinated fashion. The initial movement of food from the mouth is voluntary. The pharyngeal swallow response is triggered by stimulation of the pharynx and involves sequential contraction of the oopharyngeal musculature, together with simultaneous closure of the nasal and respiratory passages, and opening of the upper oesophageal sphincter. The body of the oesophagus then propels the food bolus by primary peristalsis, through a relaxed lower oesophageal sphincter, into the stomach, taking air with it (Fig. 50.3). Primary peristalsis is under vagal control.

The upper oesophageal sphincter is normally closed at rest and serves as a protective mechanism against regurgitation of oesophageal contents into the respiratory passages, but it also serves to stop air entering the oesophagus other than the small amount that enters during swallowing. Failure to relax on swallowing may predispose to the development of a pharyngeal pouch (pulsion diverticulum).

The lower oesophageal sphincter (LOS) prevents gastric and duodenal contents from refluxing into the lower oesophagus (Fig. 50.4). The tone of the sphincter is influenced by many things including food, gastric distension, smoking and gastrointestinal hormones. The diaphragm also contributes to the action of the LOS. The function of the physiological sphincter was first demonstrated by Code by manometry using small balloons (Fig. 50.3). Nowadays LOS pressure is measured by perfused tubes or microtransducers. The normal LOS is 3—4 cm long and has a pressure of 10—25 mmHg (or cmH₂O).

Manometry may also be used to assess peristalsis (Fig. 50.6). The LOS relaxes in advance of the peristaltic wave. Primary peristalsis is induced by a swallow Secondary peristalsis is the normal response to a stubborn food bolus or refluxed material and also clears the oesophagus (Fig. 50.7). Clearance and neutralisation of refluxed gastric acid is mainly achieved by primary peristalsis which carries saliva with its high bicarbonate content down to the lower oesophagus. Tertiary contractions occur occasionally and are non-peristaltic waves (Fig. 50.8).

Symptoms

Dysphagia

Dysphagia is the term used to describe difficulty, but not necessarily pain, on swallowing. The localisation of the hold-up may help to differentiate between an obstruction at the criopharyngeal sphincter in the body of the oesophagus or at the lower end. The type of dysphagia is important. It may be dysphagia for solids or fluids, intermittent or progressive, precise or vague in its appreciation.

Odynophagia

Odynophagia refers to pain on swallowing. Patients with reflux oesophagitis often feel burning retrosternal discomfort within a few seconds of swallowing hot beverages, citrus drinks or alcohol. Odynophagia may be particularly severe in chemical injury of the oesophagus.

Regurgitation and reflux

Regurgitation and reflux are terms that are often used synonymously. It is helpful to differentiate between the two symptoms although it is not always possible. Regurgitation should strictly refer to the return of oesophageal contents from above an obstruction in the oesophagus that may be functional or mechanical. Reflux is the passive return of gastroduodenal contents to the mouth as part of the symptomatology of gastro-oesophageal reflux disease. Loss of weight, anaemia, cachexia, change of voice due to refluxed material irritating the vocal cords or recurrent laryngeal nerve palsy, and cough or dyspnoea due to tracheal aspiration are all important symptoms of oesophageal disorders.

Chest pain

Chest pain similar in character to angina pectoris may arise from an oesophageal cause, especially gastro-oesophageal reflux and motility disorders.

Investigations

Radiography

Contrast radiography has been somewhat overshadowed by endoscopy, but remains a very useful investigation for demonstrating narrowing, space-occupying lesions, anatomical distortion or abnormal motility. An adequate barium swallow takes time to do and should be tailored to the problem under investigation. It may be helpful to give a solid bolus (bread or marshmallow) if a motility disorder is suspected. Video recording is also useful to allow subsequent replay and detailed analysis. However, it should be stressed that barium radiology is very inaccurate in the diagnosis of gastro-oesophageal reflux, unless the reflux is gross, and should not be used for this purpose. Plain radiographs will show opaque foreign bodies.

Endoscopy

Endoscopy is necessary for the investigation of most oesophageal conditions. It is required to view the inside of the oesophagus and the oesophagogastric junction, to obtain a biopsy or cytology specimen, for the removal of foreign bodies and to dilate strictures. Traditionally there
are two types of instrument available — the rigid oesophagoscopy and the flexible fibre-optic endoscopy.

**Rigid oesophagoscopy**

Rigid oesophagoscopy is now virtually obsolete, but some surgeons still cling to this traditional method. The most commonly used instrument is the Negus oesophagoscope although there are newer varieties with better quality distal lighting, such as the Earlam oesophagoscope which is circular in cross section. Passage of a rigid oesophagoscope is a skilful business and is relatively safe in the hands of an expert, but there is still a significant risk of perforation. There may be something to be said for the occasional use of a rigid instrument to examine the lower pharynx and the cricopharyngeal area, since the view can be rather poor with a flexible endo-scope, in which case a shorter (and safer) laryngoscope is used. Most foreign bodies may be removed with a flexible gastroscope and an overtube to protect the oesophagus, but some may prefer to use the rigid instrument and large grasping forceps especially for a large foreign body such as a set of dentures as a set of dentures (Fig. 50.9). It should be noted that most modern dentures are not radio-opaque. Dilatation of oesophageal strictures has been done for many years with the rigid instru-ment and the classic Chevalier Jackson bougie (Fig. 50.10), but dilators that are passed over a guidewire are much safer and they are now in general use.

**Fibre-optic endoscopy (see Chapter 51)**

The flexible fibre-optic gastroduodenoscope has virtually supplanted the rigid instrument for diagnostic and therapeu-tic endoscopy of the oesophagus because it has many advan-tages. General anaesthesia is not required, most examinations can be done on an out-patient basis, the quality of the magnified image is superb, especially with modern video-endoscopes, the instrument is much safer to pass and there is a greater range of therapeutic devices. The technology of fibre-optic endoscopy continues to improve at a steady pace.

As a matter of routine the stomach and duodenum are examined as well as the oesophagus. If a stricture is encountered if may be helpful to dilate it to allow a complete inspection of the upper gastrointestinal (GI) tract, but this advice should be tempered by clinical common sense. All endoscopic manipulations involve a degree of risk and it is prudent to keep risks to a minimum.

**Therapeutic procedures**

**Dilatation of strictures**

The advent of guidewire directed dilatation of the oesophagus in the 1970s has been a major advance. The Eder—Puestow dilator (Fig. 50.11) was the first to be used. This had been produced by the Eder instrument company many years previously. The guidewire was intended to be passed blindly, but the method did not become popular until it was realised that the guidewire could be passed down the biopsy channel of an endoscope and through a stricture under vision. The endoscope is withdrawn leaving the guidewire in place and the dilators are passed over the guidewire. X-ray screening can be used to check that the wire is in satisfactory position and the dilators pass safely. With experience X-ray screening is rarely required, but may be reserved for difficult cases. To restore normal swallowing the stricture should be dilated to at least 16 mm diameter or 50 Fr. Charriêre, a French instrument maker, originally measured dilators in millimetres circumference, hence the use of French gauge. Guidewire directed dilatation of oesophageal strictures is now normal practice in most units and there are many different types of dilator. The Celestin stepped dilators (Fig. 50.12) are widely used in the UK and have the merit of being easy to pass since only two are required for complete dilatation.

Balloons may also be used for dilatation of strictures. They come in many varieties. Some are designed for passage down the biopsy channel, others for passage in the X-ray depart-ment. In general balloons achieve rather less effective dilata-tion than solid dilators, but they may be useful to begin dilatation of difficult strictures.

**Laser therapy**

Lasers may be used to core a channel through a cancer for palliation of dysphagia. Similar effects may be produced by bipolar diathermy, injection of absolute alcohol or argon beam plasma coagulation.

**Oesophageal manometry**

Manometry is now widely used to diagnose oesophageal motility disorders. Recordings are usually made by passing a multilumen catheter with three to eight recording orifices at different levels down the oesophagus and into the stomach. The catheter channels are perfused with water by a low com-pliance pneumohydraulic pump for accurate measurement of rapid pressure changes. The catheter is withdrawn progressively up the oesophagus and recordings are taken at intervals of 0.5—1.0 cm to measure the length and pressure of the LOS and to assess motility in the body of the oesophagus during swallowing. Catheters with solid-state transducers are easier to use and are becoming more popular, but are still rather expensive.

**24-hour pH recording**

Prolonged measurement of oesophageal pH is now accepted as the most accurate method for the diagnosis of gastro-oesophageal reflux. A small pH probe is passed into the distal oesophagus and positioned 5cm above the upper margin of the LOS as defined by manometry. The probe is then con-nected to a miniature digital recorder which is worn on a belt and allows most normal activities. A 20—24-hour recording period is usual and the pH record is analysed by an auto-mated computer program using DeMeester’s criteria. In some cases with atypical symptoms it is useful to compare the relationship between symptoms and reflux episodes.
Congenital abnormalities

Atresia and tracheo-oesophageal fistula

Congenital atresia of the oesophagus is usually associated with a tracheo-oesophageal fistula. In 85 per cent of cases it is the Lower segment that communicates with the trachea (Fig. 50.13).

It is important to be aware of this abnormality because its recognition within 48 hours of birth, and subsequent surgical correction, is the only hope of survival.

Suspect atresia in early feeding problems

Clinical features

The newborn baby regurgitates all of its first and subsequent feeds. Saliva pours almost continuously from its mouth. This is the sign of oesophageal atresia — it does not occur in any other condition. Attacks of coughing and cyanosis occur on feeding. It should be suspected in all cases of hydramnios, a condition that is present in 50 per cent of cases of atresia. Oesophageal atresia may occur as part of the VACTER group of anomalies (V — vertebral body segmentation defects; A — anal atresia; C — cardiovascular: patent ductus arteriosus, ventricular septal defect; TE — tracheo-oesophageal fistula; R — radial ray hypoplasia, unilateral renal agenesis).

Clinical confirmation of the diagnosis

A nasogastric tube typically comes against an obstruction within 10 cm. If this occurs the diagnosis is virtually certain.

Radiological confirmation

A lateral chest X-ray shows a lucent proximal pouch that may displace the trachea anteriorly. If bowel gas is present there must be a fistula to the distal oesophagus (Fig. 50.14). In cases of doubt air (preferred) or a small amount of contrast can be injected through the nasogastric tube. If contrast is injected it should be remembered that there may be a fistula between the upper segment and the trachea.

Remember to locate the aortic arch

The side that the aortic arch is on needs to be determined because a thoracotomy will be done on the side opposite to the aortic arch. If the position of the aorta is not clear from the chest X-ray an echocardiogram should be done.

Treatment

Corrective surgery is normally performed shortly after the diagnosis is made. If there is a long distance between the two ends there is no need for hurry because there is no fistula to the trachea. It is usual to wait for several weeks so that the two ends of the oesophagus can grow towards each other to reduce the distance between them. In the meantime the child is fed through a gastrostomy tube.

Operation

The best approach is through a thoracotomy on the side opposite to the aortic arch, usually the right, at the level of the fifth intercostal space. The lower segment is divided at its entrance into the trachea and the fistula closed. It is usually possible to perform an anastomosis between the blind upper segment and the lower segment. If this is not possible part of the colon may be interposed.

Prognosis

The two most feared complications are pneumonia and leakage from the anastomosis. Following recovery from the immediate postoperative period the long-term prognosis is excellent. Most enter adult life with an essentially normal upper GI tract. Some have problems with gastro-oesophageal reflux and there can sometimes be a problem with a peristalsis of the distal segment giving rise to dysphagia.

Oesophageal stenosis

This is a rare congenital organic narrowing of the lumen of the oesophagus and is a cause of dysphagia. It occurs anywhere in the oesophagus.

Dysphagia lusoria

Several vascular anomalies may produce dysphagia by compression of the oesophagus. Classically this is due to an aberrant right subclavian artery [arteria lusoria (Fig. 50.15)]. However, the oesophagus is more commonly compressed by vascular rings, such as a double aortic arch. Dysphagia occurs in only a minority of cases and usually presents early in childhood, although it can occur in the late teens. Treatment is usually by division of the nondominant component of the ring.

‘Short’ oesophagus with hiatus hernia is mentioned only to say that it is not a congenital abnormality. True shortening of the oesophagus is secondary to severe reflux oesophagitis (see below).
Foreign bodies in the oesophagus

All manner of foreign bodies have become arrested in the oesophagus such as coins, pins and dentures. Button batteries may be a troublesome problem in children. The commonest impacted material is food (Fig. 50.16). Plain radiographs are the most useful examination. A contrast examination is not usually required and may make endoscopy more difficult.

Food impaction is almost always a sign of underlying pathology, most commonly a stricture or carcinoma.

Beware of button batteries in the oesophagus

Foreign bodies that have become stuck in the oesophagus should be removed by endoscopy. Flexible endoscopy is now the method of choice and the majority of objects can be extracted with suitable grasping forceps, a snare or a basket. If the object may injure the oesophagus on withdrawal an overtube should be used, and the endoscope and object with-drawn into the overtube before removal. Button batteries can be a particular worry as they are difficult to grasp and it is tempting to push them on into the stomach. However, an exhausted battery may rapidly corrode in the GI tract and is best extracted. An impacted food bolus will often break up and pass on if the patient is given fizzy drinks and confined to fluids for a short time. The cause of the impaction can then be investigated. If symptoms are severe or the bolus does not pass on it can be extracted or broken up at endoscopy.
Perforation

Perforation of the oesophagus is a serious condition that requires prompt diagnosis and treatment.

Barotrauma — Boerhaave’s syndrome

So-called ‘spontaneous’ perforation of the oesophagus is usually due to severe barotrauma when a person vomits against a closed glottis. The pressure in the oesophagus rapidly increases and the oesophagus bursts at its weakest point in the lower third, sending a stream of material into the mediastinum and often the pleural cavity as well. The condition was first reported by Boerhaave who reported the case of a grand admiral of the Dutch fleet who was a glutton and practised the habit of autoemesis. Boerhaave’s syndrome is the most serious type of perforation because of the volume of infected material that is released under pressure.

Suspect perforation if pain follows vomiting

The clinical history is of severe pain in the chest or upper abdomen following a meal or a bout of drinking. Many cases are misdiagnosed as myocardial infarction or as a perforated peptic ulcer or pancreatitis if the pain is confined to the zipper abdomen. There may be a surprising amount of rigidity on examination of the upper abdomen even in the absence of any peritoneal contamination.

Pathological perforation

Perforation of ulcers, such as a Barrett’s ulcer (see below) or tumours of the oesophagus are unusual, but do occur. They may also erode into the aorta or ventricle with rapidly fatal results.

Penetrating injury

Perforation by knives and bullets is uncommon, even in war, since the oesophagus is a relatively small target surrounded by other vital organs.

Foreign bodies

The oesophagus may be perforated during removal of a foreign body, but occasionally an object that has been left in the oesophagus for several days will erode through the wall.

Instrumental perforation

Instrumentation is by far the commonest cause of oesophageal perforation. Modern instrumentation is remarkably safe, but perforation remains a risk that should never be forgotten. The virtual demise of the rigid oesophagoscope has been a major factor in improving safety. It can readily be imagined that passing a rigid metal tube down the oesophagus of an elderly patient with a kyphotic spine is a haz-ardous undertaking. The pharynx may be perforated above the cricopharyngeal sphincter; the oesophagus may be crushed against osteophytes in the cervical spine (Fig. 50.17), particularly during the extension of the neck that is necessary to get the instrument down to the distal oesophagus. Perforations caused by rigid endoscopes are often large and gen-erally require more energetic surgical treatment than those that occur during flexible endoscopy.

Prevention of perforation is better than cure

Perforation during diagnostic flexible endoscopy of the upper GI tract is unusual, but occurs at a frequency of one in 4000 examinations. Therapeutic endoscopy increases the risk, but the overall risk should remain low. Dilatation of the oesophagus increases the risk significantly, but biopsy does not. The oesophagus may be perforated by a guidewire or dilator above or below a stricture. Splitting of a benign stricture during dilatation is exceedingly rare and is not a significant risk. Most perforations that occur during dilatation of benign strictures are probably due to movement of the guidewire that allows the dilator to move in an unpredictable direction. For this reason guidewires should always be held firmly against an unmoving object during the passage of dilators. This single act provides the greatest protection against injury. If dilatation of a stricture is done during rigid endoscopy the unconstrained dilator may be passed through the oesophagus above or, less commonly, below the stricture. Cancers may be dilated safely, but it should be remembered that they are unpredictably friable and may split as the dilator passes. It is therefore prudent to limit the dilatation of a cancer to the extent that is necessary for the matter in hand, such as passage of the endoscope for laser treatment of a cancer. A side viewing duodenoscope [for an endoscopic retrograde cholangiopancreatography (ERCP)] that forms a loop in the oesophagus during insertion may cause a split. This is a particularly un-pleasant situation because if a loop does form there is no safe method of undoing the loop. The oesophagus may be per-forated by the large balloons that are used for the treatment of achalasia by forceful dilatation since these are inflated to a diameter (30—40 mm, 94—125 Fr) that is greater than that of the normal oesophagus. The incidence of perforation appears greater with the larger balloons and these should probably be reserved for repeat dilations if a smaller balloon has failed to achieve the desired effect. Perforation may occur during the insertion of plastic tubes or expanding stents for the palliation of cancer. In such cases the leak may be sealed partially or completely once the stent is in place.

Diagnosis

Beware and be aware of perforation

Look for surgical emphysema

Perforation of the oesophagus usually produces severe chest pain and should be suspected if this occurs after instrumentation. Subcutaneous emphysema may be present in the neck and sometimes over the upper chest as well. Emphysema is more likely to appear if the oesophagus is perforated during flexible endoscopy because of the air insufflation that is an essential part of the procedure. Emphysema around the pericardium can sometimes be detected on auscultation as a mediastinal ‘crunch’ which sounds like footsteps in soft snow A chest X-ray may show gas in the mediastinum, a pleural effusion or a pneumothorax (Fig. 50.18).

Water-soluble contrast media may miss small perforations

It is essential to obtain a contrast swallow whenever a perforation is suspected. The only possible exception to this rule is when the diagnosis is obvious, for example when subcuta-neous emphysema is present, and the management policy is nonoperative. In such cases it may be reasonable to avoid the additional small risk of worsening the contamination of the mediastinum by giving contrast. Contrary to popular opinion gastrograffin should not be used. This agent is hypertonic and can cause severe lung injury if aspirated. Modern nonionic contrast media are safer, but still give poorer images than barium suspension. In the author’s opinion barium is the contrast material of choice. There is no evidence that the judicious use of barium suspension is clinically harmful in this setting and it is important to obtain good quality images. It
should also be emphasised that water-soluble contrast media may miss small perforations of the oesophagus or small anastomotic disruptions.

**Treatment**

Perforation of the oesophagus usually leads to mediastinitis which is a very dangerous condition. The loose areolar tissues of the posterior mediastinum allow rapid spread of gastrointestinal contents. There may be marked systemic disturbance with cardiovascular collapse. Dysrhythmias are common, especially atrial fibrillation. The aim of treatment is to limit mediastinal contamination and deal with the existing infection. Operative repair deals with the injury directly, but imposes risks of its own. Nonoperative treatment aims to limit the effects of mediastinitis and provide an environment in which healing can take place.

**Prompt diagnosis and treatment is essential for the best results**

The management of oesophageal perforation remains controversial with strong opinions in favour of operative and nonoperative treatment. Both schools of thought have their merits. The majority of perforations can nowadays be managed nonoperatively, but it is still important to keep an open mind, to tailor management to the individual patient and to be prepared to change the treatment plan in the light of clinical progress. The essential determinants of management are the septic load, the response of the patient to the septic challenge, the age and general condition of the patient and whether the perforation is confined to the mediastinum. Perforations of the abdominal oesophagus are probably best managed by operative repair as is Boerhaave’s syndrome in which the septic load is high. Most endoscopic perforations involve minimal contamination and are ideal for non-operative management, particularly if the patient is a poor risk for a thoracotomy. The relative indications for the two forms of management are listed in Table 50.1.

The key elements of nonoperative management are analgesia, nil by mouth, antibiotics and general supportive care. When the patient is stable enteral or parenteral nutrition is started. Enteral feeding is best given by feeding jejunostomy.

Some authorities advocate a double-lumen suction catheter in the oesophagus, but this is not universally agreed. There is nothing to commend the use of a nasogastric tube which simply encourages gastro-oesophageal reflux and increases the risk of respiratory infection. Rather surprisingly even a perforated cancer will heal, given adequate time.

**Nonoperative management of perforated oesophagus**

- Analgesia
- Nil by mouth
- Antibiotics
- Intravenous fluids/nutrition

The management of oesophageal perforation can be difficult and it is important to be prepared for complications, such as the tracheo-oesophageal fistula in Fig. 50.19.

Operative management usually involves thoracotomy and repair of the perforation. This is best done within a few hours of perforation. After 12 hours the tissues become swollen and friable, and less suitable for direct suture. The hole in the mucosa is always bigger than the hole in the muscle and the muscle should be incised to see the mucosal edges clearly. It is essential that there should be no obstruction distal to the repair. Ideally the repair should be strengthened with adjacent gastric fundus, diaphragm or intercostal muscle. If the site of the perforation is not healthy, oesophageal resection should be performed.

An intermediate form of management is the insertion of a stent. This is now well established for the treatment of perforated cancers. Expanding metal stents are ideal for this purpose since they can be inserted with minimal trauma. Some clinicians use the more traditional plastic or silicone tubes for this purpose, but additional dilatation may be required for their insertion with the risk of worsening the injury.

There is a wide range of options for salvage following late diagnosis or failed nonoperative management including multiple tube drainage, oesophageal exclusion and resection, oesophagostomy, gastrostomy and delayed reconstruction. The management of such cases is challenging and highly specialised.
Mallory—Weiss syndrome

Forceful vomiting may produce a mucosal tear at the cardia rather than a full perforation of the oesophagus. The mechanism of injury is different. In Boerhaave’s syndrome vomiting occurs against a closed glottis and pressure builds up in the oesophagus. In the Mallory—Weiss syndrome vigorous vomiting produces a vertical split which is in the gastric mucosa immediately below the squamocolumnar junction at the cardia in 90 per cent of cases. In only 10 per cent is the tear in the oesophagus. The condition presents with haematemesis. Usually the bleeding is not severe, but endoscopic injection therapy may be required for the occasional case with severe bleeding. Surgery is rarely required.
Corrosive injury

Skilled early endoscopy is useful in corrosive injury

Corrosives such as sodium hydroxide (lye) or sulphuric acid may be taken in attempted suicide. Bleach may be drunk by young children. All can cause severe damage to the pharynx, larynx, oesophagus and stomach. The oesophagus is usually worst affected by sodium hydroxide. The key to management is early endoscopy by an experienced endoscopist to inspect the whole of the oesophagus and stomach unless there is a severe necrotising lesion. Air insufflation should be kept to a minimum. Minor injuries resolve rapidly with no late sequelae. Severe mucosal injury (Fig. 50.21) should be treated with steroids for 3 weeks and a programme of regular dilatations started thereafter. If full-thickness necrosis is suspected resection should be done at an early stage.

Cases that present late may have extensive strictureing of the oesophagus that is difficult to dilate (Figs 50.22 and 50.23). Oesophageal resection may be required. Some advocate surgical bypass rather than resection as there may be a very marked fibrous peri-oesophagitis in late cases.
Drug-induced injury

Many medications, such as antibiotics and potassium preparations, are potentially damaging to the oesophagus as tablets may lie in the oesophagus for a long time, especially if taken without an adequate drink. Acute injury presents with dysphagia and odynophagia which may be very severe. The inflammation usually resolves within 2—3 weeks and no specific treatment is required apart from appropriate nutritional support. A stricture may follow the acute injury.
Gastro-oesophageal reflux disease

**Aetiology**

Normal competence of the gastro-oesophageal junction is maintained by the LOS. There has been considerable controversy about the relative importance of the physiology of the LOS and the anatomy of the cardia. This controversy is not completely resolved, but it is currently accepted that the most important factor in gastro-oesophageal competence is the function of the LOS, which is augmented by a normally functioning diaphragmatic hiatus.

Loss of competence of the LOS leads to gastro-oesophageal reflux disease (GORD). This rather clumsy name and inelegant acronym has come into common use because the alternatives do not describe the condition. **Sliding hiatus hernia** has a variable association with GORD. In general patients with the more severe stages of GORD tend to have a hernia, but most GORD sufferers do not have a hernia and many of those with a hernia do not have GORD. It should be noted that rolling or paraoesophageal hiatus hernia is a quite different and potentially dangerous condition (see below). **Reflux oesophagitis** is a complication of GORD that occurs in a minority of sufferers. It occurs in 40–50 per cent of those referred to hospital, but a much lower proportion of those who suffer from symptoms of GORD in the community as a whole.

A degree of gastro-oesophageal reflux is normal, particularly after meals when there is a need to regurgitate swallowed air to maintain comfort. **Physiological reflux** mostly occurs during transient lower oesophageal sphincter relaxations (TLOSRs) that are quite separate from swallow-induced relaxation. In the early stages of GORD most of the pathological reflux occurs as a result of an increased number of TLOSRs. In severe GORD a greater proportion of reflux occurs across a LOS that has lost its basal tone and has a shorter length exposed to intra-abdominal pressure. Under-standing of the function of the LOS has been largely eluci-dated by Dent, who discovered the importance of TLOSRs. and by DeMeester, who clarified the importance of the basic competence of the LOS which is governed by basal LOS pressure, the overall length of the LOS and the length that is exposed to intra-abdominal pressure.

**TLOSRs, the most important factor in gastro-oesophageal reflux**

**Length and pressure of the LOS is also important**

In westernised countries GORD is by far the commonest condition affecting the upper G I tract. This is in part a rela-tive change due to the declining incidence of peptic ulcers as the incidence of infection with Helicobacter pylori has reduced due to improved socioeconomic conditions. However, there has almost certainly been an absolute increase in the incidence of GORD in the last 20–30 years. The cause of the increase is unclear, but may be due in part to increasing obesity. In a curious way it may also be an effect of the reduced incidence of Helicobacter infection. Since chronic infection of the gastric corpus decreases acid secretion, and infection of the antrum increases acid secretion the overall effect of reduced infection on gastric acid secretion in the community is a matter of conjecture. Some suggest that the net effect is increased secretion that may increase the incidence of GORD. The epidemiology of upper G I disease is a fascinating topic of research that is evolving rapidly. It is a particularly important topic since medication for GORD is now the largest single item on the healthcare budget of many countries, and the incidence of cancer of the lower oesophagus and cardia is also increasing, possibly as a result of the changed incidence of GORD (see below).

**Clinical features**

**Dyspepsia with fatty foods is more common in GORD than gallstone disease**

Retrosternal burning pain (heartburn) and epigastric pain are the commonest symptoms. These are usually provoked by food, particularly fatty food. Indeed ‘fatty dyspepsia’ is a much more common feature of GORD than of gallstones with which the association is rather questionable. As the condition becomes more severe gastric acid may reflux to the mouth and produce an unpleasant taste. In gross cases food may reflux to the mouth and this can be a particularly trying symptom. It is in the more advanced cases there is a history of pain and reflux when lying flat or on stooping. A proportion of cases may odynophagia with hot beverages, citruss drinks or alcohol. This symptom which occurs within a few seconds of ingestion is a very useful confirmation that the patient is suffering from an oesophageal disorder and not a peptic ulcer. Some patients present with less typical symptoms such as angina-like chest pain, pulmonary or laryngeal symptoms. Dysphagia is usually a sign that a stricture has occurred, but may be caused by an associated motility disorder.

Because GORD is such a common disorder it should always be the first thought when a patient presents with oesophageal symptoms that are unusual or that defy diagnosis after a series of investigations.

**Diagnosis**

In the majority of cases the diagnosis is assumed rather than proven and treatment is empirical. Endoscopy is done mainly to exclude more serious pathology such as cancer. If the ty-pical appearance of reflux oesophagitis, peptic stricture or Barrett’s oesophagus is seen the diagnosis is clinched, but oesophagitis is not present in most cases. The endoscopic appearances of the normal oesophagus, hiatus hernia, oesophagitis and stricture are shown in Figs 50.24—3 0. In patients with severe or persistent symptoms in whom it is judged that an objective diagnosis is essential, oesophageal manometry and 24-hour oesophageal pH recording should be done. It is essential to have an objective diagnosis before embarking on an antireflux operation. It is important that manometry is done at the same sitting as a pH study since fermentation of food residue in an achalasic oesophagus produces lactic acid surprisingly rapidly, and a significant proportion of patients with achalasia has abnormal acid exposure of the lower oesophagus. Usually the form of the pH trace in achalasia is different from that of GORD with slow undulations of pH rather than rapid bursts of reflux.

However, the author has seen cases of achalasia with a pH recording identical to that of GORD and in whom the symptoms of achalasia have been completely relieved by Heller’s myotomy without a concurrent antireflux procedure and without the onset of GORD on prolonged follow-up.

Barium swallow and meal examinations give the best appreciation of gastro-oesophageal anatomy (Fig. 50.31). This may be important to the surgeon planning an operation that may be complicated by oesophageal shortening or a rolling hiatus hernia, but it is not important for the diagnosis of GORD. Radiology is at best 50 per cent accurate in the diagnosis of GORD so that one might just as well toss coins. The use of the Trendelenburg position may give good pic-tures, but does not help the assessment of reflux.

For the most part making a diagnosis of GORD is not difficult, but because it is so common there is a large number of people in whom the diagnosis is obscure. It should be borne in mind that proton pump inhibitors (PPIs), which are now quite properly in widespread use by family doctors, heal reflux oesophagitis rapidly so that there may be nothing abnormal to see at endoscopy. The effect of PPIs on acid secretion may be surprisingly prolonged, in some cases lead-ing to false-negative oesophageal pH studies. As a matter of routine, PPIs are stopped a week before oesophageal pH recording, but acid secretion is sometimes reduced for 2 weeks or more. In cases of doubt 24-hour pH recording should be repeated and it is sometimes useful to stop PPIs 4 weeks before pH recording.
Achalasia and GORD are easily confused

A further perversity in the diagnosis of GORD is the ease with which its symptoms may be confused with those of achalasia. With the more widespread use of oesophageal manometry achalasia is often diagnosed at a much earlier stage than previously, long before the classic symptom pattern is established and long before the classic X-ray appearances are seen. It is perhaps surprising that the early symptoms of achalasia may be indistinguishable from those of GORD even with hindsight. This is especially important when patients are being considered for antireflux surgery.

Management of uncomplicated GORD

Medical management

Most sufferers from GORD do not consult a doctor and do not need to do so. They self medicate with over-the-counter medicines such as simple antacids, antacid-alginate prepara-tions and \( H_2 \) receptor antagonists. Consultation is more like-ly when symptoms are severe or prolonged. By the time a patient comes to consultation, and particularly hospital consultation, it is highly likely that simple treatment will have been tried and found wanting. Nevertheless it is always worth checking. Simple measures that may have been neg-lected include advice about weight loss, smoking, excessive consump-tion of alcohol, tea or coffee and a modest degree of head up tilt of the bed. Tilting the bed has been shown to have an effect that is similar to taking an \( H_2 \) antagonist. However, the common practice of using additional pillows has no significant effect apart from causing discomfort.

PPIs are the most effective medication for severe GORD

PPIs, such as omeprazole, lansoprazole and pantoprazole are by far the most effective drug treatment for GORD. Indeed they are so effective that, once started, patients are very reluctant to stop taking them. The PPIs have been a major advance in the treatment of GORD. Given an adequate dose oesophagitis heals in the majority of cases and even most strictures respond well to one or two dilatations and long-term PPI treatment. The only reservation is whether there will be serious side effects with long-term consumption. Thus far the PPIs have an excellent safety record, but doubts have been expressed as to whether the increased incidence of adenocarcinoma of the lower esophagus and cardia in many countries may be due in part to the long-term treatment of GORD with powerful acid suppression.

Surgery

Strictly speaking the need for surgery should have been reduced since medication has improved so much. Paradoxically, the number of antireflux operations has remained rela-tively constant and may even be increasing. This is probably partly due to increased patient expectations and partly to the advent of minimal access surgery that has improved the acceptability of surgical procedures.

The results of antireflux surgery are generally good

The indication for surgery in uncomplicated GORD is essentially patient choice. The risks and possible benefits of surgery need to be discussed in detail. The risks include a small mortality rate (0.1—0.5 per cent, depending on patient selection), the risk of a failed operation (5—10 per cent) and the risk of side effects such as dysphagia, gas bloat or abdomi-nal discomfort (10 per cent). With current operative tech-niques 85—90 per cent of patients should be satisfied with the result of an antireflux operation. Patients who are asymptomatic on a PPI need a careful discussion of the risk side of the equation. Those who are symptomatic on a PPI need a careful clinical review to make sure that they will benefit from an operation. Reasons for failure on a PPI include ‘volume’ reflux (good indication for surgery), ‘hermit’ life-style in which the least deviation from lifestyle rules leads to symptoms (good indication), psychological distress with intolerance of minor symptoms (bad indication — these patients are likely to be dissatisfied with surgery), poor compliance (good indication if the reason for poor compliance is the side effects of treatment, otherwise bad indication) and misdiagnosis of GORD. Clinical trials are now in progress to compare the relative efficacy of long-term medication and surgery, and it is hoped that the results will simplify clinical decision making.

What operation?

There are many operations for GORD, but essentially the choice is between total and partial fundoplication. The major types of antireflux operation were all developed in the 1950s (Fig. 50.32). Anatomical repair of hiatus hernia has been abandoned as it is ineffective. Nissen described total fundoplication in which the fundus of the stomach is wrapped completely around the lower esophagus. The Belsey operation is a thoracic procedure in which the oesophagus is sutured to the diaphragm and to the fundus of the stomach to reduce any hiatus hernia and produce a 2400 anterior fundoplication. The Hill procedure is an operation in which the cardia is tightened and fixed to the pre aortic fascia. The completed operation looks very like a fundoplication.

Total or partial fundoplication?

Done correctly these are all effective operations. The disadvantage of the Nissen fundoplication is that it can produce an overcompetent cardia resulting in dysphagia or the gas bloat syndrome in which belching is prevented. As a result the stomach fills with air and the patient feels very full after meals and passes excessive flatus. The problem of the overcompetent cardia has been largely overcome by the floppy Nissen in which the fundoplication is made very loose around the oesophagus and also by making a short fundo-plication of 1 cm or so. Partial fundoplication is less prone to side effects, but has tended to have a higher recurrence rate. This tendency seems to have been partly overcome by improved suture materials. There are now many different partial fundoplication operations, but the principles of anti-reflux surgery remain the same.

The Angelchik prosthesis is a different type of antireflux procedure in which a silastic prosthetic collar is placed around the lower oesophagus. It probably acts by limiting distension of the cardia which is the trigger zone for TLOSRs and undoubtedly prevents reflux in the majority of cases in which it is implanted. However, it has a tendency to cause troublesome dysphagia and is much less popular than formerly.

Roux-en-Y diversion reduces reflux

In some complicated cases, such as reoperative problems, the effects of reflux can be greatly reduced by performing a partial gastrectomy with a Roux-en-Y reconstruction. This reduces gastric acid secretion and diverts bile and pancreatic secretions away from the stomach. Thus the volume of potentially refluxate in the stomach is reduced and because of its changed composition it is less damaging to the oesophagus.

What operative approach?

For many years the relative merits of the thoracic and abdominal approaches were hotly debated. The advent of minimal access surgery has
rarely, perforation. Uncomplicated reflux oesophagitis almost never gives rise to severe haemorrhage. of reflux oesophagitis that always occur at or just above the squamocolumnar junction. Barrett’s ulcers may be deep and prone to bleeding or, Barrett’s ulcer is an ulcer in the columnar-lined portion of a Barrett’s oesophagus (Fig. 50.41). Barrett’s oesophagus (columnar-lined lower oesophagus) is a metaplastic change in the lining mucosa of the oesophagus in response to chronic gastro-oesophageal reflux (Fig. 50.36). One of the great mysteries of GORD is why some people develop oesophagitis and others develop Barrett’s oesophagus often without significant oesophagitis. In Barrett’s oesophagus the junction between squamous oesophageal mucosa and gastric mucosa moves proximally. It may be difficult to distinguish a Barrett’s oesophagus from a tubular sliding hiatus hernia during endoscopy since the two often coexist (Fig. 50.35). A different type of stricture may occur in the columnar segment after healing of a Barrett’s ulcer (see below). Intestinal metaplasia, the important factor

Several types of gastric-type mucosa may be found in the lower oesophagus. When intestinal metaplasia occurs there is an increased risk of adenocarcinoma of the oesophagus of the order of 25 times that of the general population (Figs 50.39 and 50.40). Patients who are found to have Barrett’s oesophagus may be submitted to regular screening endoscopy with multiple biopsies every year or two in the hope of finding dysplasia or in situ cancer rather than allowing invasive cancer to develop and cause symptoms. There is as yet no general agreement about the benefits of screening endoscopy, nor about the ideal frequency of endoscopy. A significant problem is that the incidence of Barrett’s oesophagus in the community is estimated to be at least 10 times the incidence discovered by endoscopy in dyspeptic patients referred for endoscopy. Thus adenocarcinoma in Barrett’s oesophagus often presents with invasive cancer without any preceding reflux symptoms.

Until recently Barrett’s oesophagus was not diagnosed until there was at least 3 cm of columnar epithelium in the distal oesophagus. With the better appreciation of the importance of intestinal metaplasia Barrett’s oesophagus may be diagnosed if there is any intestinal metaplasia in the oesophagus.

When Barrett’s oesophagus is discovered the treatment is that of the underlying GORD. Several methods of ablation of Barrett’s mucosa are under active study, including laser, photodynamic therapy and argon beam plasma coagulation. In conjunction with high-dose PPI treatment or an antireflux operation these endoscopic methods can restore the squamous lining of the oesophagus. It is not yet known whether this reduces the risk of malignant transformation since there are often remnants of glandular mucosa underneath the new squamous lining.

Don’t confuse Barrett’s ulcer with oesophagitis

Barrett’s ulcer is an ulcer in the columnar-lined portion of a Barrett’s oesophagus (Fig. 50.41). These are distinct from the more usual erosions of reflux oesophagitis that always occur at or just above the squamo-columnar junction. Barrett’s ulcers may be deep and prone to bleeding or, rarely, perforation. Uncomplicated reflux oesophagitis almost never gives rise to severe haemorrhage.
**Paraesophageal (‘rolling’) hiatus hernia**

Rolling hiatus hernias are dangerous

Unlike sliding hiatus hernia a rolling hiatus hernia is a true hernia that is prone to complications. True paraesophageal hernias in which the cardia remains in its normal anatomical position are very rare and confined to museum exhibits and personal collections of interesting cases. The vast majority of rolling hernias is mixed hernias in which the cardia is displaced into the chest and the greater curve of the stomach rolls into the mediastinum (Fig. 50.42). Sometimes the whole of the stomach lies in the chest (Fig. 50.43) and may undergo volvulus with perforation or gangrene. Colon or small intestine may sometimes lie in the hernia sac, but rarely causes additional complications. The hernia is commonest in the elderly, but may occur in young fit people.

The symptoms of rolling hernia are mostly due to twisting and distortion of the oesophagus and stomach. Dysphagia is common. Chest pain may occur due to distension of an obstructed stomach. Classically the pain is relieved by a loud belch. Symptoms of GORD are variable. They may be present in the early stages of evolution of the hernia, but disappear as distortion of the cardia increases.

The hernia may be visible on a plain X-ray of the chest as a gas bubble, often with a fluid level behind the heart (Fig. 50.44). Fluid levels are not seen in sliding hernias. A barium meal is the best method of diagnosis. The endoscopic appearances may be confusing, especially in large hernias when the endoscopist feels as if they have lost their sense of direction.

Rolling hernias always require surgical repair as they are potentially dangerous. However, major surgery may not be an attractive prospect in frail elderly patients or in someone who has few symptoms. Patients who present as an emergency with acute chest pain may be treated initially by nasogastric tube to relieve the distension that causes the pain, followed by operative repair. If the pain is not relieved or perforation is suspected immediate operation is mandatory.

The type of operation that is done is somewhat controversial because of the variable occurrence of GORD. A thoracic or abdominal approach is equally acceptable. The essential part of the operation is reduction of the hernia and some form of gastropexy. Some surgeons perform a fundoplication arguing that this is a very effective means of maintaining reduction and that it deals with the associated GORD. Others argue that a fundoplication should only be done if reflux can be conclusively demonstrated beforehand. Surprisingly, both philosophies achieve good results. Laparoscopic repair has recently become popular. Full anatomical repair of a large rolling hernia can be tedious and difficult by the laparoscopic approach and it is more common simply to reduce the hernia and perform a gastropexy. Some surgeons lay a sheet of prosthetic mesh across the hiatal opening to stop the bowel entering it.
Neoplasms of the oesophagus

Benign tumours

Benign tumours of the oesophagus are rare. The commonest is a leiomyoma (Fig. 50.45). Even a large leiomyoma may produce surprisingly mild symptoms. It is usually possible to enucleate the tumour at thoracotomy without breaching the mucosa. Small polyps of the oesophagus, such as granular cell tumours and fibrovascular polyps, may be found in the course of endoscopy for other conditions.

Malignant tumours

Sarcoma

Sarcoma of the oesophagus is exceedingly rare, but leiomyosarcoma (Fig. 50.46) and rhabdomyosarcomas have been reported. Other types of sarcoma have been reported, but are confined to individual case reports.

Malignant melanoma

Malignant melanoma of the oesophagus is rare. It may represent secondary spread, but primary melanoma of the oesophagus does occur. It has a very poor prognosis.

Carcinoma of the oesophagus

Cancer of the oesophagus is the ninth most common cancer in the world. It is in general a disease of mid to late adult-hood with a poor survival rate. Only 5—10 per cent of those diagnosed will survive for 5 years. Despite this gloomy prognosis there are some encouraging signs of change.

Pathology and aetiology. Squamous cell cancer (Figs 50.47 and 50.48) and adenocarcinoma (Figs 50.49 and 50.50) are the commonest types. Squamous cell carcinoma usually affects the upper two-thirds of the oesophagus and adenocarcinoma affects the lower one-third, but there are frequent exceptions to this rule. Oat cell cancer occurs occasionally. World-wide, it is squamous cell cancer that is commonest, but adenocarcinoma is the commonest type in most westernised countries and is increasing in incidence.

Geographical variation of oesophageal cancer

The incidence of oesophageal cancer varies more than any other cancer and its epidemiology provides a fascinating story. Squamous cell cancer is endemic in the Transkei region of South Africa and in the Asian 'cancer belt' that extends across the middle of Asia from the shores of the Caspian Sea in northern Iran to China. The highest incidence in the world is in Linxian in Henan province in China where it is the commonest single cause of death with more than 100 per 100 000 population per annum. The cause of the disease in the endemic areas is not definitely known, but is probably due to a combination of fungal contamination of food with the production of a carcinogenic mycotoxin, together with nutritional deficiencies in the population. In Linxian, supplementation of the diet with beta-carotene, vitamin E and selenium has been shown to reduce the incidence of cancer.

Away from the endemic areas tobacco and alcohol are the major factors in the occurrence of squamous cancer. Incidence rates vary from less than five per 100 000 in whites in the USA to 26.5 per 100 000 in some regions of France. Contrary to popular opinion Japan does not have a particularly high incidence of oesophageal cancer.

The incidence of adenocarcinoma of the oesophagus is increasing

In many westernised countries the incidence of squamous cell cancer has fallen or remained relatively static, but the incidence of adenocarcinoma of the oesophagus has increased since the mid-1970s by 5—10 per cent per annum. The change is greater than that of any other neoplasm in this time. Adenocarcinoma now accounts for 60—75 per cent of all oesophageal cancers in several countries. The reason for the change is not understood, but is thought to be due to a changed incidence of Barrett’s oesophagus. There has been a similar increase in the incidence of carcinoma of the cardia of the stomach. This epidemiological change suggests that cancer of the cardia and adenocarcinoma of the oesophagus are, in fact, the same disease. The incidence of cancer of the gastric antrum has decreased markedly over the same period and now more than 60 per cent of all upper GI cancers involve the cardia or distal oesophagus. Survival rates remain poor although in some regions of the UK there has been a modest improvement in 5-year survival from 5 per cent to 10 per cent.

Involvement of coeliac axis nodes is a bad prognostic sign

The poor prognosis of oesophageal cancer is proof of its ability to spread. This may be locoregional or systemic. Locoregional spread occurs through the wall of the oesophagus into adjacent structures, along the length of the oesophagus in the submucosal lymphatics, and to regional lymph nodes. Locoregional spread is often discontinuous, i.e. distant regional lymph nodes may be invaded even when local nodes are free of tumour, and there may be satellite nodules in the oesophagus proximal to the main tumour. Spread to the coeliac axis nodes from a lesion in regions of the UK there has been a modest improvement in 5-year survival from 5 per cent to 10 per cent.

Early endoscopic diagnosis is the key to good results

Clinical features. Dysphagia is the usual presenting feature and is generally a sign of advanced disease. Weight loss is likewise a sign of advanced disease. An increasing number of cancers is diagnosed at a relatively early stage when the chances of cure are greater. Patients with early disease may present with rather nonspecific dyspeptic symptoms or a vague feeling of 'something that is not quite right' during swallowing. Some are diagnosed during screening of Barrett's oesophagus, but it has to be confessed that the results of formal screening are still disappointing. The widespread use of endoscopy as a diagnostic tool is the major contributor to early diagnosis (Fig. 50.51). It should be emphasised that biopsies should be taken of all lesions (Fig. 50.52) no matter how trivial they appear. Small cancers are curable. Large ones usually are not. Some benign lesions can look surprisingly 'malignant' (Fig. 50.53).

Hoarseness due to recurrent laryngeal nerve palsy is a sign of advanced and incurable disease. Palpable lymphadenopathy in the neck is likewise a sign of advanced disease.

Staging and general assessment. Methodical assessment of the patient and the cancer is essential if the best results are to be achieved. Some patients are quite obviously not candidates for radical treatment even on the most superficial inspection and common humanity must always take precedence. Staging must not delay effective palliation.
The most important aspect of staging is a careful search for metastatic disease. Ultrasonography of the liver and comput-erised tomography (CT) scanning of the chest and abdomen is mandatory before resection. The purpose of CT scanning is to exclude metastatic disease from the lungs and liver. Despite considerable improvements in CT and magnetic resonance imaging these methods are still inaccurate for staging the primary lesion and for staging lymph nodes. Endoscopic ultrasonography, if available, is the best method for preoperative staging of oesophageal cancer. Bronchoscopy should be done in lesions of the upper or middle thirds where there is potential for tracheobronchial invasion (Fig. 50.54). Laparoscopy is useful for assessing adenocarcinoma of the distal oesophagus (Fig. 50.55), particularly if it is likely to extend below the phreno-oesophageal ligament. Laparoscopy is at its best for detecting transperitoneal spread and liver metastasis. It is an inexpensive technology that deserves to be widely used. At the cost of some time and effort it is also possible to sample lymph nodes.

Short-term nutritional support has doubtful benefits

It is also important to assess the fitness of the patient to withstand major surgery. Respiratory and cardiovascular function are the most important aspects of the assessment. Nutritional assessment is also an important part of general care, but the value of preoperative nutritional support remains somewhat controversial. It is not possible to post-pone treatment for several weeks to allow full nutritional ‘resuscitation’ and short periods of nutritional support are of questionable benefit for reducing postoperative morbidity and mortality. If food intake is impaired the simplest means of providing adequate nutrition is by withdrawing all solid food and starting the patient on a high-protein liquid diet. It is surprising how much severe dysphagia improves when obstructing food material in the oesophagus has been cleared.

Treatment of malignant tumours

Principles

A gastrostomy should never be carried out as the ‘palliation’ for oesophageal cancer. Palliation in this disease demands relief of dysphagia. It is important that staging and general assessment are carried out speedily and humanely. Those who have incurable disease should not be submitted to needlessly aggressive treatment that simply prolongs the process of dying. Palliation of dysphagia can be achieved in a number of ways that do not unduly stress the patient. Pain is also a surprisingly common feature of advanced oesophageal cancer and requires careful attention.

Curative treatment involves radical surgery or radiotherapy. This should be carried out in a specialist centre with the necessary expertise. The role of palliative resection is debatable. It is wise not to embark on resection if it is clear beforehand that palliation is all that can be achieved. However, palliative resection may be appropriate if incurable disease is found when an operation is already well under way.

Surgical resection probably gives the best results for all forms of oesophageal cancer. Radical radiotherapy can cure both types of cancer, but poses technical problems at the lower end of the oesophagus. Tumours that involve the stomach are not generally accepted for radiotherapy. The results of radiotherapy have been improved by concurrent chemotherapy, so-called chemoradiotherapy. Some have suggested that this development may challenge the dominant place of surgery for cure.

Surgery

Beware of satellite nodules proximal to the primary lesion

Curative surgery involves resection of an appropriate length of the oesophagus together with any involved stomach and the locoregional lymphatics. There is controversy about the length of oesophagus that should be resected. Some surgeons feel that operative trauma should be reduced to the minimum by resecting only enough oesophagus to clear the tumour. Others advocate subtotal oesophagectomy pioneered in the UK by McKeown on the grounds that generous proximal clearance gives the best chance of clearing satellite nodules in the submucosal lymphatics and gives the best postoperative function with the least tendency to gastro-oesophageal reflux. Restoration of continuity is almost always achieved by transposition of the stomach and oesophago-gastric anastomosis. Colon or, less commonly, small intestine may be inter-posed between the oesophageal remnant and the stomach, but is a more major undertaking with a higher postoperative mortality. There is also controversy about the extent of lymph node dissection that should be done. Akiyama has pioneered the concept of three field lymph node dissection, an ultraradical operation involving extensive removal of the regional lymph nodes in the abdomen, chest and neck.

Lesions of the cardia that do not involve the oesophagus to any significant extent may be dealt with by extended total gastrectomy to include the distal oesophagus or by proximal gastrectomy and distal oesophagectomy.

Subtotal oesophagectomy. A variety of approaches is pos-sible. The most commonly used is the Ivor Lewis (or. Lewis—Tanner) approach. The stomach is first mobilised through a midline incision and then the oesophagus is approached from a right thoracotomy (Fig. 50.56). This approach is preferred by most surgeons because the access for resection and anastomosis is not hampered by the aortic arch as it is through a left thoracotomy. In the classic McKeown operation a third incision is made in the neck. However, in practice it is possible to remove just as much oesophagus by dividing the oesophagus in the chest at the thoracic inlet. A neck incision is required if a lymph node dissection is to be done or if there are technical difficulties with an anastomosis at the thoracic inlet. It is often stated that an oesophagogastric anastomosis is safest when done in the neck. In fact this only applies to an anastomosis that lies in the anterior part of the neck as for reconstruction with stomach or colon that has been brought up retrosternally or subcutaneously. The usual oesophagogastric anastomosis in the posterior neck drops back into its normal anatomical position and usually lies at the thoracic inlet. Any leak therefore has consequences that are just as serious as any other intrathoracic anastomosis.

Carefully preserve the blood supply of the stomach — venous and arterial

Mobilisation of the stomach must be done with care as it is essential to have a tension-free, well-vascularised stomach for transposition. The left gastric artery, the short gastric vessels and the left gastroepiploic are all divided. The viability of the transposed stomach mainly depends on the right gastroepiploic artery and vein with a small contribution from the right gastric. It should be noted that venousdrainage is as important as arterial supply and it is essential to perform an accurate anatomical dissection that preserves the right gastroepiploic vein as well as the artery. The stomach is divided to remove the cardia and the upper part of the lesser curve including the whole of the left gastric artery and its associated lymph nodes.

Right thoracic approach gives easy access to the oesophagus

The approach to the oesophagus through the right chest is relatively straightforward. The azygos vein is divided and this allows easy access to the whole of the intrathoracic oesophagus. A thoracotomy with entry above the fifth rib gives best access to the mid-mediastinum and the thoracic inlet. The oesophagus is divided just below the thoracic inlet. Since most lesions are in the lower third or middle third this usually gives adequate proximal clearance of at least 5 cm. If there is any doubt about clearance frozen sections should be taken from the resection margins and it may be helpful to open the oesophagus and assess whether the lesion is well circumscribed or whether it is diffusely infiltrating.
Carcinomas of the upper thoracic oesophagus are almost always incurable at the time of diagnosis and invasion of the trachea is common. If one of these lesions is resectable it is essential to use an incision in the neck and to resect more of the oesophagus than is customary in the operation of subtotal oesophagectomy.

**Oesophagogastric anastomosis** may be performed equally well by hand or stapler. Both methods require attention to detail. In experienced hands serious anastomotic leakage should be uncommon (significantly less than 5 per cent). Minor leakage detectable by contrast radiology is more common, but should not disturb the patient. The significance of these minor leaks is debated. Most surgeons still prefer to keep the patient nil by mouth for 5—7 days and then perform a contrast swallow if small leaks are to be detected it is essential to use barium for the examination. Water-soluble contrast media miss 50 per cent of anastomotic leaks. If leakage is detected the patient is kept nil by mouth until it has sealed.

Postoperative nutritional support remains controversial. There is general agreement that parenteral feeding is associated with more nosocomial infection, including pneumonia, than enteral feeding. It is also expensive. If nutritional support is given a feeding jejunostomy is probably the best method.

**Transhiatal oesophagectomy** (without thoracotomy). This approach has been popularised by Orringer in the USA and Pinotti in Brazil. The stomach is mobilised through a midline abdominal incision and the cervical oesophagus is mobilised through an incision in the neck. The diaphragm is then opened from the abdomen and the posterior mediastinum is entered. The lower oesophagus and the tumour are mobilised under direct vision and the upper oesophagus is mobilised by blunt dissection. This approach can provide an adequate removal of the tumour and lymph nodes in the lower mediastinum, but it is not possible to remove the nodes in the mid or upper mediastinum. It may be a useful procedure for lesions of the lower oesophagus, but may be hazardous for a middle third lesion that may be adherent to the bronchus or to the azygos vein.

**Left thoracoabdominal approach.** A long skin and muscle incision is made on the left side with entry into the chest above the seventh rib and removal of a short segment of costal cartilage (Fig. 50.56). The diaphragm is incised and the oesophagus and stomach are removed. Some surgeons advocate a left thoracoabdominal approach together with an incision in the neck for subtotal oesophagectomy, the ‘Birmingham’ approach popularised by Matthews.

**Thoracoscopy.** Oesophagectomy may be done by thoracoscopy or by the hybrid technique of video-assisted thoracic surgery (VATS) in which a combination of endoscopic and conventional instruments is used through small thoracic incisions. Thoracoscopic oesophagectomy in the prone position to minimise injury to the collapsed lung has been pioneered by Cuschieri. At present this is still an evolving technique and its place is not yet established. The procedure takes longer than open surgery and postoperative morbidity is still a problem.

Gastro-oesophageal reflux following oesophagogastric resection. Gastro-oesophageal reflux may be a major problem following any operation that involves resecting the cardia. Postoperative reflux may present with the typical symptoms of GORD or with a peptic stricture at the site of the anastomosis. However, the presentation may be different with a miserable patient who fails to thrive following the operation and who is then suspected of having recurrent cancer. This atypical presentation is particularly common following total gastrectomy with an inadequate reconstruction.

Reflex may be a problem following resection

**Symptoms may be atypical**

Reflex may be limited or avoided by:

1. subtotal oesophagectomy and gastric transposition high in the chest. The vertical stomach empties rapidly and functions as a barrier to reflux;
2. resection of a generous portion of proximal stomach if an anastomosis is made to the lower oesophagus. This reduces gastric secretion;
3. Roux-en-Y reconstruction with a long ascending jejunal limb (5 0—60 cm);
4. interposition of jejunum or colon (Fig. 50.57).

The old Braun or omega reconstruction with an enterointerostomalastomosis below an oesophageojunostomy is mentioned only to be condemned. The side-to-side anastomosis does not divert bile and pancreatic secretion satisfactorily from the oesophagus and several studies have shown that these patients fare badly.

Pyloroplasty. Pyloroplasty or pyloromyotomy is an option following oesophageal resection. It may avoid early problems with gastric emptying, but the stomach always seems to recover its function even without pyloroplasty. If delayed gastric emptying is a problem in the early postoperative period erythromycin, which is a motilin agonist, seems to be the best therapy.

**Radiotherapy for cure**

**Radiotherapy may be a useful alternative to surgery, especially in unfit patients**

Radical radiotherapy can produce long-term survival in oesophageal cancer (Fig. 50.58). Although traditionally used for squamous cell cancer radiotherapy may also be effective for adenocarcinomas. There has been no formal comparison of the results of radiotherapy and surgical resection and it is therefore impossible to make dogmatic statements about the relative merits of each form of treatment. At present surgical resection is generally regarded as producing the best survival rates and quality of life. Many surgical series have reported 5-year survival rates between 20 per cent and 35 per cent, with an average figure of 25 per cent. Survival following radiotherapy with a typical UK case mix is between 9 per cent and, exceptionally, 19 per cent. The average appears to be about 10 per cent. However, the technology of radiotherapy continues to improve and the advent of chemoradiotherapy is a significant advance, if at the cost of significant morbidity. The survival figures make it abundantly clear that neither surgery nor radiotherapy is a particularly effective treatment. There is therefore a real need for improvements in early diagnosis, at present the best hope of improving survival, and improvements in treatment with the use of multimodality treatment.

**Chemotherapy**

With the advent of regimens containing cis-platinum, chemo-therapy for oesophageal cancer has improved considerably. Chemotherapy never cures the disease, but can produce worthwhile shrinkage of disease in up to 60 per cent of cases. The best responses are seen in squamous
Multimodality treatment

Randomised prospective studies of preoperative and post-operative radiotherapy have not shown any improvement in survival. Thus far there is no evidence that perioperative chemotherapy improves survival, but the results of studies using modern combination chemotherapy are awaited. Significant improvement in survival will only be achieved by a treatment that has a powerful effect on systemic disease.

Palliative treatment

Surgical resection and external beam radiotherapy may be used for palliation, but are not suitable when the expected survival is short, as most of the remainder of life will be spent recovering from the ‘treatment’. Surgical bypass is likewise too major a procedure for use in a patient with a limited life expectancy. A wide variety of relatively simple methods of palliation is now available that will produce worthwhile relief of dysphagia with minimal disturbance to the patient.

Palliation should be simple and effective

Intubation has been used for many years following the invention of the Souttar tube made of coiled silver wire (Fig. 50.59). This was superseded by the Celestin tube whose design gave a better quality of swallowing and was safer to insert. The Celestin tube was originally designed to be inserted by oesophagoscopy, to place a plastic rod in the stomach, followed by laparotomy and gastrostomy, to retrieve the rod and pull the tube down into place. The development of methods of intubation that could be used with a flexible endoscope was a major advance pioneered by Atkinson of Nottingham. The Atkinson tube is still in use. It is made of silastic with a nylon spiral reinforcement and has a distal retaining flange to prevent proximal displacement. It is inserted over a guidewire with a specially designed introducer. There are now many other designs of semi rigid tubes for palliation including the Procter—Livingstone tube which is popular in South Africa where there is a very high incidence of oesophageal cancer.

The technology of intubation has now moved on with the invention of various types of expanding metal stent (Fig. 50.60). These are inserted under X-ray or endoscopic control. The stent is restrained in the collapsed state during insertion and then released when it is in the correct position. Expanding stents produce a better lumen for swallowing than rigid tubes, but are relatively expensive.

Endoscopic laser treatment may be used to core a channel through the tumour. It produces worthwhile improvement in swallowing, but has the disadvantage that it has to be repeated every few weeks. Lasers may also be used to un-block a stent that has been blocked by tumour overgrowth.

Brachytherapy is a method of delivering intraluminal radiation with a short penetration distance (hence the term brachy) to a tumour. An introduction system is inserted through the tumour and the treatment is then delivered in a single session lasting for 20 minutes or so. The equipment is expensive to purchase, but running costs are low.

Other methods of palliation that can be given endoscopically include bipolar diathermy (the BICAP probe), argon beam plasma coagulation and alcohol injection.

Malignant tracheo-oesophageal fistula

Malignant tracheo-oesophageal fistula is a sign of incurable disease and life expectancy is short. Some have advocated surgical bypass and oesophageal exclusion, but this is a major procedure. An expanding metal stent is probably the best treatment, but semi rigid prosthetic tubes may also be used (Fig. 50.61).

Postcricoid carcinoma

Postcricoid carcinoma is considered in the section on neoplasms of the pharynx (Chapter 43).
**Motility disorders and diverticula**

**Oesophageal motility disorders**

**Motility disorders may affect the whole gut** An oesophageal motility disorder can be readily understood when a patient has dysphagia in the absence of a stricture; a barium impregnated food bolus is seen to stick in the oesophagus and oesophageal manometry shows abnormal contractions in the oesophagus. The problem with oesophageal motility disorders is that the symptoms often seem disproportionately severe in comparison to the abnormality that can be demonstrated by objective investigation and the response to treatment may be so poor that the clinician is driven to questioning the very existence of motility disorders. The greatest difficulty arises when pain is the only symptom. Since surgery is advocated as a treatment for some motility disorders it is essential that the surgeon understands the nature of the condition. Much harm may be done by inappropriate enthusiastic surgery for ill defined conditions. It should also be remembered that there may be a general disturbance of GI function. It is convenient to classify oesophageal motility disorders as in Table 50.2.

**Pain in functional gastrointestinal disorders**

Pain that is assumed to arise from dysfunction of the GI tract has three components, namely, abnormal motility and ‘spasm’, visceral hypersensitivity in which the gut is relatively intolerant of distension, and psychosocial factors. All three components are still poorly understood and it is therefore impossible to give dogmatic guidelines for treatment. Dealing with these conditions involves more art than science, but scientific understanding is slowly increasing.

**Achalasia**

**Pathology and aetiology**

Selective loss of inhibitory neurons in achalasiaAchalasia is uncommon, but merits prominence because it is reasonably well understood and responds well to treatment. It is due to loss of the ganglion cells in Auerbach’s plexus. The cause of the ganglion cell loss is unknown, but may be due to neurotropic viruses such as Varicella zoster. In South America chronic infection with the parasite Trypanosoma Cruzi causes Chagas’ disease which has marked similarities to achalasia. Achalasia differs from Hirschsprung’s disease of the colon because the dilated oesophagus usually contains few ganglion cells, whereas the dilated colon contains normal ganglion cells proximal to a constricted a-ganglionic segment. Histology of muscle specimens shows reduction of ganglion cells with a variable degree of chronic inflammation. In so called vigorous achalasia, which may be an early stage of achalasia, there is inflammation and neural fibrosis, but nor-mal numbers of ganglion cells. The neural damage in achalasia is somewhat selective since there is particularly severe loss of inhibitory neurons. The observation of selective loss of inhibitory innervation prompted the first attempts at treat-ment with botulinum toxin (see below). The term achalasia is derived from the Greek word (chakos) which means failure to relax and was coined by Sir Arthur Hurst in 1910. The physiological abnormalities are incomplete or absent relaxation of the lower oesophageal sphincter and absent peristalsis in the body of the oesophagus. The oesophagus empties incompletely, almost always containing residual food and fluid. There is no gas bubble in the stomach because no bolus with its accompanying normal gas bubble ever passes through the sphincter. The oesophagus becomes dilated (‘mega esophagus’) and tortuous with a persistent retention oeso-phagitis due to fermentation of food residues (Fig. 50.62). There is an increased incidence of carcinoma of the oesophagus in patients with achalasia.

**Beware pseudoachalasia**

**Look for tumour**

**Pseudoachalasia** is an achalasia-like disorder which is usually produced by adenocarcinoma of the cardia (Fig. 50.63) and sometimes also by cancers outside the oesophagus such as bronchogenic cancer, especially oat cell cancer, and pancreatic cancer.

**Clinical features**

The disease is commonest in middle life, but can occur at any age. It typically presents with dysphagia. In patients who have remained untreated for many years regurgitation is frequent and there may be overspill into the trachea, especially at night. In the early stages achalasia may present with retrosternal discomfort and this may lead to a mistaken diagnosis of GORD.

**Diagnosis**

Achalasia may be suspected at endoscopy by finding a tight cardia and food residue in the oesophagus. Barium radiology may show hold-up in the distal oesophagus, peristaltic dys-function and a tapering stricture in the distal oesophagus often described as a bird’s beak (Fig. 50.62). The gastric gas bubble is usually absent. However, these typical features of well-developed achalasia are often absent, and endoscopy and radiology are often normal. The barium meal may even be reported as showing gastro-oesophageal reflex. A firm diagnosis can only be made by oesophageal manometry. Classically there is a hypertensive lower oesophageal sphincter that does not relax completely on swallowing, a-peristalsis of the oesophageal body and a raised resting pressure in the oesophagus (Fig. 50.64). In practice the LOS pressure is often normal.

**Treatment**

Alone among motility disorders achalasia responds well to treatment. The two main methods are forceful dilatation of the cardia and Heller’s myotomy.

**Beware perforation**

**Forceful dilatation.** This involves stretching the cardia with a balloon to disrupt the muscle and render it less competent. The treatment was first described in the Mayo Clinic by Plummer. Many varieties of balloon have been available in the past, but nowadays plastic balloons with a precisely controlled external diameter are used. If the pressure in the balloon is too high the balloon is designed to split along its length rather than expanding further. Balloons of 30—40 mm diameter are available and are inserted over a guide wire (Fig. 50.65). Perforation is the major complication. With a 30-mm balloon the incidence of perforation should be less than 0.5 per cent. The risk of perforation increases with the bigger balloons and they should be used cautiously for progressive dilatation over a period of weeks. Forceful dilatation is curative in 75—85 per cent of cases. The results are best in patients aged more than 45 years.

**Beware postoperative reflux**

**Heller’s myotomy.** This involves cutting the muscle of the lower oesophagus and cardia (Fig. 50.66). The major complication is gastro-oesophageal reflux. Reflux may be avoided by limiting the incision to the lower oesophagus and not more than 1 cm of the stomach. If
the myotomy is carried further on to the stomach a prophylactic antireflux operation should be done. It is customary to perform a partial rather than a total fundoplication in this situation because of the risk of causing dysphagia in the presence of an 'a-peristaltic oesophagus. However, a total fundoplication may be done provided that great care is taken to produce a very short and floppy fundoplication that does not cause obstruction. The proximal extent of the myotomy does not seem to matter provided that the obstructing segment is divided.

      Heller's myotomy is ideally suited to a minimal access approach by either thoracoscopy or laparoscopy. It is successful in more than 90 per cent of cases and may be used after failed myotomy.

      Botulinum toxin. This may be given by endoscopic injection into the LOS. This is a new form of treatment whose place is not yet established. It acts by interfering with cholinergic excitatory neural activity at the LOS.

      Drugs. Drugs, such as calcium channel antagonists, have been used but are ineffective for long-term use. Sublingual nifedipine may, however, be useful for transient relief of symptoms if definitive treatment has to be postponed.

Other oesophageal motility disorders

Disorders of the pharyngo-oesophageal junction

These are for the most part neurological disorders and surgery has very little place in their management. Rarely, cricopharyngeal myotomy may be performed to reduce dysphagia in a myopathy affecting the pharyngeal muscles. For this to be successful there must be some preserved contraction of the pharynx and a stable neurological condition.

Cricopharyngeal 'achalasia' is a condition in which the upper oesophageal sphincter does not open adequately during swallowing. A cricopharyngeal 'bar' may be visible on a barium swallow. The disorder is probably caused by denervation of the cricopharyngeal muscle with consequent loss of elasticity. The condition is rare, but responds well to crico-pharyngeal myotomy. A similar abnormality of the cricopharyngeal muscle occurs in Zenker's diverticulum (see below).

Disorders of the body of the oesophagus

Diffuse oesophageal spasm is a condition in which there are incoordinate contractions of the oesophagus causing dysphagia and chest pain. The condition may be dramatic with spastic pressures on manometry of 400—500 mmHg, marked hypertrophy of the circular muscle and a corkscrew oesophagus on barium swallow (Fig. 50.67). If chest pain is the only symptom and the abnormality is not particularly dramatic it may be difficult to be sure that the disorder is the cause of the pain and not an epiphenomenon. Prolonged ambulatory oesophageal manometry with a detailed record of the timing of episodes of chest pain may help to make a diagnosis.

Dysphagia due to diffuse spasm may respond to forceful dilatation of the cardia, but the results are not as predictable as in achalasia. In very severe cases extended oesophageal myotomy up to the aortic arch may be required. Surgical treatment of diffuse spasm is more successful in improving dysphagia than chest pain and caution should be exercised in patients in whom chest pain is the only symptom.

Nutcracker oesophagus is a condition in which peristaltic pressures greater than 180 mmHg are developed. It is said to cause chest pain, but there is still some debate as to whether it is a real disorder.

Hypoperistalsis of the oesophagus occurs in the CREST variant of systemic sclerosis (Fig. 50.68). It is severe GORD and sometimes for no obvious cause. Simultaneous oesophageal manometry and radiological studies have shown that a peristaltic pressure of about 30 mmHg is required to propel a bolus down the oesophagus. Peristaltic failure may cause dysphagia in its own right, but can also increase dysphagia if there is any organic obstruction. This is common in the CREST syndrome in which reflux is common as a result of the weak muscle in the lower oesophagus and even the most subtle peptic stricture causes severe dysphagia. Treatment aims at excluding organic obstruction and trying to improve the force of peristalsis with prokinetic agents such as cisapride. However, once peristaltic failure occurs it is usually irreversible.

When GORD and dysmotility occur together it is best to treat the reflux and ignore the dysmotility. It is commonly held that weak peristalsis is a contraindication to total fundoplication, but the author has not found this to be the case provided that care is taken with the construction of the fundoplication.

Eosinophilic oesophagitis is a distinct pathological entity described in patients who have intermittent dysphagia without GORD and without anatomical obstruction. Episodes of dysphagia may be severe and painful with bolus obstruction. Between episodes swallowing may be completely normal. Endoscopic biopsies show a dense eosinophilic infiltrate, sug-gestng an allergic response, but no allergens have been identified. Treatment is with antihistamines, sodium chromoglycate or steroids.

Hypertensive lower oesophageal sphincter is defined as an LOS pressure greater than 45 mmHg with normal relaxation during swallowing. It is said to be associated with chest pain and dysphagia.

Oesophageal diverticula

Most oesophageal diverticula are pulsion diverticula that develop at a site of weakness as a result of chronic pressure against an obstruction. The symptoms are mostly caused by the underlying disorder unless the diverticulum is particularly large. Traction diverticula (Fig. 50.69) are much less common. They are mostly a consequence of chronic granulo-matous disease affecting the tracheobronchial lymph nodes due to tuberculosis, atypical mycobacteria or histoplasmosis. Fibrotic healing of the lymph nodes exerts traction on the oesophageal wall and produces a focal outpouching that is usually small and has a conical shape. There may be associated broncholithiasis and additional complications may occur such as oesophagobronchial fistulation (Fig. 50.70) and bleeding.

      Zenker's diverticulum (pharyngeal pouch) is not really an oesophageal diverticulum as it protrudes posteriorly above the cricopharyngeal sphincter through the natural weak point between the oblique and horizontal fibres of the inferior pharyngeal constrictor (Figs 50.71 and 50.72).

      Never-theless it is the commonest diverticulum affecting the region of the oesophagus. The underlying abnormality is the same as in cricopharyngeal achalasia. The diverticulum may be large and extend into the posterior mediastinum. Treatment is always necessary sooner or later. The optimum treatment is excision of the diverticulum combined with cricopharyngeal myotomy to deal with the underlying obstruction. In frail patients or those who decline formal operation an endoscopic linear cutting staple gun may be inserted through the mouth and fired to divide the septum between the diverticulum and the upper oesophagus producing a diverticulo-oesophagostomy.

Excision and myotomy for Zenker's diverticulum

Mid-oesophageal diverticula are usually small pulsion diverticula of no particular consequence. The underlying motility disorder does not
usually require treatment. The exception to this rule is in areas of the world in which granulomatous diseases of the mediastinum are common, such as parts of the USA, where the possibility of a traction diverticulum should be considered. Some pulsion diverticula may fistulate into the trachea (Fig. 50.70), but this is much more common in granulomatous disease.

Epiphrenic diverticula are situated in the lower oesophagus above the diaphragm (Fig. 50.73). They may be quite large, but cause surprisingly few symptoms. If surgical treatment is required the precise cause of the symptoms, such as GORD, must be defined and corrected at the same time. The diverticulum cannot be assumed to account for the patient’s illness just because it looks dramatic on an X-ray. Large diverticula may be excised and it is usual to perform a myotomy from the site of the diverticulum down to the cardia to relieve the functional obstruction and to reduce the risk of dehiscence of the suture line in the oesophagus.

**The diverticulum may not be the cause of the symptoms**

Diffuse intramural pseudodiverticulosis is a rare condition in which there are multiple tiny outpouching from the lumen of the oesophagus. The pseudodiverticula are dilated excretory ducts of oesophageal sebaceous glands. It is questionable whether the condition produces any symptoms in its own right.
Other non-neoplastic conditions

Schatzki’s ring

Schatzki’s ring is a circular ring in the distal oesophagus (Fig. 50.74) usually at the squamocolumnar junction. The cause is obscure. The core of the ring consists of variable amounts of fibrous tissue and cellular infiltrate. Most rings are incidental findings on barium examination. Some are associated with dysphagia and a single dilatation is curative.

Monilial oesophagitis

Oesophagitis due to Candida albicans is relatively common in patients taking steroids, including steroid inhalers for asthma. It may present with dysphagia or odynophagia. There may be visible thrush in the throat. Endoscopy shows numerous white plaques that cannot be moved, unlike food residues (Fig. 50.75). Biopsies are diagnostic. In severe cases a barium swallow may show dramatic mucosal ulceration and irregularity that is surprisingly similar to the appearance of oesophageal varices (Figs 50.76 and 50.77). Treatment is with nystatin lozenges or other antifungal agents.

Acquired immunodeficiency syndrome (AIDS) and the oesophagus

Dysphagia and odynophagia may occur in immune deficiency due to infection with a variety of agents including Candida, herpes simplex virus and cytomegalovirus. Similar infections may arise in immune suppression due to any other cause.

Crohn’s disease

The oesophagus is not commonly affected by Crohn’s dis-ease. Rarely, it may be the only site of Crohn’s disease. When it occurs symptoms are severe and may be mistaken for un-usually severe reflux oesophagitis with retrosternal pain and dysphagia. Endoscopy shows extensive oesophagitis that extends much further proximally than is the case with reflux oesophagitis. Biopsies may be diagnostic, but may show only nonspecific inflammation. In severe cases a barium swallow may show deep sinuses in the oesophagus. Crohn’s oeso-phagitis responds poorly to medical treatment and resection may be required. Reconstruction can be a challenging problem in a patient with widespread Crohn’s disease at other sites.

Plummer—Vinson syndrome

Also called the Brown Kelly—Paterson syndrome or sideropenic dysphagia, this may be a pathological relic. The original descriptions are vague and poorly supported by evidence of a coherent syndrome. They describe young women with iron deficiency anaemia and dysphagia referred high in the neck. The dysphagia was said to be caused by spasm or a web in the postcricoid area. The patients were said to have an increased tendency to postcricoid cancer.

Webs certainly occur in the upper oesophagus (Fig. 50.78), but their connection with any particular syndrome is questionable. The pathology is uncertain. More recently it has been noted that there is often a patch of heterotopic gastric mucosa in the upper oesophagus. It is probably congenital and may be seen in up to 4 per cent of endoscopic examinations. Most are small, less than 1 cm², and are easily missed. Occasional complications have been reported, such as ulceration, stricture and adenocarcinoma. Perhaps the Plummer—Vinson syndrome is a case of mistaken identity.

Surgical anatomy

Introduction

The function of the stomach is to act as a reservoir for ingested food. It also serves to break down foodstuffs mechanically and commence the processes of digestion before these products are passed on into the duodenum. The surgical anatomy must be viewed in this context.

Blood supply

Arterial supply

The stomach is richly endowed with an arterial supply on both lesser and great curves (Fig. 51.1). On the lesser curve the left gastric artery, a branch of the coeliac axis, forms an anastomotic arcade with the right gastric artery which arises from the common hepatic artery. Branches of the left gastric artery pass up towards the cardia. The gastroduodenal artery, which is also a branch of the hepatic artery, passes behind the first part of the duodenum, highly relevant with respect to the bleeding duodenal ulcer. Here it divides into the superior pancreaticoduodenal artery and the right gastroepiploic artery. The superior pancreaticoduodenal artery supplies the duodenum and pancreatic head, and forms an anastomosis with the inferior pancreaticoduodenal artery, a branch of the superior mesenteric artery. The right gastroepiploic artery runs along the greater curvature of the stomach eventually forming an anastomosis with the left gastroepiploic artery, a branch of the splenic artery. This vascular arcade, however, is often variably incomplete. The fundus of the stomach is supplied by the vasa brevia (or short gastric arteries) which arise from near the termination of the splenic artery.

Veins

In general the veins are equivalent to the arteries, those along the lesser curve ending in the portal vein and those on the greater curve joining via the splenic vein. On the lesser curve the coronary vein is particularly important. It runs up the lesser curve towards the oesophagus and then passes left to right to join the portal vein. This vein becomes markedly dilated in portal hypertension.

Lymphatics

The lymphatics of the stomach are of considerable importance in the surgery of gastric cancer and are therefore described in detail in that section (later).

Innervation

As with all of the gastrointestinal tract, the stomach and duodenum possess both intrinsic and extrinsic nerve supplies. The intrinsic nerves exist principally in two plexuses, the myenteric plexus of Auerbach and the submucosal plexus of Meissner. Compared with the rest of the gut the submucosal plexus of the stomach contains relatively few ganglionic cells as does the myenteric plexus in the fundus. However, in the antrum the ganglia of the myenteric plexus are well developed. The extrinsic supply is derived mainly from the vagus nerves, fibres of which originate in the brainstem. The vagal plexus around the oesophagus condenses into bundles which pass through the oesophageal hiatus (Fig. 51.2), the posterior bundle being usually identifiable as a large nerve trunk. Vagal fibres are both afferent (sensory) and efferent. The efferent fibres are involved in the receptive relaxation of the stomach and the stimulation of gastric motility, as well as the well-known secretory function. The sympathetic supply is derived mainly from the coeliac ganglia.
Histological anatomy of the stomach and duodenum

Stomach

The gastric epithelial cells are mucous producing and are turned over rapidly. In the pyloric part of the stomach and also the duodenum mucus-secreting glands are found. Most of the specialised cells of the stomach (parietal and chief cells) are found in the gastric crypts (Fig. 51.3). The stomach is also richly endowed with endocrine cells.

Parietal cells

These are in the body (acid-secreting portion) of the stomach and line the gastric crypts, more abundant distally. These are responsible for the production of hydrogen ions to form hydrochloric acid, which has a pH of around 1. The hydrogen ions are actively pumped by the proton pump, a hydrogen—potassium ATPase (Sachs) which exchanges intraluminal potassium for hydrogen ions. The potassium ions enter the lumen of the crypts passively but the hydrogen ions are pumped against an immense concentration gradient (1 000 000:1), explaining the fact that this is an energy-consuming process.

Chief cells

These lie principally proximally in the gastric crypts and produce pepsinogen. Two forms of pepsinogen are described: pepsinogen I and pepsinogen II. Both are produced by the chief cell but pepsinogen I is produced only in the stomach. The ratio between pepsinogens I and II in the serum decreases with gastric atrophy, and this has been investigated as a means of selecting patients who are at higher risk of suffering from gastric cancer for screening. Pepsinogen is activated in the stomach to produce pepsin, the active enzyme.

Endocrine cells

The stomach is richly endowed with endocrine cells, which are critical to its function. In the gastric antrum the mucosa contains G cells which produce gastrin. Throughout the body of the stomach enterochromatin-like (ECL) cells are abundant and produce histamine, a key factor in gastric acid secretion. In addition, there are large numbers of somatostatin-producing D cells throughout the stomach, and somatostatin has a negative regulatory role. The peptides and neuropeptides produced in the stomach are discussed later.

Duodenum

The duodenum is lined by a mucus-secreting columnar epithelium. In addition, Brunner’s glands lie beneath the mucosa and are similar to the pyloric glands in the pyloric part of the stomach. Endocrine cells in duodenum produce cholecystokinin and secretin.
Physiology of the stomach and duodenum

Introduction

The stomach mechanically breaks up ingested food and, together with the actions of acid and pepsin, forms chyme that passes into the duodenum. In contrast to the acidic environment of the stomach, that of the duodenum is alkaline, as a result of the secretion of bicarbonate ions from both the pancreas and the duodenum. This neutralises the acid chyme and adjusts the osmolality to approximately that of plasma. Endocrine cells in the duodenum produce cholecystokinin that stimulates the pancreas to produce trypsin and the gall bladder to contract. Secretin is also produced by the endocrine cells of the duodenum. This hormone inhibits gastric acid secretion and promotes production of bicarbonate by the pancreas.

Gastric acid secretion

The secretion of gastric acid and pepsin tends to run in parallel, although the understanding of the mechanisms of gastric acid secretion is considerably greater than that of pepsin. Numerous factors are involved to some degree in the production of the gastric acid. These include neurotransmitters, neuropeptides and peptide hormones, and several other factors. This complexity need not detract from the fact that there are basic principles that are relatively easily understood (Fig. 51.4). As mentioned above, hydrogen ions are produced by the parietal cell by the proton pump. Although there is a multiplicity of factors that can act on the parietal cell, it is now widely accepted that the most important of these transmitters is histamine, which acts via the H2 receptor. Histamine in turn is produced by the ECL cells of the stomach and acts in a paracrine (local) fashion on the parietal cells. These relationships explain why proton pump inhibitors can abolish gastric acid secretion, as they act on the final common pathway secretion, and why H2-receptor antagonists have such profound effects on gastric acid secretion, even though this is not insurmountable (Fig. 51.4). The ECL cell produces histamine in response to a number of stimuli that include the vagus and gastrin. Gastrin is released by the G cells in response to the presence of the food in the stomach. The production of gastrin is inhibited by acid, hence creating a negative-feedback loop. Various other peptides, including secretin, inhibit gastric acid secretion.

Classically, three phases of gastric secretion are described. The cephalic phase is mediated by vagal activity secondary to sensory arousal as first demonstrated by Pavlov. The gastric phase is a response to food within the stomach that is mediated principally, but not exclusively, by gastrin. In the intestinal phase, the presence of chyme in the duodenum and small bowel inhibits gastric emptying and, as mentioned above, the acidification of the duodenum leads to the production of secretin that also inhibits gastric acid secretion, along with numerous other peptides originating from the gut. The stomach also possesses somatostatin containing D cells. Somatostatin is released in response to a number of factors including acidification. This peptide acts probably on the G cell, the ECL cell and the parietal cell itself to inhibit the production of acid both directly and via intermediate pathways.

Gastric mucus and the gastric mucosal barrier

The gastric mucous layer is essential to the integrity of the gastric mucosa. It is a viscid layer of mucopolysaccharides produced by the mucus-producing cells of the stomach and the pyloric glands. Gastric mucus is an important physio-logical barrier to protect the gastric mucosa from mechanical damage, and also the effects of acid and pepsin. Its consider-able buffering capacity is enhanced by the presence of bicar-bonate ions within the mucus. Many factors can lead to the break down of this gastric mucous barrier. These include bile, nonsteroidal anti-inflammatory drugs (NSAIDs), alcohol, trauma and shock. Tonometry studies have shown that of all the gastrointestinal tract the stomach is the most sensitive to ischaemia following a hypovolaemic insult and also the slowest to recover. This may explain the high incidence of stress ulceration in the stomach.

Peptides and neuropeptides in the stomach and duodenum

As with most of the gastrointestinal tract, the stomach is richly endowed with sources of peptide hormones and neurotransmitters. Previously nerves and endocrine cells were considered distinct in terms of their products. However, it is increasingly realised that there is enormous overlap within these systems. Many peptides recognised as hormones may also be produced by neurons, hence the term neuropeptides. The term ‘messenger’ can be used to describe all such products. There are three conventional modes of action which overlap.

- **Endocrine** — the messenger is secreted into the circulation where it affects tissues which may be remote from the site of origin (Bayliss and Starling).
- **Paracrine** — messengers are produced locally and have local effects on tissues. Neurons and endocrine cells both act in this way.
- **Neurocrine** (classical neurotransmitter) — messengers are produced by the neuron via the synaptic knob and pass across the synaptic cleft to the target.

The **autocrine** mode of action should be mentioned for completeness. Here messengers are released from cell to act on receptors on the same cell’s surface membrane. Many growth factors such as epidermal growth factor and transforming growth factors exert both paracrine and autocrine effects on the parietal cells. These relationships explain why proton pump inhibitors can abolish gastric acid secretion, as they act on the final common pathway secretion, and why H2-receptor antagonists have such profound effects on gastric acid secretion, even though this is not insurmountable (Fig. 51.4). The ECL cell produces histamine in response to a number of stimuli that include the vagus and gastrin. Gastrin is released by the G cells in response to the presence of the food in the stomach. The production of gastrin is inhibited by acid, hence creating a negative-feedback loop. Various other peptides, including secretin, inhibit gastric acid secretion.

Gastroduodenal motor activity

The motility of the entire gastrointestinal tract is modulated to a large degree by its intrinsic nervous system. Critical in this discussion is the migrating motor complex (MMC). In the fasted state and after food has cleared the small bowel there is a period of quiescence lasting in the region of 40 minutes (phase I). There follows a series of waves, also lasting for about 40 minutes, of electrical and motor activity propagated from the fundus of the stomach in a caudal direction at a rate of about three per minute (phase II). These pass as far as the pylorus but not beyond. Duodenal slow waves are generated in the duodenum at a rate of about 10 per minute that carry down the small bowel. The amplitude of these contractions increases to a maximum in phase III that lasts for about 10 minutes. This 90-minute cycle of activity is then repeated. From the duodenum the MMC moves distally at 5—10 cm/minute reaching the terminal ileum after 1.5 hours.

Following a meal the stomach exhibits receptive relaxation which lasts for a few seconds. Following this adaptive relaxation occurs which allows the proximal stomach to act as a reservoir. Most of the peristaltic activity is found in the distal stomach (the antral mill) and the proximal stomach demonstrstrates only tonic activity. The pylorus, which is most com-monly open, contracts with the peristaltic wave and allows only a few millilitres through at a time. The antral contraction against the closed sphincter is important in the milling activity of the stomach. Although the duodenum is capable of generating 10 waves per minute, after a meal it only contacts after an antral wave reaches the pylorus. The coordination of the motility of the antrum, pylorus and duodenum means that only small quantities of food reach the small bowel at a time.
Motility is influenced by numerous factors including mechanical stimulation and neuronal and endocrine influences.
Investigation of the stomach and duodenum

Flexible endoscopy

Amongst all of the methods used to investigate and image the stomach and duodenum, flexible endoscopy is now the ‘gold standard’. The original gastrosopes were fibre-optic (Hirschowitz), but now most use a solid-state camera mounted at the instrument’s tip (Figs 51.5, 51.9). The main advantage of the modern instruments is that they do not need the fragile fibre optic fibre bundle to transmit the image. In addition, as the output is via a monitor rather than an eyepiece, the other members of the endoscopy team see the image. This is useful when taking biopsies or performing interventional techniques, and also facilitates teaching and training.

Flexible endoscopy is more sensitive than conventional radiology in the assessment of the majority of gastroduodenal conditions. This is particularly the case with peptic ulceration, gastritis and duodenitis. In upper gastrointestinal bleeding endoscopy is far superior to any other investigation and in most circumstances is the only imaging required. Although in Japan double-contrast barium meals performed by very experienced radiologists are able to detect quite small gastric cancers, endoscopy is far superior in most centres and also allows biopsies to be taken.

Although fibre-optic endoscopy is a safe and commonly used investigation, it is important that all personnel under-taking this procedure are adequately trained and that resuscitation facilities are always available. Although the morbidity and mortality associated with upper gastrointestinal endoscopy is extremely low, it is not without hazard. Careless and rough handling of the endoscope during intubation of a patient may result in perforations of the pharynx and oesophagus. Any other part of the upper gastrointestinal tract may also be perforated. An inadequately performed endoscopy is also dangerous as a serious condition may be overlooked. This is particularly the case in respect of early and curable gastric cancer, the appearances of which may often be extremely subtle and may be missed by inexpert-enced endoscopists with tragic consequences. In general, a more experienced endoscopist will have a higher index of suspicion for any mucosal abnormalities and will take more biopsies.

Upper gastrointestinal endoscopy is normally carried out under sedation usually with incremental doses of diazepam or midazolam until the patient is adequately sedated. Midazolam is often preferred for its amnesic effect. Sedation is of particular concern in the case of gastrointestinal bleed-ing as it may have a more profound effect on the patient’s cardiovascular stability. It has now become the standard to use pulse oximetry to monitor patients during upper gastrointestinal endoscopy, and nasal oxygen is often also administered. Opiates are not usually necessary, although they are commonly used for endoscopic retrograde cholangio-pancreatography (ERCP). Buscopan is useful to abolish duodenal motility for examinations of the second and third parts of the duodenum. Examinations of this type are best carried out using a side-viewing endoscope such as is used for ERCP.

Some patients are relatively resistant to sedation with benzodiazepines, particularly those who are accustomed to alcoholic beverages. Increasing the dose of benzodiazepines in these patients may not afford any useful sedation but merely make the patient more restless and confused. Such patients are sometimes better endoscoped fully awake using a local anesthetic throat spray and a narrow-gauge endoscope. Whatever the circumstances, it is important that resuscitation facilities are available including agents that reverse the effects of benzodiazepines, such as flumazenil.

The technology associated with upper gastrointestinal endoscopy is continuing to advance. Instrumentation is now available in many centres which allows both endoscopy and endoluminal ultrasound to be performed simultaneously (see later). Intervention via the endoscope is also developing rapidly. A variety of haemostatic measures is used in the treatment of bleeding ulcers such as injection with various substances, diathermy, heater probes and lasers. These approaches appear to have utility in the treatment of bleed-ing ulcers, although good controlled trials in this area are not abundant. There is no good evidence that such interventional procedures at the moment work in patients who are bleeding from very large vessels, such as the gastroduodenal artery or splenic artery.

Contrast radiology

Upper gastrointestinal radiology is not used as much as in previous years as endoscopy is a more sensitive investigation for most gastric problems. There is, however, a number of circumstances where the barium meal is of great value and augments the value of endoscopy. These include large hiatus hernias of the rolling type and chronic gastric volvulus where it may be difficult for the endoscopists to determine exactly the anatomy or, indeed, negotiate the deformity to see the distal stomach. Linitus plastica may be missed by even relatively experienced endoscopists as the mucosal aspect of the stomach may not look particularly abnormal. This condition may be diagnosed more easily by using contrast radiology, although this is of limited value to the patient as the outlook is so poor.

Ultrasoundography

Standard ultrasound imaging can be used to investigate the stomach, particularly in patients with neoplasia. Thickening of the gastric wall can be seen in malignancy, some assessment made of local invasion, and liver and peritoneal disease is often detected. However, used, conventionally, it is less sensitive than other modalities. By contrast, endoluminal ultrasound and laparoscopic ultrasound are probably the most sensitive techniques available in the preoperative staging of gastric cancer. In endoluminal ultrasound the transducer is usually attached to the distal tip of the instrument. However, devices have been developed which may be passed down the biopsy channel, albeit with poorer image quality. Five layers (Fig. 51.7) of the gastric wall may be identified on endoluminal ultrasound and the depth of invasion of a tumour can be assessed with exquisite accuracy (90 per cent accuracy for the ‘T’ component of the staging). Enlarged lymph nodes can also be identified and the technique’s accuracy in this situation is about 80 per cent. Finally, it may be possible to identify liver metastases not seen on axial imaging. Laparoscopic ultrasound is also a very sensitive imaging modality, espe-cially when combined with the laparoscopy (see later). It is one of the most sensitive methods of detecting liver metastases from gastric cancer.

An additional use of ultrasound is in the assessment of gastric emptying. Swallowed contrast is utilised which is designed to be easily seen using an ultrasound transducer. The emptying of this contrast is then followed directly. The accuracy of the technique is similar to that of radioisotope gastric emptying studies (below).

Computerised tomography (CT) scanning and magnetic resonance imaging (MRI)

The resolution of the CT scanners is continuing to improve and this form of axial imaging is of increasing value in the investigation of the stomach, especially gastric malignancies (Fig. 51.8). The presence of gastric wall thickening associated with a carcinoma of any reasonable size can be easily detected by CT but the investigation lacks sensitivity in detecting smaller and curable lesions. It is much less accurate in ‘T’ staging than endoluminal ultrasound. Lymph node enlargement can be detected and, based on the size and shape of the nodes, it is possible to be reasonably accurate in detecting nodal involvement with tumour. However, as with all imaging techniques, it is limited. Microscopic tumour deposits in lymph nodes cannot be detected when the node is not enlarged and, by contrast, lymph nodes may undergo reactive
enlargement but not contain tumour. These problems apply to all imaging techniques. The detection of small liver metastases is improving, although in general terms metastases from gastric cancer are less easy to detect using CT than those, for instance, from colorectal cancer. This is because metastases from gastric cancer may be of the same density as liver and may not handle the intravenous contrast any differently. MRI scanning does not at present offer any specific advantage in assessing the stomach, although it has a higher sensitivity for the detection of gastric cancer liver metastases than conventional CT imaging.

Laparoscopy

This technique is now well used in the assessment of patients with gastric cancer. Its particular value is in the detection of peritoneal disease that is difficult by any other technique, unless the patient has ascites or bulky intraperitoneal disease. Its main limitation is in the evaluation of posterior extension but other techniques are available to evaluate posterior invasion, especially CT and endoluminal ultrasound. Usually laparoscopy is combined with peritoneal cytology unless laparotomy follows immediately.

Gastric emptying studies

These are useful in the study of gastric dysmotility problems, particularly those that follow gastric surgery. The principle of the examination is that a radioisotope-labelled liquid and solid meal are ingested by the patient and the emptying of the stomach is followed on a gamma camera. This allows the proportion of activity in the remaining in the stomach to be assessed numerically, and it is possible to follow liquid and solid gastric emptying independently (Fig. 51.9).

Tests of gastric acid secretion and of pH monitoring

In the past tests of gastric acid secretion were frequently performed, particularly by surgeons. Recent advances, however, have made these tests virtually redundant except in the context of physiological and pharmacological studies. Part of the interest in these tests related to the higher levels of gastric acid secretion commonly found in patients with duodenal ulcer disease (see later).

Traditionally, basal and maximal acid output is measured. A nasogastric tube is passed into the stomach, the basal secretion collected over 1 hour and the acid output in millimoles calculated. To obtain the maximal acid output intramuscular injection of the gastrin analogue pentagastrin is given at a dose of 6 pg/kg body weight and the secretions are collected over the ensuing hour. The maximal acid output is calculated as the peak 15-minute collection multiplied by 4 or twice the peak 30-minute collection in two consecutive collections.

A wealth of data exists on the acid outputs in a whole range of populations. Ultimately, the peak acid output is related to the parietal cell mass; larger stomachs produce more acid. Although traditionally patients with duodenal ulcers do secrete more acid than normal, there is considerable overlap between normal and duodenal ulcer populations. Patients with gastric ulcers produce acid at approximately normal levels. In a patient with a gastrinoma the basal acid output is unusually high and there may be little response to pentagastrin, the parietal cell mass already being near maximally stimulated by the gastrin produced by the tumour. It is now known that other nongastrin peptide products also may result in the Zollinger—Ellison syndrome.

The insulin test was previously beloved of gastric surgeons, particularly those interested in the quality of vagotomy. The test was originally described by Hollander and involves the induction of hypoglycaemia in a postvagotomy patient using an intravenous soluble dose of insulin of 0.2 units/kg body weight. Gastric acid secretion is then measured in the 2 hours following insulin injection. The theoretical basis of the test is that the hypoglycaemia stimulates the hypothalamic nuclei inducing a parasympathetic response. If the vagus is intact to any degree this is reflected in a rise in gastric acid secretion. Various criteria are used to determine whether a test is positive or not. Distinction is often made between an ‘early’ positive test, thought to mean that a substantial vagal innervation remains, and a ‘late’ positive test, the significance of which is less clear. Although in these tests they did correlate to some degree with ulcer relapse following vagotomy, their use in patient management was always limited as they are performed postoperatively and therefore could not influence patient management. In this respect the intraoperative Grassi test may have been a more useful method of controlling the quality of vagotomy. However, all of these tests are virtually redundant as vagotomy is now uncommonly performed on the elective situation.

24-hour intragastric pH monitoring

Studies of this type became very popular during the 198 Os, particularly in the investigation of new gastric antisecretory agents. The pH within the stomach is measured over a 24-hour period either by the passage of a nasogastric tube and regular aspiration or by placing a radiotelemetry capsule on a tether within the stomach and monitoring the pH with an externally worn aerial. The median daytime, night-time or 24-hour intragastric pH can thus easily be calculated and, by converting the pH to hydrogen ion concentration, the median intragastric acidity over various periods can be studied. This latter manoeuvre allows the percentage reduction in acidity produced by a pharmacological agent to be measured (the step of converting pH to hydrogen ion concentration is obviously vital as pH is a logarithmic scale). Although of great physiological and pharmacological interest, these tests have little clinical relevance.

Measurement of plasma gastrin

The measurement of plasma gastrin by radioimmunoassay is of use in the diagnosis of gastrinoma (Zollinger—Ellison syn-drome). In most assays the normal fasting gastrin level is about 50 ng/litre, but in gastrinomas very high levels, some-times many thousands of ng/litre, can be found. However, the other common cause of hypergastrinaemia is hypochlorhydria associated with gastric atrophy and very high gastrin levels are found in pernicious anaemia. Antral gastrin is released to excess as a result of the negative feedback loop. A condition is said to exist when there is autonomous production of gastrin by the antrum but this condition, if it exists, is of little clinical importance.
Paediatric disorders

Hypertrophic pyloric stenosis of infancy

Aetiology

The incidence of this condition is approximately three cases per 1000 births. It is four times as common in males as in females and the aetiology is unknown. It may be that the condition is analogous to achalasia of the oesophagus in which there is a failure of the pylorus to relax, leading to the muscular hypertrophy. In some cases there seems to be a familial association. In such families the mother has suffered from the condition in 50 per cent of cases, and 10 per cent of male siblings and 2 per cent of female siblings are affected.

Pathology

The classical feature is that the musculature of the pylorus and adjacent antrum is grossly hypertrophied, the hypertrophy being maximum in the pylorus itself. The mucosa is compressed such that only a probe can be inserted.

Clinical features

Characteristically it is a first-born male child that is most commonly affected. The condition is most commonly seen at 4 weeks after birth ranging from the third week to, on rare occasions, the seventh. Inexplicably, it is the time following birth that seems important and not the child’s gestational age. A premature infant will also develop the condition at about 4 weeks after birth. Vomiting is the presenting symptom that after 2–3 days becomes forcible and projectile. The child vomits milk and no bile is present. Immediately after vomiting the baby is usually hungry. Weight loss is a striking feature and rapidly the infant becomes emaciated and de-hydrated. Diagnosis can usually be made with a test feed. This may produce characteristic peristaltic waves that can be seen to pass across the upper abdomen. At the same time, using a warm hand, the abdomen is palpated to detect the lump (Fig. 51.10).

Imaging

Ultrasonography is the investigation of choice as it can, without difficulty, detect the classical features in the pyloric canal. Contrast radiology is not now necessary.

Differential diagnosis

The common conditions from which pyloric stenosis must be differentiated are gastro-oesophageal reflux, feeding problems, urinary tract infection and raised intracranial pressure. The condition cannot normally be confused with duodenal atresia or intestinal obstruction because of the absence of bile in the milk vomit.

Ramstedt's operation

In preparing the child for operation it is important that the stomach is emptied and washed out with saline, and that hypothermia is avoided. To achieve this the patient is encased in cotton wool allowing exposure of the upper abdomen. Operation is performed under general anaesthesia, although it is possible to perform the procedure under a local anesthetic. The skin is opened through a transverse incision placed in the upper abdomen over the right rectus sheath, which is opened in the same line. The rectus muscle is then split along the line of its fibres and the posterior rectus sheath opened in the line of the skin incision. The hypertrophied pylorus is delivered and rotated so that its superior surface comes into view (Fig. 51.11). Thus, the least vascular portion can be selected for incision. To ascertain the distal limit of the hypertrophy the surgeon invaginates the duodenum with the index finger. The incision is made through the serosa only and from this point along the whole length of the pylorus and, importantly, the distal antrum. The hypertrophied pylorus has the consistency of an unripe pear, hence splitting the muscle coats can be accomplished by blunt dissection (Fig. 51.11). On separating the edges with artery forceps the pyloric mucosa bulges into the cleft which has been made in the muscle. Great care is taken not to penetrate the mucosa. When this injury occurs it is almost always in dividing the most distal part of the constricting fibres which are in the vicinity of the duodenal fornix. To be sure that there is no perforation some air is squeezed from the stomach into the duodenum. If a perforation has occurred it is closed and a piece of omentum placed over the closure. Haemostasis should be meticulous.

After operation the nasogastric tube can be removed and feeding commenced on the morning after operation. If the infant manages to feed without difficulty it can be discharged early from hospital. If the mucosa is inadvertently opened it is wise to delay feeding for 48 hours and to retain the child in hospital longer.

Complications of operation

Postoperative pyrexia is common and usually treated with paracetamol elixir. Wound disruption is rare and is more liable to occur in emaciated subjects. The incidence of wound infection is around 5 per cent, and 1 per cent will suffer wound disruption.

Duodenal atresia

This occurs at the point of fusion between the foregut and midgut, and therefore lies in the neighborhood of the ampulla of Vater. There is a diaphragm, which is usually complete, across the duodenum at this point (Fig. 51.12) and the condition is frequently accompanied by other defects. The diagnosis is now made antenatally in most cases through the use of ultrasound. This shows the characteristic appearance of a dilated stomach and first part of the duodenum (double bubble). The child vomits from birth and the vomitus is bile stained. The differential diagnosis includes high intestinal obstruction. Occasionally, however, the diaphragm may be proximal to the ampulla and in these circumstances the condition can be confused with pyloric stenosis, although in pyloric stenosis vomiting does not start from birth. Treatment is by the operation of the duodenoduodenostomy in which the dilated proximal duodenum is anastomosed to the atrophic distal duodenum (Ladd). This disparity in luminal size can produce delays in emptying and some surgeons have advocated the use of a transanastomotic tube. However, this has been demonstrated to delay emptying and is not now commonly used.
Helicobacter pylori

Over the last 20 years this organism has proved to be of overwhelming importance in the aetiology of a number of common gastroduodenal diseases such as chronic gastritis, peptic ulceration and gastric cancer. The organism had unquestionably been observed by a number of workers since Bircher’s first description in 1874, but it was not until 1980 that Warren and Marshall, with enthusiasm but perhaps a lack of caution, ingested the organism to confirm that Koch’s postulates could be fulfilled with respect to the gastritis that they succeeded in causing in themselves. Eradication therapy was then employed with mixed success. The organism is spiral shaped and is fastidious in its requirements, being difficult to culture outside the mucous layer of the stomach.

One of the characteristics of the organism is its ability to hydrolyse urea, resulting in the production of ammonia, a strong alkali. The effect of ammonia on the antral G cells is to cause the release of gastrin via the previously described negative-feedback loop. This is probably responsible for the modest but inappropriate hypergastrinaemia in patients with peptic ulcer disease which, in turn, may result in gastric acid hypersecretion. The organism’s obligate urease activity is utilised by various tests used to detect the presence of the organism, including the C13 and C14 breath tests and the CLÖ test (which is a commercially available urease test kit), which is performed on gastric biopsies. The organism can also be detected histologically (Fig. 51.13), using the Giemsa or the Ethin—Stary silver stains, and cultured using appro-priate media. Previous or current infection with the organism may also be detected serologically.

Infection leads to the disruption of the gastric mucous barrier by the enzymes produced by the organism, and the inflammation induced in the gastric epithelium is the basis of many of the associated disease processes. The association of the organism with chronic (type B) gastritis is not in doubt as Koch’s postulates have been fulfilled, most notably by Marshall and Warren. Some strains of H. pylori produce cytotoxins, and the production of cytotoxin seem to be associated with the ability of the organism to cause both gastritis and peptic ulceration (Crabtree). The effect of the organism on the gastric epithelium is to incite a classical inflammatory response that involves the migration and degranulation of acute inflammatory cells, such as neutrophils, and also the accumulation of chronic inflammatory cells, such as macrophages and lymphocytes.

It is evident how H. pylori infection results in chronic gastritis and also how this may progress to gastric ulceration, but it remained for a while an enigma how the organism could be involved in duodenal ulceration as the normal duodenum is not colonised. As mentioned above, the production of ammonia does increase the level of circulating gastrin and it has subsequently been shown that eradication of the organism in patients with duodenal ulcer disease will reduce the acid levels to normal. However, the overlap in gastric acid secretion between normal subjects and those with duodenal ulcers is considerable and the modestly increased acid levels in patients with Helicobacter-associated gastritis are insufficient to explain the aetiology of duodenal ulceration.

The explanation can probably be found in the phenomenon of duodenal gastric metaplasia. Gastric metaplasia is the normal response of the duodenal mucosa to excess acidity. It can be thought of as any other metaplasia in the gastrointestinal tract: an attempt by the mucosa to resist an injurious stimulus. Although normal duodenal mucosa cannot be infected with H. pylori gastritis in the duodenum is commonly infected and this infection results in the same inflammatory process that is observed in the gastric mucosa (Wyatt and Dixon). The result is duodenitis, which is almost certainly the precursor of duodenal ulceration.

Infection with H. pylori may be the most common human infection. The incidence of infection within a population increases with age, and in many populations infection rates of 80—90 per cent are not unusual. The possibility of infection is inversely related to socioeconomic group. The means of spread has not been identified, but the organism can occur in the faeces and faecal—oral spread seems most likely. The organism is not normally found in saliva or dental plaque. There is evidence in different environments and in different population groups that the manifestations of the infection may be different. Predominantly antral gastritis, which is commonly seen in the West, results initially in increased levels of acid production and peptic ulcer disease whereas gastritis affecting the body, common in the developing world, may lead to hypochlorhydria and gastric neoplasia.

It has been known since 1984 that Helicobacter infection is amenable to treatment with antibiotics and, in addition, that bismuth compounds are toxic for the organism. The profound hypochlorhydria produced by proton pump inhibitors combined with antibiotics is also effective in eradicating the organism. Commonly used eradication regimes include a bismuth compound and two antibiotics, such as metronidazole and amoxycillin, or a proton pump inhibitor, such as omeprazole, again in combination with antibiotics. High eradication rates in the region of 90 per cent can be achieved with combinations which include the antibiotic clarithromycin, although it may be that in the future antibiotic resistance becomes a problem.

At present eradication therapy is recommended for patients with duodenal ulcer disease but not for patients with non ulcer dyspepsia or in asymptomatic patients who are infected. However, recent data show that a proportion of patients with nonulcer dyspepsia does respond to treatment. Helicobacter pylori is now classed by the World Health Organisation as a class 1 carcinogen and it may be that the further epidemiological studies on the risk of gastric cancer change the current advice on treatment.
Gastitis

The understanding of gastitis has increased markedly following elucidation of the role of H. pylori in chronic gastitis.

Type A gastritis

This is an autoimmune condition in which there are circulating antibodies to the parietal cell. This results in the atrophy of the parietal cell mass, hence hypochlorhydria and ultimately achlorhydria. As intrinsic factor is also produced by the parietal cell there is malabsorption of vitamin B₁₂ which, if untreated, may result in pernicious anaemia. In type A gastritis the antrum is not affected and the hypochlorhydria leads to the production of high levels of gastrin from the antral G cells. This results in chronic hypergastrinaemia. This in turn results in hypertrophy of the ECL cells in the body of the stomach which are not affected by the autoimmune damage. Over time it is apparent that microadenomas develop in the ECL cells of the stomach, sometimes becoming identifiable tumour nodules. Very rarely these tumours can become malignant. Patients with type A gastritis are predisposed to the development of gastric cancer and screening such patients endoscopically may be appropriate.

Type B gastritis

There are abundant epidemiological data to support the association of this type of gastritis with H. pylori. Most commonly type B gastritis affects the antrum, and it is these patients who are prone to peptic ulcer disease. Helicobacter-associated pangastritis is also a very common manifestation of infection, but gastritis affecting the corpus alone does not seem to be associated. However, there are some data to suggest that Helicobacter may be involved in the initiation of the process. Patients with pangastritis seem to be most prone to the development of gastric cancer.

Intestinal metaplasia is associated with chronic pangastritis with atrophy. Although intestinal metaplasia per se is common, intestinal metaplasia associated with dysplasia has significant malignant potential and if this condition is identified the patient should be regularly screened endoscopically.

Reflux gastritis

This is caused by enterogastric reflux and is particularly common after gastric surgery. Its histological features are distinct from other types of gastritis. Although commonly seen after gastric surgery, it is occasionally found in patients with no previous surgical intervention or who have had a cholecystectomy. Bile chelating or prokinetic agents may be useful in treatment and as a temporising measure to avoid consideration of revisional surgery. Operation for the condition should be reserved for the most severe cases.

Erosive gastritis

This is caused by agents which disturb the gastric mucosal barrier; NSAIDs and alcohol are common causes. The nonsteroidal-induced gastric lesion is associated with inhibition of the cyclo-oxygenase type 1 (Cox 1) receptor enzyme, hence reducing the production of cytoprotective prostaglandins in the stomach. Fortunately, many of the beneficial anti-inflammatory activities of NSAIDs are mediated by Cox 2, and there is at present much activity to produce Cox 2 inhibitors which will spare some of the side effects of these agents.

Stress gastritis

This is a common sequel of serious illness or injury and is characterised by a reduction in the blood supply to superficial mucosa of the stomach. Although common, this is not usually recognised unless stress ulceration and bleeding supervene, in which case treatment can be extremely difficult. The condition also sometimes follows cardiopulmonary bypass. Prevention of the stress bleeding from the stomach is much easier than treating it, and hence the routine use of H₂ antagonists with or without barrier agents, such as sucralfate, in patients who are on intensive care. These measures have been shown to reduce the incidence of bleeding from stress ulceration.

Ménétrier’s disease

This is an unusual condition characterised by gross hyper-trophy of the gastric mucosal folds, mucus production and hypochlorhydria. The condition is premalignant and may present with hypoproteinaemia and anaemia. There is no treatment other than a gastrectomy. The disease seems to be caused by overexpression of transforming growth factor alpha (TGF-alpha). Like epidermal growth factor (EGF), this peptide also binds to the EGF receptor. The histological features of Ménétrier’s disease may be reproduced in transgenic mice overexpressing TGF-alpha (Coffey).

Lymphocytic gastritis

This type of gastritis is seen rarely. It is characterised by the infiltration of the gastric mucosa by T cells and is probably associated with H. pylori infection.

Other forms of gastritis

Eosinophilic gastritis appears to have an allergic basis, and is treated with steroids and chromoglycate. Granulomatous gastritis is seen rarely in Crohn’s disease and also may be associated with tuberculosis. Acquired immunodeficiency syndrome (AIDS) gastritis is secondary to infection with cryptosporidiosis. Phlegmonous gastritis is a rare bacterial infection of the stomach found in patients with severe intercurrent illness. It is usually an agonal event.
Peptic ulcer

Peptic ulcers are so named because, in addition to acid being a requirement for their occurrence, pepsin is probably also required. Certainly, it is clear that patients with duodenal ulcers tend to have a higher than average pepsin level within the gastric juice. However, this is of little practical importance as in the absence of acid, for instance in type A gastritis with atrophy, peptic ulcers do not occur. All peptic ulcers can be healed by using proton pump inhibitors, such as omeprazole, that can render a patient virtually achlorhydric.

Common sites for peptic ulcers are the first part of the duodenum and the lesser curve of the stomach, but they also occur on the stoma following gastric surgery, the oesophagus and even in a Meckel’s diverticulum, which contains ectopic gastric epithelium. In general, the ulcer occurs at a junction between different types of epithelia, the ulcer occurring in the epithelium least resistant to acid attack.

In the past much distinction has been made between acute and chronic peptic ulcers, but this difference can sometimes be difficult to determine clinically. It is probably best to consider that there is a spectrum of disease from the superficial gastric and duodenal ulceration, frequently seen at endoscopy, to deep chronic penetrating ulcers. This does not minimise the importance of acute stress ulceration. These ulcers can both perforate and bleed (see ‘Stress ulceration’ later).

For many years and despite enormous research endeavour the cause of peptic ulceration remained an enigma. Acid, which is so easy to measure, was studied incessantly, such studies being particularly beloved by gastric surgeons. How-ever, it is clear that although acid levels are higher comparing groups of patients with duodenal and prepyloric peptic ulcers with normal subjects the overlap is very considerable. Patients with gastric ulceration have normal levels of gastric acid secretion or, in the view of some, lower levels. As peptic ulceration will occur in the presence of very high acid levels, such as those found in patients with a gastrinoma (Zollinger—Ellison syndrome, see the section on ‘Duodenal tumours’ later), and as all ulcers can be healed in the absence of acid it is clear that acid is important. In some cases it may be the only aetiological factor. This is clearly not the case in the majority of patients. As with most diseases there clearly are genetic components as exemplified by the often quoted and clinically irrelevant finding that patients with blood group 0 are over-represented amongst the duodenal ulcer population. Similarly, social stress has also been implicated, falsely (Asher).

It is now widely accepted that infection with H. pylori is the most important factor in the development of peptic ulceration. The other factor of major importance at present is ingestion of NSAIDs. Cigarette smoking predisposes to peptic ulceration and increases the relapse rate after treatment with either gastric antisecretory agents or, in the past, elective surgery. Although other factors exist, and multi-ple other factors may be involved in transition between the superficial and the deep penetrating chronic ulcer, they are of lesser importance.

Duodenal ulceration

Incidence

There have been marked changes in the last two decades in the demography of patients presenting with duodenal ulceration in the West. First, even before the introduction of H₂-receptor antagonists, the incidence of duodenal ulcers fell and the frequency of elective surgery for the condition were falling. This trend has continued and now, in the West, dyspeptic patients presenting with a duodenal ulcer at gastroscopy are uncommon. In part, this may relate to the liberal prescription of gastric antisecretory agents and eradication therapy for patients with dyspepsia. Secondly, the peak incidence is now in a much older age group than previously and, although it is still more common in men, the difference is less marked. These changes, at least in part, mirror the changes in the epidemiology of H. pylori infection. A cohort effect can be demonstrated (Susser), the age group in whom Helicobacter infection was prevalent in the early part of the twentieth century was ageing and suffering the complications of the infection late in life. This probable relationship with H. pylori can also be seen in relation gastric to ulceration and, indeed, gastric cancer. Similarly, the incidence of perforation and bleeding duodenal ulcers in young and middle-aged patients appears to be falling but, by contrast, there is currently a marked increase in the numbers of elderly and often infirm patients suffering these complications. This latter trend can be explained not only by the H. pylori cohort effect but also by the increased use of NSAIDs in the elderly. In Eastern Europe the disease remains common and, from having been uncommon in some developing nations, it is now observed more frequently. Again, the relationship with H. pylori appears compelling.

Pathology

Most occur in the first part of the duodenum (Figs 51.14 and 51.15). A chronic ulcer penetrates the mucosa and into the muscle coat leading to fibrosis. The fibrosis causes defor-mities such as pyloric stenosis. When an ulcer heals a scar can be observed in the mucosa. Sometimes there may be more than one duodenal ulcer. The situation in which there is both a posterior and an anterior duodenal ulcer is referred to as ‘kissing ulcers’. Anteriorly placed ulcers tend to perforate and, by contrast, posterior duodenal ulcers tend to bleed, sometimes by eroding a large vessel such as a gastroduodenal artery. Occasionally the ulceration may be so extensive that the entire duodenal cap is ulcerated and devoid of mucosa. With respect to the giant duodenal ulcer, malignancy in this region is so uncommon that under normal circumstances surgeons can be confident that they are dealing with benign disease even though from external palpation it may not appear so. In the stomach the situation is different.

Histo pathology

Microscopically, destruction of the muscular coat is observed and the base of the ulcer is covered with granulation tissue, the arteries in this region showing the typical changes endarteritis obliterans. Sometimes the terminations of nerves can be seen amongst the fibrosis. The pathological appear-ances of the healing ulcer must be carefully interpreted as some of the epithelial down-growths can be misinterpreted as invasion. This is unlikely to be important in duodenal ulcers when malignancy rarely, if ever, occurs but it is much more important with gastric ulcers.

Gastric ulcers

Incidence

As with duodenal ulceration, H. pylori and NSAIDs are the important aetiologi-cal factors. Gastric ulceration is also associated with smoking, other factors are of lesser importance.

There are marked differences between the populations afflicted by chronic gastric ulceration compared with duodenal ulceration. First, gastric ulceration is substantially less common than duodenal ulceration. The sex incidence is equal and the population with gastric ulcers tends to be older. It is more prevalent in low socioeconomic groups and is considerably more common in the developing world than in the West.

Pathology

This is essentially similar to that of a duodenal ulcer, except that gastric ulcers tend to be larger. Fibrosis, when it occurs, may result in the now
rarely seen hour-glass contraction of the stomach. Large chronic ulcers may erode posteriorly into the pancreas and on other occasions into major vessels such as the splenic artery. Less commonly, they may erode into other organs such as the transverse colon. Chronic gastric ulcers are much more common on the lesser curve, especially at the incisura angularis (Figs 51.16 and 51.17), than the greater curve, and even when high on the lesser curve they tend to be at the boundary between the acid-secreting and the non acid-secreting epithelia. With atrophy of parietal cell mass nonacid-secreting epithelium migrates up the lesser curvature

**Malignancy in gastric ulcers**

Chronic duodenal ulcers are not associated with malignancy and, by contrast, gastric ulcers are. Widely varying estimates are made of the incidence of gastric malignancy in gastric ulcers. The reason for this is that the authors reporting such diverse incidences are describing different clinical situations. Two clinical extremes must be distinguished to understand this problem properly. First, there is the situation in which a benign chronic gastric ulcer undergoes malignant transformation. This is known to happen, albeit rarely, and can be observed histologically in specimens in which there are the classical histological features of benign gastric ulceration associated with an area of malignant transformation. It is impossible to estimate the incidence of such an occurrence but it is uncommon. The contrasting clinical extreme is the patient identified as having an ulcer in the stomach, either endoscopically or on contrast radiology, which is assessed as benign but biopsies reveal malignancy. In this situation the patient does not have, and probably never has had, chronic peptic ulceration in the stomach but has presented with an ulcerated cancer. This situation is common, although whether a lesion found in the stomach is described as being benign or malignant on clinical grounds depends very much on the skill and experience of the endoscopist or radiologist.

It is fundamental that any gastric ulcer should be regarded as being malignant no matter how classical the features of a benign gastric ulcer. Multiple biopsies should always be taken, perhaps as many as 10 well-targeted biopsies, before an ulcer can be tentatively accepted as being benign. Even then it is important that further biopsies are taken whilst the ulcer is healing and when healed. Modern antisecretory agents can frequently heal the ulceration associated with gastric cancer but clearly are ineffective in treating the malignancy itself. At operation even experienced surgeons may have difficulty distinguishing between the gastric cancer and a benign ulcer. Operative strategies differ so radically that it is essential, if at all possible, that a confident diagnosis be made before operation. The patechial haemorrhages found on the serosa of the patient with peptic ulceration are a useful sign but not entirely reliable. If, at operation, it are determined that the ulcer is probably benign it should, none the less, be excised, in totality if possible, and submitted for histological examination. It is not known whether a patient’s survival is compromised by this approach if the ulcer turns out to be malignant on biopsy as convincing data are not available.

**Other peptic ulcers**

Prepyloric gastric ulcers require special mention. In terms of acid secretion they are similar to duodenal ulcers and in the past have proved to be more difficult to treat, a problem overcome with the advent of proton pump inhibitors. Pyloric channel ulcers are similar to duodenal ulcers. Both prepyloric and pyloric ulcers may be malignant, and biopsy is essential. Stomal ulcers occur after a gastroenterostomy or a gastrectomy but have presented with an ulcerated cancer. This situation is common, although whether a lesion found in the stomach is described as being benign or malignant on clinical grounds depends very much on the skill and experience of the endoscopist or radiologist.

**Clinical features of peptic ulcers**

Whilst many textbooks try and create differences in the clinical feature of gastric and duodenal ulceration, detailed analysis has shown that they cannot be differentiated on the basis of symptoms. Certainly, the demographic characteristics of groups of patients with gastric and duodenal ulceration do differ but this does not allow discrimination.

**Pain**

The pain is epigastric, often described as gnawing and may radiate to the back. Eating may sometimes relieve the discomfort. The pain is normally intermittent rather than intractable.

**Periodicity**

One of the classical features of untreated peptic ulceration is periodicity. Symptoms may disappear for weeks or months to return again. This periodicity may be related to the spontaneous healing of the ulcer.

**Vomiting**

Whilst this occurs, it is not a notable feature unless the stenosis has occurred.

**Alteration in weight**

Weight loss or, sometimes, weight gain may occur. Patients with gastric ulceration are often underweight but this may precede the occurrence of the ulcer.

**Bleeding**

All peptic ulcers may bleed. The bleeding may be chronic and presentation with anaemia is not uncommon. Acute presentation with haematemesis and melaena is discussed later.

**Clinical examination**

Examination of the patient may reveal epigastric tenderness but except in extreme cases (for instance gastric outlet obstruction) there is unlikely to be much else to find.

**Investigation of the patient with suspected peptic ulcer**

In the investigation of such patients, imaging, preferably with flexible gastroduodenoscopy, is required.

**Gastroduodenoscopy**

This is the most sensitive investigation in the management of suspected peptic ulceration and in the hands of a well trained operator is highly sensitive and specific. In the stomach any abnormal lesion should be multiply biopsied, and in the case of a suspected benign gastric ulcer numerous biopsies must be taken in order to exclude, as far as possible, the presence of a malignancy. Commonly biopsies of the antrum will be taken to see whether there is histologi-cal evidence of gastritis and a CLO test performed to determine the presence of *H. pylori*. A ‘U’ manoeuvre should be performed to exclude ulcers around the gastro-oesophageal junction. This is important as the increasing incidence of
cancer at the gastro-oesophageal junction requires that all mucosal abnormalities in this region should undergo multiple biopsy. Similarly, if a stoma is present, for instance after gastroenterostomy or Billroth II gastrectomy, it is important to enter both afferent and efferent loops. Almost all stomal ulcers will be very close to the junction between the jejunal and gastric mucosa. Attention should be given to the pylorus to note whether there is any prepyloric or pyloric channel ulceration and also whether it is deformed, which is often the case with chronic duodenal ulceration. In the duodenum care must be taken to view all of the first part. It is not infrequent for an ulcer to be just beyond the pylorus and easily overlooked.

**Treatment of peptic ulceration**

The vast majority of uncomplicated peptic ulcers is treated medically. Surgical treatment of uncomplicated peptic ulceration has decreased markedly since the 1960s and in the West is now seldom performed. Surgical treatment was aimed principally at reducing gastric acid secretion and, in the case of gastric ulceration, removing the diseased mucosa. When originally devised medical treatment also aimed to reduce gastric acid secretion, initially using the highly successful H2-receptor antagonist and subsequently proton pump inhibitors. This has now largely given way to eradication therapy.

**Medical treatment**

It is reasonable that a doctor managing a patient with an uncomplicated peptic ulcer should suggest modifications to the patient’s lifestyle, particularly the cessation of cigarette smoking. This advice is rarely followed and pharmacological measures form the mainstay of treatment.

**H2-receptor antagonists**

H2 antagonists (Black) revolutionised the management of peptic ulceration. Most duodenal ulcers and gastric ulcers can be healed by a few weeks of treatment with these drugs provided that they are taken and absorbed. There remained, however, a group of patients who were refractory to conventional doses of H2-receptor antagonists. This is largely now irrelevant as proton pump inhibitors can effectively render a patient achlorhydric and all benign ulcers will heal using these drugs. The problem with H2-receptor antagonists alone, as with other gastric antisecretory agents, is that relapse is virtually inevitable once treatment is discontinued.

**Proton pump inhibitors**

All ulcers will heal on proton pump inhibitors, such as omeprazole, the majority within 2 weeks. Symptom relief is impressively rapid, most patients being asymptomatic within a few days. Like H2-antagonists, omeprazole is safe and rela-tively devoid of serious side effects. As with H2-receptor antagonists relapse following cessation of therapy is almost universal.

**Eradication therapy**

Eradication therapy is now routinely given to patients with peptic ulceration, and this is described earlier in this chapter. Evidence suggests that if a patient has a peptic ulcer and H. pylori is the principal aetiological factor (essentially the patient not taking NSAIDs) then complete eradication of the organism will cure the disease and reinfection as an adult is uncommon. Eradication therapy is therefore the mainstay of treatment with peptic ulceration. It is extremely economical by comparison with prolonged courses of antisecretory agents or surgery. It is also considerably safer than surgical treatment.

There are some patients with peptic ulcers in whom eradication therapy may not be appropriate and this includes patients with NSAID-associated ulcers. Such patients should avoid these drugs if possible and if not they should be co-prescribed with a potent antisecretory agent. Similarly, patients with Stomal ulceration are not effectively treated with eradication therapy and require prolonged pre-description of antisecretory agents or surgery. Patients with Zollinger—Ellison syndrome should be treated long term with omeprazole, unless the tumour can be adequately managed by surgery.

**Surgical treatment of uncomplicated peptic ulceration**

From its peak in the 1960s the incidence of surgery for uncomplicated peptic ulceration has fallen markedly, to the extent that peptic ulcer surgery is now of little more than historical interest. A description of operations used in the treatment of peptic ulcers is still necessary because surgery is commonly employed for the complicated ulcer and, in addition, many patients are left suffering from the consequences of the more destructive operations.

**Operations for duodenal ulceration**

**Duodenal ulcer surgery — rationale**

Procedures devised for the treatment of duodenal ulcers have the common aim of excluding the damaging effects of acid from the duodenum. This has been achieved by diversion of the acid away from the duodenum, reducing the secretory potential of the stomach, or both. It has long been known that patients with duodenal ulceration have higher than aver-age levels of gastric secretion. All of the operations devised achieved their aim to some extent, but with varying degrees of morbidity, mortality and postoperative side-effects. The operations are described in historical sequence.

**Billroth II gastrectomy**

The first successful gastrectomy was performed by Billroth in January 1881 (Fig. 51.18) and Wolfer performed the first gastroenterostomy in the same year. The original Billroth operations consisted of a gastric resection with gastroduodenal anastomosis (Billroth I technique) (Fig. 51.18). The Billroth II operation was devised more by accident than design (Fig. 51.19). A gastroenterostomy (Fig. 51.20) was performed on a gravely ill patient with a pyloric cancer who was not expected to survive. Contrary to expectations the patient improved and the stomach distal to the anastomosis was resected. It soon became evident that the use of gastro-enterostomy after gastric resection could be safer and easier than the Billroth I procedure, and it became popular and effective in the surgical treatment of duodenal ulcer. Because of its disadvantages, such as higher operative mor-tality and morbidity, it has not been used for many years in the patient with an uncomplicated ulcer but it is still used occasionally in the treatment of a complicated ulcer with a ‘difficult’ duodenum. In Billroth II gastrectomy, or its close relation Polya gastrectomy, the antrum and distal body of the stomach are mobilized by opening the greater and lesser omentum and dividing the gastrosplenic arteries, (right) gastric artery and the (left) gastric artery arcade at the limit of the resection. The duodenum is closed off either by suture or using staples, sometimes with difficulty in patients with a very deformed duodenum. Various techniques are available to close the difficult duodenum and in extremis a catheter may be placed in the duodenal stump, the duodenum closed around it and a catheter brought out through the abdominal wall. Following resection the distal end of the stomach is narrowed by the closure of the lesser curve aspect.
of the remnant. The greater curve aspect is then anastomosed, usually in a retrocolic fashion, to the jejunum leaving as short an afferent loop as feasible (Fig. 51.19). Even when well performed this procedure has an operative mortality rate of a few per cent and morbidity is not unusual. A common cause of morbidity is leakage from the duodenal stump, which is particularly associated with kinking of the afferent loop. Leakage from the gastrojejunostomy anastomosis is unusual unless either it is under tension or the stomach has been devascularised during the mobilisation. The incidence of side effects following gastrectomy is considerable, as shown in Table 51.2. Recurrence of the ulcer at the stoma is uncommon but can occur, especially as this procedure is traditionally not combined with the vagotomy.

**Gastrojejunostomy**

Because of the potential for mortality after gastrectomy the use of gastrojejunostomy alone in the treatment of duodenal ulceration was developed (Fig. 51.20). Reflux of alkali from the small bowel into the stomach reduced duodenal ulceration and was often successful in healing the ulcer. However, because the jejunal loop was exposed directly to gastric acid stomal ulceration was extremely common, hence the procedure in isolation was ineffective.

**Truncal vagotomy and drainage**

Truncal vagotomy was first introduced in 1943 by Dragstedt, and for many years this truncal vagotomy combined with drainage was the mainstay in the treatment of duodenal ulceration. The principle of the operation is that section of the vagus nerves, which are critically involved in the secretory aspect of gastric acid, reduces the maximal acid output by approximately 50 per cent. This is similar to the effect of conventional doses of H₂-receptor antagonists. Because the vagal nerves are motor to the stomach, denervation of the antro-pyloroduodenal segment results in gastric stasis in a substantial proportion of patients on whom truncal vagotomy alone is performed. This was first noted by Dragstedt who, when he first introduced the operation, did not perform a drainage procedure.

In performing truncal vagotomy the lower oesophagus is exposed by division of the overlying peritoneum. By gentle blunt dissection the oesophagus, which should contain a nasogastric tube, is encircled and slang with a tape. The posterior vagal trunk can be felt as a light cord posteriorly and is divided between ligatures as it may be accompanied by blood vessels. On the front of the oesophagus the anterior vagus consists of a plexus which is divided. The lower 7 cm of oesophagus should be completely cleared of nerve fibres to achieve an adequate vagotomy (Fig. 51.21). The most popular drainage procedure is the Heineke—Mikulicz pyloroplasty (Fig. 51.22). It is simple to perform and involves the longitudinal section of the pyloric ring. This need not be an extensive excision when performed in the elective situation. The incision is closed transversely, usually with a single layer of interrupted sutures. Gastrojejunostomy (Fig. 51.20) is the alternative drainage procedure to pyloroplasty. This is performed through opening the lesser sac and an anastomosis performed between the most dependent part of the antrum and the first jejunal loop. An isoperistaltic anastomosis is most commonly performed. The operation of truncal vagotomy and drainage is substantially safer than gastrectomy (Table 51.2). However, the side effects of surgery are, in fact, little different from those that follow gastrectomy.

**Selective vagotomy and drainage**

In an attempt to reduce the side effects of truncal vagotomy, selective vagotomy was developed. In contrast to truncal vagotomy, where a complete vagal denervation is performed, in selective vagotomy the hepatic and coeliac nerves are preserved but the stomach is still completely vagally denervated. Drainage is required and, as this operation had all the disadvantages of truncal vagotomy but not the merit of simplicity, it was abandoned in favour of highly selective vagotomy.

**Highly selective vagotomy**

In 1968 Johnston and Andrup independently devised the operation of highly selective vagotomy in which only the parietal cell mass of the stomach was denervated. This proved to be the most satisfactory operation for duodenal ulceration with a low incidence of side effects and acceptable recurrence rates when performed to a high technical standard. This operation became the gold standard for operations on duodenal ulceration in the 1970s. The operative mortality was lower than any other definitive operation for duodenal ulceration, in all probability because the gastro-intestinal tract is not opened during this procedure. The untoward effects of peptic ulcer surgery are largely avoided, although loss of receptive relaxation of the stomach does occur, leading to epigastric fullness and sometimes mild dumping. However, the severe symptoms that occur after other more destructive gastric operations do not occur. It is often said that recurrent ulceration is the Achilles’ heel of this operation, although when performed well recurrence should be no more common than after truncal vagotomy.

In highly selective vagotomy the nerves of Latarjet supplying the antrum are preserved and a complete neurovascular clearance of the proximal lesser curve is carried out (Fig. 51.23). This is achieved by commencing the dissection from the anterior aspect and then opening the lesser sac through the greater omentum to perform the posterior dissection. Dissection is continued up to the oesophagogastric junction and the lower 7 cm of oesophagus cleared of nerve fibres. Particular attention must be paid to the nerve of Grassi which passes posteriorly to the greater curve, but the greater curvature itself need not be cleared. Attention must also be given to ‘adhesions’ within the lesser sac as these may carry nerve fibres. Using 24-hour pH-monitoring studies it has been demonstrated that this operation will achieve a reduction in the 24-hour intragastric acidity greater than can be obtained with conventional doses of H₂-receptor antagonists.

The advent of laparoscopic surgery renewed some interest in the surgery for duodenal ulceration but the technical difficulties in performing a full highly selective vagotomy laparoscopically are considerable. For this reason some centres adopted the procedure of anterior highly selective vagotomy and posterior truncal vagotomy as an alternative. However, as surgery for uncomplicated duodenal ulceration is to all intents and purposes unnecessary, there is now little interest in developing operations further.

**Truncal vagotomy and antrectomy**

For completeness this operation should be mentioned as it was at one stage popular in the USA. In addition to a truncal vagotomy, the antrum of the stomach is removed thus removing the source of gastrin, and the gastric remnant joined to the duodenum. The recurrence rates after this procedure are exceedingly low. However, the operative mortality is higher than after vagotomy and drainage (Table 51.2) and the incidence of unpleasant side effects is similar.

**Operations for gastric ulcer**

By contrast with duodenal ulcer surgery, where the principal objective is to reduce duodenal acid exposure, in gastric ulceration the diseased tissue is usually removed as well. This has the advantage that malignancy can then be confidently excluded. Although levels of gastric acid secretion are not abnormally high in the patients with gastric ulceration, acid is still a prerequisite and hence operations to lower acid secretion have been commonly employed.
**Billroth I gastrectomy**

This was the standard operation (Fig. 51.18) for gastric ulceration until medical treatments became prevalent. The distal stomach is mobilised and resected in the same way as in the Billroth II gastrectomy. This resection should include the ulcer that is usually situated on the lesser curve. The cut edge of the remnant is then partially closed from the lesser curve aspect leaving a stoma at the greater curve aspect which should be similar in size to the duodenum. Reconstruction may be facilitated by mobilising the duodenum using Kocher’s manoeuvre. The incidence of recurrent ulceration after this operation is low, but it carries with it the morbidity and mortality associated with any gastric resection.

**Billroth II gastrectomy**

This may be used for the high and lesser curve gastric ulcer where a gastroduodenostomy is technically difficult.

**Vagotomy, pyloroplasty and ulcer excision**

Truncal vagotomy, drainage and ulcer excision was developed because of the concerns about morbidity and mortality following gastric resection for gastric ulcer. Highly selective vagotomy and gastric excision has a similar rationale, although is much more favourable in terms of side effects compared with truncal vagotomy and drainage. As with duodenal ulcers, most operations for uncomplicated gastric ulcers are of historical significance.

**The complications of peptic ulceration**

The common complications of peptic ulcer are perforation, bleeding and stenosis. Bleeding and stenosis are considered below in the relevant sections on ‘Haematemesis and melaena’ and ‘Gastric outlet obstruction’.

**Perforated peptic ulcer**

**Epidemiology**

Overall and despite the widespread use of gastric antisecretory agents and eradication therapy, the incidence of perforated peptic ulcer has changed little. There has, however, been a considerable change in the epidemiology of perforated peptic ulcer over the last two decades. Previously, most patients were middle aged, with a ratio of 2:1 of male/female. With time there has been a steady increase in the age of the patients suffering this complication and an increase in the numbers of females, such that now perforations most commonly occur in elderly female patients. NSAIDs appear to be responsible for most of these perforations.

**Clinical features**

The classical presentation of perforated duodenal ulcer is instantly recognisable (Fig. 51.24). The patient, who may have a history of peptic ulceration, develops sudden onset severe generalised abdominal pain due to the irritant effect of gastric acid on the peritoneum. Although the contents of an acid-producing stomach are relatively low in bacterial load, bacterial peritonitis supervenes over a few hours usually accompanied by a deterioration in the patient’s condition. Initially, the patient may be shocked with a tachycardia but a pyrexia is not usually observed until some hours after the event. The abdomen exhibits a board-like rigidity and the patient is disinclined to move because of the pain. The abdomen does not move with respiration. Patients with this form of presentation need an operation without which the patient will deteriorate with a septic peritonitis.

This classical presentation of the perforated peptic ulcer is observed less commonly than in the past. Very frequently the elderly patient who is taking NSAIDs will have a less dramatic presentation, perhaps because of the use of potent anti-inflammatory drugs. The board-like rigidity seen in the abdomen of younger patients may also not be observed and a higher index of suspicion is necessary to make the correct diagnosis. In other patients the leak from the ulcer may not be massive. They may present only with pain in the epigastrium and right iliac fossa as the fluid may track down the right paracolic gutter. Sometimes perforations will seal owing to the inflammatory response and adhesion within the abdominal cavity and so the perforation may be self-limiting. All of these factors may combine to make the diagnosis of perforated peptic ulcer difficult.

By far the most common site of perforation is the anterior aspect of the duodenum. However, the anterior or incisural gastric ulcer may perforate and, in addition, gastric ulcers may perforate into the lesser sac, which can be particularly difficult to diagnose. These patients may not have obvious peritonitis.

**Investigations**

An erect plain chest radiograph will reveal free gas under the diaphragm in excess of 50 per cent of cases with perforated peptic ulcer (Fig. 51.25). All patients should have serum amylase performed, as distinguishing between peptic ulcer, perforation and pancreatitis can be difficult. Measuring the serum amylase, however, may not remove the diagnostic difficulty. It can be elevated following perforation of a peptic ulcer although, fortunately, the levels are not usually as high as the levels commonly seen in acute pancreatitis. Several other investigations are useful if doubt remains. A water soluble contrast swallow will show a free peritoneal leak. Diagnostic peritoneal lavage will usually easily distinguish between perforation and pancreatitis, and a CT scan will normally be diagnostic in both conditions, although this is seldom necessary.

**Treatment**

The initial priorities are resuscitation and analgesia. Analgesia should not be withheld for fear of removing the signs of an intra-abdominal catastrophe. If anything, adequate analgesia makes the clinical signs more obvious. It is important, however, to titrate the analgesia so that the patient is not rendered unconscious. Following resuscitation and the diagnosis being established the treatment is principally surgical. Laparotomy is performed usually through an upper midline incision if the diagnosis of perforated peptic ulcer can be made with confidence. This is not always possible, and hence it may be better to place a small incision around the umbilicus to localise the perforation with more certainty. Alter-natively, laparoscopy may be employed. The most important component of the operation is a thorough peritoneal toilet to remove all of the fluid and food debris. If the perforation is in the duodenum it can usually be closed by several well-placed sutures, closing the ulcer in a transverse direction as with a pyloroplasty. It is important that sufficient tissue is taken in the suture to allow the edges to be approximated, and the sutures should not be tied so tight that they tear out. It is common to place an omental patch over the perforation in the hope of enhancing the chances of the leak sealing. Gastric ulcers should, if possible, be excised and closed, so that malignancy can be excluded. Occasionally a patient is seen who has a massive duodenal or gastric perforation such that simple closure is impossible and in these patients a Billroth II gastrectomy is a useful operation.
All patients should be treated with systemic antibiotics and there may be some advantage in washing out the abdominal cavity with tetracycline, 1 g in 1 litre of isotonic saline. In the past many surgeons performed definitive procedures such as either truncal vagotomy and pyloroplasty or, more recently and probably more successfully, highly selective vagotomy during the course of an operation for a perforation. Studies show that in well-selected patients and in expert hands this is a very safe strategy. However, most commonly nowadays surgery is confined to first-aid measures and the peptic ulcer treated medically as described earlier in this chapter. Following operation gastric antisecretory agents should be started immediately.

Perforated peptic ulcers can often be managed by minimally invasive techniques if the expertise is available. The principles of operation are, however, the same; thorough peritoneal toilet is performed and the perforation closed by intracorporeal suturing. Whatever technique is used it is important that the stomach be kept empty postoperatively by nasogastric suction, and gastric antisecretory therapy commenced to promote healing in the residual ulcer.

A great deal has been written about the conservative management of perforated ulcer. Some writers say that virtually all patients can be managed conservatively, whereas most surgeons have difficulty in understanding how a patient who is ill with widespread peritonitis and who has food debris widely distributed through the abdominal cavity will improve without an operation. However, there are undoubtedly patients who have small leaks from perforated peptic ulcer and relatively mild peritoneal contamination who may be managed with intravenous fluids, nasogastric suction and antibiotics. These patients are in the minority.

Patients who have suffered one perforation may suffer another one. They should therefore be managed aggressively to ensure that this does not happen. In patients with Helicobacter-associated ulcers, eradication therapy is appropriate. Patients on NSAIDs, who now form the majority of such patients, should have the drug withdrawn and another analgesic substituted. If it is necessary to continue the NSAIDs the patient should have concomitant treatment with a proton pump inhibitor such as omeprazole.

Sequelea of peptic ulcer surgery

There is a number of sequelae of peptic ulcer surgery which include recurrent ulceration, small stomach syndrome, bile vomiting, early and late dumping, diarrhoea and malignant transformation. These sequelae principally follow from the more destructive operations that are now seldom performed. However, a substantial number of patients suffers from side effects from operations undertaken in the past. Approximately 30 per cent of patients can expect to suffer a degree of dysfunction following peptic ulcer surgery, and in about 5 per cent of such patients the symptoms will be intractable.

Recurrent ulceration

Although mentioned first, this is by far the easiest problem to treat. Just as all peptic ulcers will heal with potent anti-secretory agents so will ulcers that are recurrent after ulcer surgery. The incidence of recurrent ulceration after the various operations is shown in Table 51.2.

The recurrent ulcer normally presents with pain, although some may develop a complication without any prior warning. Following an operation such as highly selective vagotomy the ulcer is in a similar position to the original ulcer, usually the first part of the duodenum. In patients with gastrojejunostomy, recurrent ulcer will commonly be at the anastomosis but on the jejunal side. Jejunal mucosa is much more sensitive to acid digestion compared with the stomach. Similarly, following gastrectomy the recurrent ulcer will be normally found on the jejunal side of the stoma.

A number of factors has been convincingly related to the development of recurrent ulceration. First and foremost, if the original operation was technically inadequate, such as the vagotomy being incomplete, then the incidence of recurrent ulceration is much higher. In this respect it is noteworthy that recurrent ulceration after, for instance, highly selective vagotomy is highly surgeon dependent. Cigarette smoking has been convincingly associated with an increased incidence of recurrent ulceration, and it has been shown that patients who had ulcers that are resistant to treatment with pharmacological agents before operation are more likely to develop recurrence afterwards.

If recurrent ulceration is diagnosed electively then long-term antisecretory agents are probably the treatment of choice if the patient has had an anatomically destructive operation. In patients with recurrent ulcer after highly selective vagotomy, then eradication therapy may be effective. As with other peptic ulcers, recurrent ulcers may present with complications, particularly bleeding and perforation. In this respect the complication of gastrojejunal colic fistula requires a particular mention. In this rare condition the anastomotic ulcer penetrates into the transverse colon. The patient suffers from diarrhoea that is severe and follows every meal. They have foul breath and may vomit formed faeces. Severe weight loss and dehydration are rapid in onset, and for this reason the condition may be mistaken for malignancy. The major factor producing the nutritional disturbance is the severe contamination of the jejunum with colonic bacteria. A number of imaging techniques can be used to detect the fistula. A barium enema will normally demonstrate the problem, and CT scanning is also accurate. Endoscopy may not convincingly demonstrate the fistula and, in about half of such cases, the barium meal will not reveal the problem. The treatment of gastrocolic fistula consists of, first, correcting the dehydration and malnutrition and then performing revisional surgery.

Small stomach syndrome

Early satiety follows most ulcer operations to some degree, including highly selective vagotomy. In this latter circumstance, although there is no anatomical disturbance of the stomach there is loss of receptive relaxation. Fortunately, this problem does tend to get better with time and revisional surgery is not necessary.

Bile vomiting

Bile vomiting can occur after any form of vagotomy with drainage or gastrectomy. Commonly, the patient presents with vomiting a mixture of food and bile or sometimes some bile alone after a meal. Often eating will precipitate abdominal pain and reflux symptoms are common. Bile chelating agents can be tried but are usually ineffective. In intractable cases revisional surgery may be indicated. The nature of that revisional surgery depends very much on the original operation. Following gastrectomy Roux-en-Y diversion is probably the best treatment. In patients with a gastroenterostomy, this can be taken down and in most circumstances a small pyloroplasty performed. In patients with a pyloroplasty, reconstruction of the pylorus has been attempted but in general terms the results of this operation have been rather poor. Antrectomy and Roux-en-Y reconstruction may be the better option.

Early and late dumping

Although considered together because the symptoms are similar, early and late dumping have different etiologies (Table 51.3). A common feature, however, is early rapid gastric emptying. Many patients have both early and late dumping.
Early dumping.

Early dumping consists of abdominal and vasomotor symptoms that are found in about 10 per cent of patients following gastrectomy or vagotomy and drainage. It also affects a few per cent of patients following highly selective vagotomy due to the loss of receptive relaxation of the stomach. The small bowel is filled with foodstuffs from the stomach which have a high osmotic load and this leads to the sequestration of fluid from the circulation into the gastrointestinal tract. This can be observed by the rise in the packed cell volume while the symptoms are present. All of the symptoms shown in Table 51.3 can be related to this effect on the gut and the circulation.

Treatment. The principal treatment is dietary manipulation. Small dry meals are best, and avoiding fluids with a high carbohydrate content also helps. Fortunately, with time following operation the syndrome tends to improve. For some reason, however, there is a group of patients who suffer intractable dumping regardless of any of these measures. The somatostatin analogue octreotide given before meals has been shown to be useful in some individuals and the long-acting preparation may also be useful. However, this treatment can lead to the development of gallstones and it does not help the diarrhoea from which many patients with dumping also suffer.

Revisional surgery may be occasionally required. In patients with a gastroenterostomy, the drainage may be taken down or, in the case of a pyloroplasty, repaired. Alternatively, antrectomy with Roux-en-Y reconstruction is often effective, although the procedure is of greater magnitude. Following gastrectomy it is the revisional procedure of choice.

Late dumping.

This is reactive hypoglycaemia. The carbohydate load in the small bowel causes a rise in the plasma glucose which in turn causes insulin levels to rise causing a secondary hypoglycaemia. This can be easily demonstrated by serial measurements of blood glucose in a patient following a test meal. The treatment is essentially the same as for early dumping. Octreotide is very effective in dealing with this problem.

Postvagotomy diarrhoea

This can be the most devastating symptom to afflict patients having peptic ulcer surgery. Most patients will suffer some looseness of bowel action to some degree (with the exception of highly selective vagotomy) but in about 5 per cent it may be intractable. In spite of much investigation the precise etiology of the problem is uncertain. It is related, to some degree, to rapid gastric emptying. In all probability, the denervation of the upper gastrointestinal tract as a result of the vagotomy is also important. Exaggerated gastrointestinal peptide responses may also aggravate the condition.

The diarrhoea in postvagotomy patients may take several forms. It may be severe and explosive, the patient experiencing a considerable degree of urgency. The patients sometimes describe the diarrhoea as feeling like passing boiling water. At the other extreme some patients only have minor episodes of diarrhoea which are not as directly related to food.

Many authors regard diarrhoea and dumping as being essentially the same problem. However, many patients with severe diarrhoea do not have any of the other symptoms of dumping, and likewise some patients with dumping do not experience any significant diarrhoea.

The condition is difficult to treat. The patient should be managed as for early dumping and antidiarrhoeals may be of some value. Octreotide is not effective in this condition and the results of revisional surgery are too unpredictable to make this an attractive treatment option.

Malignant transformation

Many large studies now confirm that operations such as gastrectomy or vagotomy and drainage are independent risk factors for the development of gastric cancer. The increased risk appears to be approximately four times compared with the control population. It is interesting to note that this phenomenon is seen only in areas with already a significant incidence of gastric cancer; in areas such as Scandinavia with a low incidence it is difficult to observe such a phenomenon.

It is not difficult to understand the increased incidence of gastric cancer as bile reflux gastritis, intestinal metaplasia and gastric cancer are linked. The lag phase between operation and the development of malignancy is at least 10 years. Highly selective vagotomy does not seem to be associated with an increased incidence of gastric cancer in the long term.

Nutritional consequences

Nutritional disorders are more common after gastrectomy than after vagotomy and drainage. Weight loss is common after gastrectomy and the patient may, in fact, never return to their original weight. Nutritional advice advising the taking of small meals is often more useful. Anaemia may be due to either iron or B12 deficiency.

Iron deficiency anaemia occurs after both gastrectomy and vagotomy and drainage and is probably multifactorial in origin. Reduced iron absorption is probably the most important factor, although the loss of blood from the gastric mucosa may also be important. B12 deficiency is prone to occur after total gastrectomy. However, because of the very large B12 stores that most patients have, this may be very late in occurring. B12 supplementation after total gastrectomy is, however, sensible. B12 deficiency may rarely occur after lesser forms of gastrectomy. In such patients the cause is probably a combination of reduced intrinsic factor production and also the fact that some patients have bacterial colonisation which results in the destruction of the B12 in the gut.

Bone disease is seen principally after Polya gastrectomy and mainly in women. The condition is essentially indistinguishable from the osteoporosis commonly seen in post-menopausal women. It is only the frequency and magnitude of the disorder that distinguish it. Treatment is by dietary supplementation, with calcium and vitamin D, and exercise.

Gallstones

The development of gallstones is strongly associated with truncal vagotomy. Following truncal vagotomy the biliary tree, as well as the stomach, is denervated leading to stasis and, hence, stone formation. Patients developing symptomatic gallstones will require cholecystectomy. This, however, may induce or worsen other postpeptic ulcer surgery syndromes such as bilious vomiting and postvagotomy diarrhoea.
Haematemesis and melena

Upper gastrointestinal haemorrhage remains a major medical problem and in spite of improvements in diagnosis and the proliferation in treatment modalities over the last few decades is still attended by significant mortality. A hospital mortality in the region of 5 per cent can be expected. In patients in whom the cause of bleeding is still found the most common causes are bleeding peptic ulcer, erosions, Mallory—Weiss tear and bleeding oesophageal varices (Table 51.4).

Whatever the cause the principles of management are identical. First, the patient should be adequately resuscitated and following this investigated urgently to determine the cause of the bleeding. Only then should treatment of a definitive nature be instituted. For any significant gastrointestinal bleed intravenous access should be established and, for those with severe bleeding, central venous pressure monitoring set up and bladder catheterisation performed. Blood should be cross matched and the patient transfused as clinically indicated. As a general rule most gastrointestinal bleeding will stop, albeit temporarily, but there are sometimes instances when this is not the case. In these circumstances the vessel in the ulcer under run. If the ulcer is not excised then a biopsy of the edge needs to be taken to exclude malignant ulcer. The pyloroplasty is then closed with interrupted sutures in a transverse direction as in the usual fashion.

Surgical treatment

The aim of the operation is to stop the bleeding. The advent of endoscopy has greatly helped in the management of upper gastrointestinal bleeding as a surgeon can usually be confident about the site of bleeding prior to operation. The most common site of bleeding from a peptic ulcer is the duodenum. In tackling this it is most important essential that the duodenum is fully Kocherised. This should be done before the duodenum is opened as it makes the ulcer much more accessible and also allows the surgeon’s hand to be placed behind the gastroduodenal artery that is commonly the source of major bleeding. Following mobilisation, the duodenum and usually the pylorus are opened longitudinally as in a pyloroplasty. This allows good access to the ulcer, which is usually found posteriorly or superiorly. Accurate haemostasis is important. It is the vessel within the ulcer that is bleeding and this should be controlled using well-placed sutures which under run the vessel. The placing of more and more inaccurately positioned sutures is counter productive. Following under running it is possible often to close the mucosa over the ulcer. The pyloroplasty is then closed with interrupted sutures in a transverse direction as in the usual fashion.

The principles of management of bleeding gastric ulcers are essentially the same. The stomach is opened at an appropriate position anteriorly and the vessel in the ulcer under run. If the ulcer is not excised then a biopsy of the edge needs to be taken to exclude malignant transformation. Sometimes the bleeding is from the splenic artery and if there is a lot fibrosis present then the operation may be challenging. Most patients, however, can be managed by conservative surgery. Gastrectomy for bleeding has been widely practised in the past but is attended by higher levels of perioperative mortality even if the incidence of recurrent bleeding is less.

Much argument still remains about the use of definitive acid-lowering operations versus haemostatic surgery alone. Bearing in mind that most patients nowadays are elderly and unfit, the minimum surgery that stops the bleeding is probably optimal. Acid can be inhibited by pharmacological means and appropriate eradication therapy will prevent ulcer recurrence. Patients on long-term NSAIDs can be managed as outlined earlier.

Stress ulceration

This commonly occurs in patients with major injury or ill-ness, who have undergone major surgery or who have major comorbidity. Previously, many such patients were to be found in intensive care units. There seems little doubt that the incidence of this problem has reduced in recent years owing to the widespread use of prophylaxis. Ranitidine has been shown to reduce the incidence of stress ulceration, as has the nasogastric administration of sulcrate. There is no doubt that the prevention of this condition is far better than trying to treat it once it occurs. Endoscopic means of treating stress ulceration may be ineffective and operation required. The principles of management are the same as for the chronic ulcer.

Gastric erosions

Erosive gastritis has a variety of causes, especially NSAIDs. Fortunately, most such bleeding settles spontaneously but when it does not it can
be a major problem to treat. In general terms, although there is a diffuse erosive gastritis, there is one (or more) specific lesion which has a significant sized vessel within it. This should be dealt with appropriately, preferably endoscopically, but sometimes surgery is necessary.

**Mallory—Weiss tear**

This is a longitudinal tear below the gastro-oesophageal junction, which is induced by repetitive and strenuous vomiting. Doubtless, many such lesions occur and do not cause bleeding. When it is a cause of haematemesis the lesion may often be missed as it can be difficult to see as it is just below the gastro-oesophageal junction, a position that can be difficult for the inexperienced endoscopist. Occasionally these lesions continue to bleed and require surgical treatment. Often the situation arises that the surgeon does not have guidance from the endoscopists as regards the site of bleeding, and a high index of suspicion in such circumstances is important. The stomach is opened by longitudinal gastroscopy and carefully inspected high up. It is normally possible to palpate the longitudinal mucosal tear with a little induration at the edges which gives a clue to the lesion’s location. Under-running is all that is required.

**Dieulafoy’s disease**

This is essentially a gastric arterial venous malformation that has a characteristic histological appearance. Bleeding due to this malformation is one of the most difficult causes of upper gastrointestinal bleeding to treat. The lesion itself is covered by normal mucosa and, when not bleeding, it may be invisible. If it can be seen whilst bleeding all that may be visible is profuse bleeding coming from an area of apparently normal mucosa. If this occurs cause is instantly recognisable. If the lesion can be identified endoscopically there are various means of dealing with it, including injection of sclerosant. If it is identified at operation then only a local excision is necessary. Occasionally a lesion is only recognised after gastrectomy and sometimes not even then. The pathologist, as well as the endoscopist, may have difficulty in finding it.

**Tumours**

All of the gastric tumours described below may present with chronic or acute upper gastrointestinal bleeding. Bleeding is not normally torrential but can be unremitting. Gastric smooth muscle tumours commonly present with bleeding and have a characteristic appearance, as the mucosa breaks down over the tumour in the gastric wall (Fig. 51.26). Whatever the nature, the tumours should be dealt with as appropriate.

**Portal hypertension and portal gastropathy**

The management of bleeding gastric varices is very challenging. Fortunately, most bleeding from varices is oesophageal and this is much more amenable to sclerotherapy, banding and balloon tamponade. Gastric varices may also be injected, although this is technically more difficult. Banding can also be used, again with difficulty. The gastric balloon of the Sengstaken—Blakemore tube can be used to arrest the haemorrhage if it is occurring from the fundus of the stomach. Octreotide is a somatostatin analogue which reduces portal pressure in patients with varices and trials suggest that it is of value in arresting haemorrhage in these patients, although its overall effect on mortality remains in doubt. Glypressin is also said to be of use.

Most surgeons prefer to avoid acute surgery on bleeding varices as, by contrast with elective operations for portal hypertension, acute shunts are attended by considerable operative mortality. For this reason the acute TIPSS procedure (transjugular intrahepatic portosystemic shunt) which is described in Chapter 52 can be an extremely useful, although technically demanding, procedure.

**Portal gastropathy**

Portal gastropathy is essentially the same disease process as described above. The mucosa is affected by the increased portal pressure and may exude blood even in the absence of well-developed visible varices. The treatment is as above.

**Aortic enteric fistula**

This diagnosis should be considered in any patient with haematemesis and melaena which cannot be otherwise explained. Contrary to expectation, the bleeding from such patients is not always massive, although it can be. Very often there is nothing much to distinguish the bleeding from the aortic enteric fistula from any other recurrent upper gastrointestinal bleeding. The vast majority of patients will have had an aortic graft and in the absence of this the diagnosis is unlikely. However, it is occasionally seen in patients with an untreated aortic aneurysm. A well-performed CT scan will commonly allow the diagnosis to be made with certainty. The condition should be managed by an expert vascular surgeon as, whether secondary or primary, the morbidity and mortality are high.
Gastric outlet obstruction

The two common causes of gastric outlet obstruction are gastric cancer (see below) and pyloric stenosis secondary to peptic ulceration. Previously the latter was more common. Now, with the decrease in the incidence of peptic ulceration and the advent of potent medical treatments, gastric outlet obstruction should be considered malignant until proven otherwise, at least in the West. The term pyloric stenosis is normally a misnomer. The stenosis is seldom at the pylorus. Commonly, when the condition is due to underlying peptic ulcer disease, the stenosis is found in the first part of the duodenum, the most common site for a peptic ulcer. True pyloric stenosis can occur due to fibrosis around a pyloric channel ulcer. However, in recent years the most common cause of gastric outlet obstruction has been gastric cancer. In this circumstance the metabolic consequences may be somewhat different from those of benign pyloric stenosis because of the relative hypochlorhydria found in patients with gastric cancer.

Clinical features

In benign gastric outlet obstruction there is usually a long history of peptic ulcer disease. Nowadays, as most patients with peptic ulcer symptoms are treated medically, it is easy to understand why the condition is becoming much less common. In some patients the pain may become unremitting and in other cases may largely disappear. The vomitus is characteristically unpleasant in nature and is totally lacking in bile. Very often it is possible to recognise foodstuff taken several days previously. The patient commonly complains of losing weight, and appears unwell and dehydrated. Examining the patient it may be possible to see the distended stomach and a succussion splash may be audible on shaking the patient’s abdomen.

Metabolic effects

These are most interesting, as the metabolic consequences of benign pyloric stenosis are unique. The vomiting of hydrochloric acid results in hypochloraeic alkalosis. Initially the sodium and potassium may be relatively normal. However, as dehydration progresses more profound metabolic abnormalities arise, partly related to renal dysfunction. Initially the urine has a low chloride and high bicarbonate content reflecting the primary metabolic abnormality. This bicarbonate is excreted along with sodium, and so with time the patient becomes progressively hyponatraemic and more profoundly dehydrated. Because of the dehydration, a phase of sodium retention follows and potassium and hydrogen are excreted in preference. This results in the urine becoming paradoxically acidic and hypokalaemia ensues. Alkalosis leads to a lowering in the circulating ionised calcium, and tetany can occur.

Management

Treating the patient involves correcting the metabolic abnormality and dealing with the mechanical problem. The patient should be rehydrated with intravenous isotonic saline with potassium supplementation. Replacing the sodium chloride and water allows the kidney to correct the acid—base abnormality. Following rehydration it may become obvious that the patient is also anaemic, the haemoglobin being spuriously high on presentation.

It is noteworthy that the metabolic abnormalities may be less if the obstruction is due to malignancy as the acid—base disturbance is less pronounced.

The stomach should be emptied using a wide-bore gastric tube. A large nasogastric tube may not be sufficiently large to deal with the contents of the stomach and it may be necessary to pass an orogastric tube and lavage the stomach until it is completely emptied. This then allows investigation of the patient with endoscopy and contrast radiology. Biopsy of the area around the pylorus is essential to exclude malignancy. The patient should also have a gastric antisecretory agent such as ranitidine, given initially intravenously to ensure absorption.

Early cases may settle with conservative treatment, presumably as the oedema around the ulcer diminishes as the ulcer is healed. Traditionally severe cases are treated surgically, usually with a gastroenterostomy rather than a pyloroplasty. The addition of a vagotomy in these circumstances may be appropriate. Endoscopic treatment with balloon dilatation has been practised and may be most useful in early cases. This treatment is, however, not devoid of problems. Dilating the duodenal stenosis may result in perforation. The dilatation may have to be performed several times and sometimes may not be successful in the long term.

Other causes of gastric outlet obstruction

Adult pyloric stenosis

This is a rare condition and its relationship to the childhood condition unclear, although some patients have a long history of problems with gastric emptying. It is commonly treated by pyloroplasty rather than pyloromyotomy.

Pyloric mucosal diaphragm

The origin of this rare condition is unknown. It usually does not become apparent until middle life. When found simple excision of the mucosal diaphragm is all that is required.
Gastric polyps

A number of conditions manifests as gastric polyps. Their main importance is that they may actually represent early gastric cancer. Biopsy is essential.

The most common type of gastric polyp is metaplastic. These are associated with *H. pylori* infection and regress following eradication therapy. Inflammatory polyps are also common. Fundic gland polyps deserve particular attention. They seem to be associated with the use of proton pump inhibitors and are also found in patients with familial polyposis. None of the above polypoid lesions has proven malignant potential. True adenomas have malignant potential and should be removed, but account for only 10 per cent of polypoid lesions. Gastric carcinoids, arising from the ECL cells, are seen particularly in patients with pernicious anaemia, and usually appear as small polyps.
Gastric cancer

Carcinoma of the stomach has been described as one of the 'Captains of the men of death'. Examining the survival statistics from the UK it is not hard to agree with this gloomy view. Some series demonstrate overall 5-year survival statistics in the region of 5 per cent. These data obscure the fact that gastric cancer is an eminently curable disease provided that it is detected at an appropriate stage and treated adequately. Gastric cancer rarely disseminates widely before it has involved the lymph nodes and therefore there is an opportunity to cure the disease prior to dissemination. Early diagnosis is therefore the key to success with this disease. The only treatment modality able to cure the disease is resectional surgery.

Incidence

There are marked variations in the incidence of gastric cancer worldwide. In the UK it is approximately 15 per 100 000 per year, in the USA 10 per 100 000 per year and in Eastern Europe 40 per 100 000 per year. In Japan the disease is much more common with an incidence of approximately 70 per 100 000 per year, and there are small geographical areas in China where the incidence is double that in Japan. These underlying epidemiological data make it clear that this is an environmental disease. In general men are more affected by the disease than women and, as with most solid organ malignancies, the incidence increases with age.

Currently marked changes are being observed in the West in terms of both the incidence and site of gastric cancer and the population affected, changes that to date have not been observed in Japan. First, the incidence of gastric cancer is continuing to fall at about 1 per cent per year. This reduction exclusively affects carcinoma arising in the body and distal stomach. By contrast, there appears to be an increase in the incidence of carcinoma in the proximal stomach, particularly the oesophagogastric junction. Carcinoma of the distal and body of the stomach is most common in low socioeconomic groups, whereas the increase in proximal gastric cancer seems to affect principally higher socioeconomic groups. Proximal gastric cancer does not seem to be associated with H. pylori infection, in contrast to carcinoma of the body and distal stomach.

Aetiology

Gastric cancer is a multifactorial disease (Correa). Epidemiological studies point to a role for H. pylori although there is argument about how important this factor is. Certainly the EUROGAST study revealed a correlation between the incidence of gastric cancer in various populations and the prevalence of H. pylori infection, although there was a considerable scatter about the regression line indicating that other factors were also important. There is insufficient evidence at the moment to support eradication programmes in asymptomatic patients who are infected with Helicobacter with a view to reducing the population incidence of gastric cancer. However, clinical trials may subsequently change this view. As mentioned above Helicobacter seems to be principally associated with carcinoma of the body, stomach and distal stomach rather than the proximal stomach. As Helicobacteris associated with gastritis, gastric atrophy and intestinal metaplasia the association with malignancy is perhaps not surprising.

Several other risk factors have been identified as being important in the aetiology of gastric cancer. Patients with pernicious anaemia and gastric atrophy are at increased risk, as are those with gastric polyps. Patients who have had peptic ulcer surgery, particularly those who have had drainage procedures such as Billroth II or Polya gastrectomy, gastro-enterostomy or pyloroplasty are at approximately four times the average risk. There is no direct evidence to date that highly selective vagotomy is associated with an increased risk of gastric cancer. Presumably duodenogastric reflux and reflux gastritis are related to the increased risk of malignancy in these patients. Intestinal metaplasia is a risk factor. Carcinoma is associated with cigarette smoking and dust ingestion from a variety of industrial processes. Diet appears to be important, as illustrated by the often quoted example of the change in the incidence of gastric cancer as Japanese families moved to the USA. The high incidence of gastric cancer in some pockets in China is probably environmental and probably diet related. The ingestion of substances such as spirits may induce gastritis and, in the long term, cancer. Excessive salt intake, deficiency of antioxidants and exposure to N-nitroso compounds are also related. The aetiology of proximal gastric cancer remains an enigma. Genetic factors are also important but imperfectly elucidated (see below).

The molecular pathology of gastric cancer

In contrast to colorectal cancer, the molecular pathology of gastric cancer is less well worked out. However, it is likely that with time the importance of the genetic events in gastric cancer will similarly be realised. The oncogenes H-ras and c-erb B2 have both been studied. Evidence suggests that H-ras mutations occur at an early stage of gastric carcinogenesis and it is not clear that ras mutations are of importance in tumour progression. c-erb B2 encodes for a transmembrane tyrosine kinase receptor which has sequence homology with epidermal growth factor receptor. c-erb 132 is amplified and overexpressed in well-differentiated gastric carcinomas of the intestinal type and, as it is commonly seen in metastases, it may therefore be important in tumour progression.

The role of tumour suppressor genes has also been examin-ed. The APC gene that is responsible for familial polyposis is mutated in 25 per cent of moderately/well-differentiated carcinomas, and loss of heterozygosity of this region is seen in about 60 per cent of tumours. However, loss of the APC gene has not been detected in poorly differentiated gastric cancers making its role unclear. p53 is the archetypal tumour suppressor gene. p53 protein is overexpressed in many trans-formed cells and this overexpression is often related to a p53 mutation, the protein product of the mutant gene being more stable. Again, the role of p53 in gastric cancer is unclear. Abnormalities in p53 have been found in intestinal meta-plasia in the stomach but not in the primary tumours except at a late stage.

Microsatellite instability is a form of genetic instability resulting from deficiencies in the mismatch repair genes. The result of this phenotype is the rapid accumulation of mUlti-tions within the genome (mutator phenotype), hence predisposing to malignant transformation. Inherited mismatch repair deficiency is responsible for hereditary nonpolyposis colorectal cancer (HNPPC). Gastric cancers are also found in families with this phenotype. Microsatellite instability is found in about 15 per cent of sporadic colorectal cancers and apparently in a similar per centage of sporadic gastric cancers.

Clinical features

The features of advanced gastric cancer are usually obvious. However, curable gastric cancer has no specific features to distinguish it symptomatically from benign dyspepsia. The key to improving the outcome of gastric cancer is early diagnosis and, although in Japan there is a screening programme, most curable cases are picked up by the liberal use of gastroscopy in patients with dyspepsia. Present guidelines suggest gastroscopy for any new dyspepsia, however mild, in a patient over 40 years of age. The same advice applies to a patient of any age with persistent dyspepsia or any unusual feature. It is important to note that gastric antisecretory agents will improve the symptoms of gastric cancer so the disease must be excluded, preferably before therapy is started.

In advanced cancer early satiety, bloating, distension and vomiting may occur. The tumour frequently bleeds resulting in iron deficiency anaemia. Obstruction leads to dysphagia, epigastric fullness or vomiting. With pyloric involvement the presentation may be of gastric outlet obstruction leading to dysphagia, epigastric fullness or vomiting.
obstruction, although the alkalosis is usually less pronounced or absent compared to when duodenal ulceration leads to obstruction. In recent years gastric outlet obstruction is more commonly associated with malignancy than benign disease. Nonmetastatic effects of malignancy are seen, particularly thromboplebitis (Trousseau’s sign) and deep venous thrombosis. These feature result from the effects of the tumour on thrombotic and haemostatic mechanisms. mass lesions but spreads widely in the gastric wall. Not surprisingly, this has a much worse prognosis. A small proportion of gastric cancers are of mixed morphology.

Gastric cancer can be divided into early gastric cancer and advanced gastric cancer. Early gastric cancer is defined as cancer limited to the mucosa and submucosa with or without lymph node involvement (T1, any N). The classification is shown in Fig. 51.28. This can be either protruding, super-ficial or excavated in the Japanese classification (Fig. 51.29). This type of cancer is eminently curable and even early gastric cancers associated with lymph node involvement have 5-year survival rates in the region of 90 per cent (Fig. 51.29). In Japan approximately one-third of gastric cancers diag-nosed are in this stage. However, in the UK it is uncommon to detect gastric cancers at this stage. A number of reasons probably still accounts for this. First, because gastric cancer is less common in the UK dyspeptic patients are not always referred for endoscopy at an appropriate stage. Secondly, endoscopists are unfamiliar with the appearances of early gastric cancer and in all probability many such cases are missed.

Advanced gastric cancer involves the muscularis. Its macroscopic appearances have been classified by Bormann into four types (Figs 51.30 and 51.31). Types III and IV are commonly incurable.

### Staging

The International Union Against Cancer (UICC) staging is shown in Table 51.5.

### Spread of carcinoma of the stomach

No better example of the various modes by which carcinoma spreads can be given than the case of stomach cancer. It is important to note that this distant spread is unusual before the disease spreads locally and distant metastases are uncommon in the absence of lymph node metastases. The intestinal and diffuse types of gastric cancer spread differently. The diffuse type spreads via the submucosal and subserosal lymphatic plexus and it penetrates the gastric wall at an early stage.

#### Direct spread

The tumour penetrates the muscularis, serosa and ultimately adjacent organs such as the pancreas, colon and liver.

#### Lymphatic spread

This is both by permeation and emboli to the affected tiers (see below) of nodes. This may be extensive, the tumour even appearing in the supraclavicular nodes (Tosier’s sign). Unlike malignancies such as breast cancer, nodal involvement does not imply systemic dissemination.

#### Blood-borne metastases

This occurs first to the liver and subsequently to other organs including lung and bone. This is uncommon in the absence of extensive nodal disease.

#### Trans peritoneal spread

This is a common mode of spread once the tumour has reached the serosa of the stomach and indicates incurability. Tumours can manifest anywhere in the peritoneal cavity and commonly give rise to ascites. Advanced peritoneal disease may be palpated either abdominally or rectally as a tumour ‘shelf’. The ovaries may sometimes be the sole site of transcoelomic spread (Krukenberg’s tumours). Tumour may spread via the abdominal cavity to the umbilicus (Sister Joseph’s nodule).

### Lymphatic drainage of the stomach

Understanding the lymphatic drainage of the stomach is the key to comprehending the radical surgery of gastric cancer. The lymphatics of the antrum drain into the right gastric suprapyloric nodes superiorly and the subpyloric lymph nodes situated around the gastroduodenal artery inferiorly. The efferent lymphatics from suprapyloric lymph nodes converge on the para aortic nodes around the coeliac axis, while the efferent lymphatics from the subpyloric lymph nodes pass up to the main superior mesenteric lymph nodes situated around the origin of the superior mesenteric artery. The lymphatic vessels related to the cardiac orifice of the stomach communicate freely with those of the oesophagus.

Whether or not there is histological evidence of regional lymph node involvement affects the prognosis of operable cases of carcinoma of the stomach. Retrograde (downward) spread may occur if the upper lymphatics are blocked. In Japan the lymph node dissection is highly advanced and the Japanese Society for Gastric Cancer has assigned a number to each lymph node station to aid the pathological staging (Fig. 51.32). Many centres in the West now perform surgery that involves a radical lymphadenectomy, but in others both the staging and surgery are inadequate.

### Operability

It is important that patients with incurable disease are not subjected to radical surgery that cannot help them. Un-equivocal evidence of incurability is haematogenous metastases, involvement of the distant peritoneum, N4 nodal disease and disease beyond the N4 nodes, and fixation to structures that cannot be removed. It is important to note that involvement of another organ per se does not imply incurability provided that it can be removed. Controversies with respect to operability include N3 nodal involvement and involvement of the adjacent peritoneum. Curative resection should be considered on the remaining patients.

### Total gastrectomy

This is best performed through a long upper midline incision. The stomach is removed en bloc including the tissues of the entire greater omentum and lesser omentum (Fig. 51.33). In commencing the operation the transverse colon is completely separated from the greater omentum. The dissection may then be commenced either proximally or, more usually, distally. The subpyloric nodes are dissected and the first part of the duodenum is divided, usually with a surgical stapler. The hepatic nodes are dissected down to clear the hepatic artery; this dissection also includes the suprapyloric nodes. The right gastric artery is taken on the hepatic artery. The lymph node dissection is continued to the origin of the left gastric artery which is divided flush with its origin. The dissection is continued along the splenic artery taking all of the nodes at the superior aspect of the pancreas and in the splenic hilum. Separation of the stomach from the spleen, if this organ is not going to
he removed, is carried out and this then allows access to the nodal tissues around the upper stomach and oesophagogastric junction. The oesophagus can then be divided at an appropriate point using a combination of stay sutures and a soft noncrushing clamp, usually of the right-angled variety. It is important that the resection margins are well clear of the tumour. Involvement of either proximal or distal resection margin carries an appalling prognosis and if in doubt frozen section should be performed. There is some controversy regarding the management of the spleen and distal pancreas in this procedure and this is discussed below.

Gastrointestinal continuity is reconstituted by means of a Roux loop. Other methods of reconstruction should be discouraged because of poor functional results. The Roux loop should be at least 50 cm long to avoid bile reflux oesophagitis. The simplest means of effecting the oesophagojejunalostomy is to place a purse string in the cut end of the oesophagus and, using a circular stapler introduced through the blind end of the Roux loop, staple the cut end of the oesophagus on to the side of the Roux loop. The blind open end of the Roux loop may then be closed either with sutures or, alternatively, with a linear stapler. The anastomosis can also be fashioned end to end. The Roux loop may placed in either an anticoelic or retrocoelic position. The jejunojejunostomy is undertaken at a convenient point in the usual fashion (end to side, Fig. 51.34).

There remains some controversy about the extent of the lymphadenectomy required for the optimal treatment of curable gastric cancer. In Japan a D2 gastrectomy (removal of the second tier of nodes) at least is performed on all operable gastric cancer and some centres are practising more radical surgery (D3 and even D4 resections). Certainly, the results of surgical treatment stage for stage in Japan are much better than commonly reported in the West, and the Japanese contention is that the difference is principally related to the staging and the quality of the surgery. It is observed that the build of the average Japanese patient favours the performance of more radical procedures compared with the average patient in the West. However, radical lymphadenectomies above D2 have not been subjected to any randomised controlled trials. In the UK and Europe randomised trials have been set up to compare D1 and D2 gastrectomy but the results are difficult to interpret. One of the problems relates to standardisation of the operation. Overall, it seems that the oncological outcome may be better following a D2 gastrectomy but this operation is associated with higher levels of morbidity and perioperative mortality. It is clear that most of this morbidity and mortality relates to the removal of the spleen with or without the distal pancreas. The traditional radical gastrectomy removes the spleen and distal pancreas en bloc with the stomach and, although this is indeed an adequate means of performing clearance of the lymph nodes around the splenic artery, there seems now little doubt that adding this substantially increases the complication rate. The Japanese D2 gastrectomy will commonly preserve spleen and pancreas.

The differentiation between a D1 and a D2 operation depends upon the tiers of nodes removed. Different tiers need to be removed depending on the positions of primary tumour and this is outlined in Table 51.6. In general, a D1 resection involves the removal of the perigastric nodes and a D2 resection involves the clearance of the major arterial trunks.

**Subtotal gastrectomy**

For tumours distally placed in the stomach it appears unnecessary to remove the whole stomach. The operation, however, is very similar to that of a total gastrectomy except that the proximal stomach is preserved, the blood supply being derived from the short gastric arteries. Following the resection the simplest form of reconstruction is to close the stomach from the lesser curve near the oesophagogastric junction with either sutures or staples and then perform an anastomosis of the greater curve to the jejunum. Although this can be performed as in a Billroth II/Polya-type gastrectomy, this reconstruction results in quite marked enterogastric reflux and bile reflux oesophagitis, and the preferred reconstruction is to perform the reconstruction using a Roux loop.

**Palliative surgery**

In patients suffering from significant symptoms of either obstruction or bleeding, palliative resection is appropriate. A palliative gastrectomy need not be radical and it is sufficient to remove the tumour and reconstruct the gastrointestinal tract. Sometimes it is impossible to resect an obstructing tumour in the distal stomach and other palliative procedures need to be considered, although the prognosis in such patients, even in the short term, is poor. A high gastroenterostomy is a bad operation that very frequently does not allow the stomach to empty adequately but may produce the additional problem of bile reflux. A Roux loop with a wide anastomosis between the stomach and jejunum may be a better option, although even this may not allow the stomach to empty particularly well. Gastric exclusion and oesophagojejunalostomy is practised by some surgeons. For inoperable tumours situated in the cardia either palliative intubation, stenting or another form recanalisation can be used (Chapter 50).

**Postoperative complications of gastrectomy**

Radical gastrectomy is complex major surgery and predictably there is a large number of potential complications of the operation. Leakage of the oesophagojejunalostomy should be uncommon in experienced hands. When it occurs it can often be managed conservatively as the Roux-en-Y reconstruction means that it is mainly saliva and ingested food that leaks. Some patients may establish a fistula from the wound or drain site and others may need radiological or surgically placed drains. It is unclear whether a nasoenteric tube should be used routinely. Many surgeons use such tubes routinely but this is not supported by any evidence base. It is common practice to perform a water-soluble contrast swallow at 5–7 days after the operation to determine whether the anastomosis is intact, and finding a small radiological leak is not uncommon. It is unusual to detect a major leak in the absence of clinical signs.

With any gastrectomy, leakage from the duodenal stump can occur. This is usually due to a degree of distal obstruction and care must be taken when performing the Roux-en-Y anastomosis that there is no kinking. Para-duodenal collections can be drained radiologically which will often convert the collection into an external fistula. Biliary peritonitis requires a laparotomy and peritoneal toilet, and in this circumstance it is best to leave a Foley catheter in the duodenum to establish a controlled duodenal fistula. If it is established that there is no distal obstruction, or any such obstruction is dealt with, then with time the fistula will close.

The presence of septic collections along with a very radical vascular dissection may lead to catastrophic secondary haemorrhage from the exposed or divided blood vessels. This situation may be very difficult to manage whether reoperation or interventional radiology is employed.

**Long-term complications of surgery**

It is surprising that, considering the radical nature of the total gastrectomy, many patients, particularly the younger ones, have a good functional results. Most patients, however, will have a reduced capacity particularly in the short term. They need to be given detailed nutritional advice, the substance of which is to eat small meals and often while the jejunum or small gastric remnant adapts. There is, in fact, very little functional difference between patients who have a total and subtotal gastrectomy. Various attempts have been made to try and improve the short-term functional results by forming a jejunal pouch and attaching this to the oesophagus. Most surgeons do not perform this as in the long term there seems little functional advantage. It is surprising that these patients only infrequently suffer from the complications of gastric surgery such as dumping and diarrhoea. Nutritional deficiencies may occur and the patient should be monitored with this in view. The loss of the parietal mass leads to vitamin B12 deficiency and replacement should be given routinely.
Outlook after surgical treatment

The outlook after surgical treatment varies considerably between the West and Japan. In Japan, approximately 75 per cent of patients will have a curative resection and of these the overall 5-year survival rate will be in the region of 50—70 per cent. By contrast, in the West most series show that only 25—50 per cent of patients undergoing surgery will have a curative operation and the 5-year survival rate in such patients is only about 25—30 per cent, although in some series it approaches Japanese levels. These figures need some qualification to explain the differences in outcome between patients with gastric cancer in the West and in Japan. The allegation by some authors, not surprisingly all in the West, that gastric cancer is a somewhat different disease in Japan and that such differences explain the better outcome has no basis in evidence. Indeed, all of the studies in which the molecular pathology of gastric cancer has been studied suggest quite the reverse. A combination of differences in staging and a higher standard of surgery in Japan probably accounts for the differences. Staging is clearly crucial when survival figures are being compared. The more thorough the staging the higher the stage is likely to be and therefore stage for stage the outcome seems better in patients who are adequately staged pathologically. This phenomenon is termed ‘stage migration. Studies in the UK have shown that the lymph node yield after gastrectomy is minute in comparison to Japan. The pathologist will have considerable difficulty orientating a fixed specimen and finding lymph node groups, and therefore the optimal approach is for the surgeon to dissect the nodes from the specimen and send them separately to the pathologist, a practice commonly followed in Japan. Only in this way can an accurate staging be achieved.

Other treatment modalities

Because of the failure of radical surgery to cure advanced gastric cancer there has been an interest in the use of radio-therapy and chemotherapy.

Radiotherapy

The routine use of radiotherapy has not been supported by clinical trials. There is a number of radiosensitive tissues in the region of the gastric bed which limit the dose that can be given; this may partly explain the disappointing results. Radiotherapy has a role in the palliative treatment of painful bony metastases.

Chemotherapy

Gastric cancer may respond well to combination cytotoxic chemotherapy, and interest now focuses on the utility of such treatment in improving outcome. In treating advanced gastric cancer there is a number of well-investigated regimes but the best results are currently obtained using a combination of epirubicin, cisplatinum and 5-FU (5-fluorouracil) (ECF) by continuous infusion. A significant proportion of patients will respond to this regimen and, although studies comparing best supportive care with chemotherapy are not abundant, there is a consensus that improvement in survival of several months at least can be achieved by treatment. However, combination chemotherapy of this type is quite intensive and such benefits have to be set against the morbidity associated with chemotherapy. Systemic adjuvant chemotherapy has been investigated in a number of trials and has proved disappointing.

However, many patients in these studies have not actually completed the course of chemotherapy and the total dose given was rather low compared with the regimens used for advanced disease. Good results have been obtained in Japan from the use of mitomycin C-impregnated charcoal given by the intraperitoneal route. The rationale for this is that this is taken up by the peritoneal lymphatics and may target the principal site of recurrence, which is the gastric bed. This treatment has not been widely used in the West. There is current interest in neoadjuvant chemotherapy given with a view to down-staging gastric cancer prior to surgical resection. Whether treatment of this type is effective awaits the results of randomised trials.

Pattern of relapse following surgical treatment

As might be expected, the most common site of relapse following radical gastrectomy is the gastric bed and represents inadequate extirpation of the primary tumour. Widespread nodal intraperitoneal metastases, distant nodal metastases and liver metastases are all common. Dissemination to the lung and bones usually only occurs after liver metastases are already established.
Gastric stromal tumours

Previously named leiomyoma and leiomyosarcoma, the rather bland name of stromal tumour is now used because the biological behaviour of these tumours is unpredictable. Although it is reasonably straightforward for a pathologist to say that one particular lesion has a benign appearance and, at the other extreme, a tumour is highly malignant, there is a large number of tumours in which the distinction between benign and malignant is unclear. In general terms the larger the tumour and the greater mitotic activity the more likely it is to metastasise. Within the gastrointestinal tract the stomach is the commonest site for such tumours.

The incidence of the condition is unclear as small stromal tumours of the stomach are probably quite common and remain unnoticed. Clinically obvious tumours are considerably less common than gastric cancer. The aetiology is unknown.

The only way that many stromal tumours are recognised is either that the mucosa overlying the tumour ulcerates (Fig. 51.26) leading to bleeding or that they are noticed incidentally at endoscopy. Because the mucosa overlying the tumour is normal, endoscopic biopsy can be uninformative unless the tumour has ulcerated. The appearance on barium meal is usually typical. Larger tumours present with nonspecific gastric symptoms and in many instances may initially be thought to be gastric cancer.

As the biological behaviour is difficult to predict the best guide is to consider the size of the tumour. Smaller tumours can be treated by wedge excision but larger ones require a gastrectomy. By their nature these tumours spread via the blood, and lymphatic metastases are relatively uncommon.

Common sites of spread include the liver, lungs and bone. Surgery is the only treatment modality that can cure the disease; adjuvant chemotherapy has not been shown to be beneficial. These tumours sometimes respond to systemic chemotherapy, but this is palliative.
Gastric lymphoma

Gastric lymphoma is an interesting disease and some aspects of the management are controversial. It is first important to distinguish primary gastric lymphoma from involvement in the stomach in a generalised lymphomatous process. This latter situation is more common than the former. Unlike gastric carcinoma, the incidence of lymphoma seems to be increasing. Primary gastric lymphoma accounts for approximately 5 per cent of all gastric neoplasms.

Gastric lymphoma is the most common in the sixth decade and the presentation is no different from gastric cancer, the common symptoms being pain, weight loss and bleeding. Acute presentations of gastric lymphoma such as haematemesis, perforation or obstruction are not common. Primary gastric lymphomas are B-cell-derived, the tumour arising from the mucosa-associated lymphoid tissue (MALT). Primary gastric lymphoma remains in the stomach for a prolonged period before involving the lymph nodes. At an early stage the disease takes the form of a diffuse mucosal thickening which may ulcerate. Diagnosis is made as a result of the endoscopic biopsy and seldom on the basis of the endoscopic features alone, which are not specific.

Following diagnosis adequate staging is necessary, primarily to establish whether the lesion is a primary gastric lymphoma or part of more generalised process. A CT scan of the chest and abdomen and bone marrow aspirate are required, as well as a full blood count.

Although the treatment of primary gastric lymphoma is somewhat controversial, it seems most appropriate to use surgery alone for the localised disease process. No benefit has been shown from adjuvant chemotherapy, although some oncologists contend that primary gastric lymphoma can be treated by chemotherapy alone. Chemotherapy alone is appropriate for patients with systemic disease.

Some of the more controversial aspects of gastric lymphoma concern the role of *H. pylori*. Lymphocytes are not found to any degree in normal gastric mucosa but are found in association with *Helicobacter* infection. It has also been shown that early gastric lymphomas may regress and disappear when the *Helicobacter* infection is treated (Iissacson). This is an extremely surprising finding as it suggests that the neoplasm, which is demonstrably mono-clonal, may be a response to the infective agent. It may be that the immunological response to the organism, probably a T-cell-related process, is important in maintaining the B-cell malignancy.

Gastric involvement with the diffuse lymphoma

These patients are treated with chemotherapy, sometimes with dramatic and rapid responses. Surgeons are frequently asked to deal with the complications of gastric involvement. The two common complications are bleeding and perforation. Both may occur at presentation but more usually may follow the chemotherapy when there is rapid regression and necrosis of the tumour. These operations can be technically very challenging and normally require gastrectomy.
Duodenal tumours

Benign duodenal tumours

Duodenal villous adenomas occur principally in the periampullary region. Although generally uncommon, they are often found in patients with familial adenomatous polyposis. Indeed, malignant transformation in such adenomas is the commonest cause of death in patients with polyposis who have had the colon removed. The appearances are similar to those adenomas arising in the colon and, as they have malignant potential, should be locally excised with histologically clear margins.

Endocrine tumours

A number of endocrine neoplasms occurs in the duodenum. It is a common site for primary gastrinoma (Zollinger—Ellison syndrome). Other endocrine tumours include carcinoid tumours that, by comparison with ileal carcinoids, are uncommon.

Zollinger—Ellison syndrome

This syndrome is mentioned here because the gastrin-producing endocrine tumour is often found in the duodenal loop, although it also occurs in the pancreas, especially the head. It is a cause of persistent peptic ulceration. Before the development of potent gastric antisecretory agents the condition was recognised by the sometimes fulminant peptic ulceration which did not respond to gastric surgery short of total gastrectomy. It was also recognisable from gastric secretory studies in which the patient had a very high basal acid output but no marked response to pentagastrin, as the parietal cell mass was already near maximally stimulated by pathological levels of gastrin. The advent of proton pump inhibitors such as omeprazole has rendered this extreme endocrine condition fully controllable, but also less easily recognised.

Gastrinomas may be either sporadic or associated with the autosomal dominantly inherited multiple endocrine neoplasia (MEN) type I (in which a parathyroid adenoma is almost invariable). The tumours are most commonly found in the ‘gastrinoma triangle’ (Passaro) defined by the junction of the cystic duct and common bile duct superiorly, the junction of the second and third parts of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially (essentially the superior mesenteric artery). Many are found in the duodenal loop, presumably arising in the G cells found in Brunner’s glands. It is extremely important that the duodenal wall is very carefully inspected endoscopically and also at operation. Very often all that can be detected is a small nodule which projects into the medial wall of the duodenum.

Even malignant sporadic gastrinomas may have a very indolent course. The palliative resection of liver metastases may be beneficial and liver transplantation is practised in some centres, as for other gut endocrine tumours, with reasonable long-term results. However, the minority of tumours found to the left of the superior mesenteric artery (outside the ‘triangle’) seems to have a worse prognosis, more having liver metastases at presentation. In MEN type I the tumours may be multiple and the condition is incurable. Even in this situation, as with sporadic gastrinoma, surgical treatment should be employed to remove any obvious tumours and associated lymphatic metastases as the palliation achieved may be extremely gratifying.

Duodenal adenocarcinoma

Although uncommon, this is the commonest site for adenocarcinoma arising in the small bowel. Most tumours originate in the periampullary region and commonly arise in pre-existing villous adenomas. Patients present with anaemia due to ulceration of the tumour or obstruction as the polypoid neoplasm begins to obstruct the duodenum. Direct involvement in the ampulla leads to obstructive jaundice. Histologically, the lesion is a typical adenocarcinoma and the metastases are commonly to regional lymph nodes and the liver. At presentation about 70 per cent of the patients have resectable disease and for those who survive operation the 5-year survival rate is in the region of 20 per cent, this approximately equating to cure. Poor prognostic features in the resected specimen include regional lymph node metastases, transmural involvement and perineural invasion. Curative surgical treatment will normally involve a pancreatecto-duodenectomy (Whipples procedure). Patients with familial polyposis, which is due to a mutation in the APC gene on chromosome 5, are predisposed to periampullary cancer which is one of the most common causes of death in patients who have had their colon removed.

Other duodenal malignancies are rare.
Duodenal obstruction

Duodenal obstruction in the adult is usually due to malignancy, and cancer of the pancreas is the most common cause. About one-third of patients with pancreatic cancer treated by endoscopic stenting will develop obstruction. Treatment is by gastroenterostomy. In patients having a surgical biliary bypass for pancreatic cancer gastric drainage may be necessary.

A variety of other malignancies can cause duodenal obstruction including metastases from colorectal and gastric cancer. Primary duodenal cancer is much less common as a cause of obstruction than these other malignancies.

Annular pancreas may rarely cause duodenal obstruction. Obstruction usually follows an attack of pancreatitis and on occasions the obstruction may be mistaken for malignancy. Arteriomesenteric compression is an ill-defined condition in which it is proposed that the fourth part of the duodenum is compressed between the superior mesenteric artery and the vertebral column. Where it is convincingly demonstrated and causing weight loss duodenolecjunostomy may be performed.

Gastroplasty for morbid obesity

A number of surgical treatments has been devised for morbid obesity, but of these the most commonly used is the vertical banded gastroplasty (Mason). Some surgeons prefer a gastric bypass operation which has some similarities. Indeed, gastric bypass can be used as a revisional procedure following stomal obstruction, one of the more common complications of gastroplasty.

Indications for operation

Selection of patients for operation should ideally be made by a team that includes a nutritionist/endocrinologist and a psychiatrist, as well as a surgeon, as it is important that major metabolic problems and severe psychiatric disorders are elucidated before operation. The patient should be 100 per cent over their ideal weight for height or have a body mass index (weight (kg)/height (m)\(^2\)) of greater than 45. This figure is selected because the increase in morbidity and mortality at this level of obesity is excessive. Very often the patient will have some of the morbidity associated with severe obesity such as hypertension, diabetes or osteo-arthritis. Preoperative counselling should include discussion of the possibility of perioperative mortality (which is in the region of 1—4 per cent). This is very much an elective procedure and the patient is at risk of postoperative respiratory problems and pulmonary thromboembolism. Intensive or high-dependency care facilities must be available.

Operation

The operation is performed under general anaesthesia and the addition of an epidural greatly aids both the perioperative and postoperative management. The procedure should be undertaken by an anaesthetist very experienced in this area.

The abdomen is opened from the midline incision and adequate retraction provided to gain access to the upper part of the stomach. Approximately 50 per cent of patients will already have gallstones and, if this is the case, cholecystectomy should be carried out. Some surgeons advocate prophylactic cholecystectomy but this is difficult to substantiate. A large orogastric tube is placed in the stomach and the lesser sac is opened through the greater omentum by careful blunt dissection. A window is made between the lateral side of the oesophagus and the lesser sac (Fig. 51.35). It is important to take great care during this part of the operation to avoid damaging the spleen or short gastric arteries. Once this has been carried out it is convenient to place a tape through this window to avoid losing access. A position is selected on the anterior wall of the stomach above the level of the incisura. A circular stapler with the head removed and the spike inserted is placed in the lesser sac with edge of the instrument up against the tube in the stomach. The handle of the stapler is then rotated to introduce the spike through the front and back wall of the stomach. Once this has been done the spike can be removed and the anvil of the stapler inserted in the usual fashion. Tightening up and firing the stapler produces a stapled circular defect in the mid body of the stomach with the space about 15 mm between the lesser curve and the window. Following this a stapler, such as the Auto suture TA90B, is inserted through the circular window and through the gap made at the lateral side of the oesophagus. This instrument is particularly recommended as it places four rows of staples in the stomach (Fig. 51.35) which greatly reduces the possibility of staple line disruption. These manoeuvres lead to the creation of a pouch of about 30 ml, the volume being checked before the linear stapler is fired. It is then important to band the outlet of this pouch to avoid dilatation with time. A number of materials may be used including polypropylene mesh and expanded polytetrafluoroethylene (PTFE). Whatever material is used, the width should be approximately 1.5 cm and the circumference of the band about 5 cm. It has been shown in a variety of studies that if the band has a larger circumference than this there is a high incidence of inadequate weight loss, and if it made as small as 4.5 cm there is a high incidence of stomal stenosis. The exact dimensions of the band, however, are a critical part of the operation and the experience of the surgeon will often subtly alter the band circumference.

Postoperatively the patients should be managed on an intensive care or a high-dependency care unit until the possibility of anogastric and other complications is diminished. Epidural anaesthesia is useful as it avoids the amount of opiate given to the patient. The patient may be introduced to fluids on the first postoperative day and small quantities of food around the fourth or fifth day. Dietary advice is very important at this point. It is important that the patient understands that liquidized food or high-calorie supplements ate to be avoided and that only small quantities of food are to be eaten to avoid blocking the narrow pouch outlet.

Patients can be expected to lose between a third and a half of their body weight in the 2 years following operation. Over this period it is advisable to take a vitamin supplement to avoid deficiencies which may otherwise occur. Following the first 2 years it is possible for the patient to begin weight gain, and it is important that they understand that moderation and self-control will be necessary in the long term. This is often possible because after 2 years the patient’s eating habits have been quite radically changed and the apparently insurmountable task of losing almost a half of their body weight has been overcome.

Complications

Pulmonary embolism is a risk for all such patients and hence they should be managed with adequate doses of prophylaxis (5000 units of heparin tid). Although it might be expected that wound herniation would be a common sequel of this operation, in practice if the abdominal wound is repaired well with a continuous nonabsorbable suture such problems are not uncommon. As with any procedure that involves opening the gastrointestinal tract, prophylactic antibiotics are important. Unlike small bowel bypass, vertical banded gastroplasty is not associated with major metabolic consequences or liver disease. The two commonest long-term complications are inadequate weight loss, which usually relates either to technical aspects of the procedure or to patient noncompliance, and stomal stenosis which may occur if the band is too tight or if fibrosis occurs in this region. The former complication can be dealt with only by revisional surgery. Stomal stenosis can be treated endoscopically by balloon dilatation, although very often this is unsuccessful in the long term.
Other gastric conditions

Acute gastric dilatation

This condition usually occurs in association with some form of ileus which is not treated by nasogastric suction. The stomach, which may also be atonic, dilates enormously. Often the patient is also dehydrated and has electrolyte disturbances. Failure to treat this condition can result in a sudden massive vomit with aspiration into the lungs. The treatment is nasogastric suction, fluid replacement and treatment of the underlying condition.

Trichobezoar and phytobezoar

Trichobezoar (hair balls) (Fig. 51.36) are unusual and are virtually exclusively found in female psychiatric patients, often young. It is caused by the pathological ingestion of hair which remains undigested in the stomach. The hair ball can lead to ulceration and gastrointestinal bleeding, perforation or obstruction. The diagnosis is made easily at endoscopy or, indeed, from a plain radiograph. Treatment consists of removal of the bezoar which may require open surgical treatment. Phytobezoars are made of the vegetable matter and found principally in patients who have gastric stasis.

Foreign bodies in the stomach

A variety of ingested foreign bodies reaches the stomach and very often these can be seen on a plain radiograph. If possible they should be removed endoscopically but if not most can be left to pass normally. Even objects such as needles, with which there is understandable anxiety, will seldom cause harm. In general, an object which leaves the stomach will pass spontaneously. By contrast, attempted removal at laparotomy can be very difficult as the object may be much more difficult to find than might be expected. Most adults who swallow foreign bodies have ill-defined psychiatric problems and may appear to relish the attention associated with serial laparotomies. The treatment should therefore be expectant and intervention reserved for patients with symptoms in whom the foreign body is failing to progress.

Volvulus of the stomach

Rotation of the stomach usually occurs around the axis and between its two fixed points, i.e. the cardia and the pylorus. In theory, rotation can occur in the horizontal (organoaxial) or vertical (mesenterioaxial) direction but commonly it is the former which occurs. This condition is usually associated with a large diaphragmatic defect around the oesophagus (paraoesophageal herniation) (Fig. 51.37). What commonly happens is that the transverse colon moves upwards to lie under the left diaphragm, thus taking the stomach with it, and the stomach and colon may both enter the chest through the evagination of the diaphragm. The condition is commonly chronic, the patient presenting with difficulty in eating. An acute presentation with ischaemia may occur.

Endoscopically, it can be extremely difficult to sort out the anatomy and this is one situation in which the contrast radiograph is superior.

Treatment

If the problem is causing symptoms then surgical treatment is the only satisfactory approach. Traditionally open surgery has been employed but this problem is suitable for laparoscopic treatment if appropriate skill is available. If there is a hernia, the sac and its contents (usually the stomach) should be reduced. The defect in the diaphragm should be closed, if necessary, with a mesh. It is advisable to separate the stomach from the transverse colon and then perform an anterior gastropexy to fix the stomach to the anterior abdominal wall. The results from this treatment are good.

Anatomy of the liver

General

The liver is the largest organ in the body, weighing 1.5 kg in the average 70-kg male. Its position under the right hemidiaphragm allows it to be protected from trauma by the costal margin. The liver parenchyma is entirely covered by a thin capsule and by visceral peritoneum in all but the posterior surface of the liver, termed the 'bare area'. At first appearance the liver is divided into two main lobes: a large right lobe which comprises three-quarters of the liver parenchyma and a smaller left lobe the remaining quarter. Surgical resection of these lobes would be termed a right or left lobectomy.

Ligaments and peritoneal reflections

The liver is fixed in the right upper quadrant by peritoneal reflections which form ligaments. On the superior surface of the left lobe is the left triangular ligament. Dividing the anterior and posterior folds of this ligament allows the left lobe to be mobilised from the diaphragm and the left lateral wall of the inferior vena cava (IVC) to be exposed. Large veins drain venous blood from the diaphragm to the hepatic veins and IVC at this level. The right triangular ligament fixes the entire right lobe of the liver to the undersurface of the right hemidiaphragm. Division of this ligament allows the liver to be mobilised from the diaphragm and rotated to the left. Another major supporting structure is the falciform ligament, which runs from the umbilicus to the liver between the right and left lobes, passing into the interfossa. Embryologically this ligament contained the umbilical vein which carried maternal nutrients to the liver of the foetus. From the fissure it passes anteriorly on the surface of the liver attaching it to the posterior aspect of the anterior abdominal wall. On the superior aspect of the liver the falciform ligament divides into two leaves, between which is loose areolar tissue and some small vessels. Division of this layer allows exposure of the suprahepatic IVC lying within a thin sheath of fibrous tissue. The final peritoneal reflection is between the stomach and the liver. This lesser omentum is often thin and fragile but contains the hilar structures in its free edge.

Liver blood supply

The blood supply to the liver is unique, being derived 80 per cent from the portal vein and 20 per cent from the hepatic artery. The arterial blood supply in most individuals is derived from the coeliac trunk of the aorta where the hepatic artery arises along with the splenic artery. After branching to form the gastroduodenal artery it branches at a very variable level to produce the right and left hepatic arteries. The right artery supplies the majority of liver parenchyma and is therefore the larger of the two arteries. There are many anatomical variations which are essential knowledge for safe surgery on the liver. The blood supply to the right lobe of the liver may be partly or completely supplied by a right hepatic artery arising from the superior mesenteric artery. This vessel passes posterior to the celiac and head of pancreas, and runs to the liver on the posterior wall of the bile duct. Similarly, the arterial blood supply to the left lobe of liver may be derived from the coeliac trunk via the left gastric branch. This vessel runs between the lesser curve of the stomach and the left lobe of the liver in the lesser omentum (Fig. 52.1).

Structures in the hilum of the liver

The hepatic artery, portal vein and bile duct are present within the free edge of the lesser omentum or the 'hepato-duodenal ligament'. To expose these structures requires the peritoneum overlying the hilar triad to be divided followed by division of small vessels and an extensive lymphatic plexus. The standard relationship of these three structures is for the bile duct to be within the free edge, the hepatic artery to be above and medial, and for the portal vein to lie posteriorly. Within this ligament the common hepatic duct is joined by the cystic duct at varying levels to form the common bile duct. The common hepatic artery branches at a variable level within the ligament to form two or often three main arterial branches to the liver. The right hepatic artery often crosses the bile duct anteriorly or posteriorly before giving rise to the cystic artery. Multiple small hepatic arterial branches provide blood to the bile duct, principally from the right hepatic artery. The portal vein arises from the joining of the splenic vein with the superior mesenteric vein behind the neck of pancreas. It rarely branches until close to the liver parenchyma but has some important tributaries, including the left gastric vein joining just above the pancreas and a tributary anteriorly from the head of pancreas.

Division of structures at the hilum

At the hilum the major structures are divided into right and left branches. The right and left hepatic ducts arise from the hepatic parenchyma and join to form the common hepatic duct. The left duct has a longer extra hepatic course of approximately 2 cm. Once within the liver parenchyma the duct accompanies the branches of the hepatic artery and portal vein within a fibrous sheath. The portal vein often gives off two large branches to the right lobe which are accessible outside the liver for a short length before giving rise to the cystic duct. The right hepatic artery arising from the superior mesenteric artery. This vessel passes posterior to the uncinate process and head of pancreas, and runs to the liver on the posterior wall of the bile duct. Similarly, the arterial blood supply to the left lobe of liver may be derived from the coeliac trunk via its left gastric branch. This vessel runs between the lesser curve of the stomach and the left lobe of the liver in the lesser omentum (Fig. 52.1).

Venous drainage of the liver

The venous drainage of the liver is via the hepatic veins into the IVC. The vena cava lies within a groove in the posterior wall of the liver. Above the liver it immediately penetrates the diaphragm to join the right atrium, whereas below the liver parenchyma there is a short length of vessel before the insertion of the renal veins. The inferior hepatic veins are short vessels which pass directly between the liver parenchyma and the anterior wall of the IVC. The major venous drainage is through three large veins which join the IVC immediately below the diaphragm. Outside the liver these vessels are sur-rounded by a thin fibrous layer. The right hepatic vein can be exposed fully outside the liver, but the middle and left veins usually join within the liver parenchyma. Immediately above the retro hepatic IVC lies the right kidney and adrenal gland. The right adrenal vein drains into the IVC at this level, usually via one main branch. The IVC can be mobilised fully from the retroperitoneal tissues and in the healthy state there are no significant vessels in this tissue plane. The right inferior phrenic vein often drains to the IVC via the right hepatic vein.

The internal anatomy of the liver

Safe liver surgery has been enormously facilitated by a better understanding of the internal anatomy of the liver which has been extensively investigated by the French anatomist Couinaud. He described the liver as being divided into eight segments (Fig. 52.2). Each of these segments can be considered as functional units, each with a branch of hepatic artery, portal vein and bile duct, and drained by a branch of the hepatic vein. The overall anatomy of the liver is divided into a functional right and left along the line between gallbladder fossa and the middle hepatic vein. Liver segments (V—VIII) to the right of this line are supplied by the right hepatic artery and the right branch of portal vein, and drain bile via the right hepatic duct. The liver parenchyma to the left of this line (segments I—IV) is functionally the left liver and is supplied by the left branch of the hepatic artery and the left portal vein branch, and drains bile via the left hepatic duct.

The hepatic lobules

The functional units within the liver segments are the liver lobules. These comprise plates of liver cells separated by the hepatic sinusooids,
large thin-walled venous channels which carry blood to the central vein, a tributory of the hepatic vein from the portal tracts which contains branches of the hepatic artery and portal vein. During passage through the sinusoids the many functions of the liver take place, including bile formation which is channeled in an opposite direction to the blood flow to drain via the bile duct tributaries within the portal tracts.

**Embryology**

The liver is a foregut structure and forms as a small endodermal bud early in gestation. The cell population within the bud grows rapidly and forms two cell populations which differentiate into the liver and extra hepatic biliary tree and gallbladder. The liver cells are bipotential and may develop into hepatocytes or intrahepatic ductal cells. The liver endothelium is derived from the vitelline and umbilical veins which merge with the endodermal bud to form the liver sinusoids. The supporting connective tissue, haemopoietic cells, which are important during intrauterine life, and the Kupffer cells are derived from the mesoderm of the septum transversum.
Signs and tests of acute and chronic liver disease

Liver function and tests

Adequate liver function is essential to survival; humans will survive for only 24—48 hours in the an hepatic state despite full supportive therapy. The main functions of the liver are shown in Table 52.1. Routinely available tests of liver function are shown in Table 52.2. Bilirubin is synthesised in the liver and excreted in the bile. Increased levels may be associated with increased haemoglobin breakdown, hepato-cellular dysfunction resulting in impaired bilirubin transport and excretion or from biliary obstruction. In patients with known parenchymal liver disease progressive elevation of bilirubin level in the absence of a secondary complication suggests deterioration in liver function. The serum alkaline phosphatase is particularly elevated with cholestatic liver dis-ease or biliary obstruction. The transaminase levels [aspartate transaminase (AST) and alanine transaminase (ALT)] reflect acute hepatocellular damage, as does the gamma-glutamyl transpeptidase (GGT) level which may be used to detect the liver injury associated with acute alcohol ingestion. The syn-thetic functions of the liver are reflected in the ability to synthesise proteins (albumin level) and clotting factors (pro-thrombin time). The standard method of monitoring liver function in patients with chronic liver disease is serial measurements of bilirubin, albumin and prothrombin time.

Signs of impaired liver function

The clinical signs associated with impaired liver function depend on the severity of dysfunction and whether it is acute or chronic.

Acute liver failure

The main causes of acute liver failure are shown in Table 52.3. In the early stages there may be no objective signs, but with severe dysfunction the onset of clinical jaundice may be associated with neurological signs of liver failure consisting of a liver flap, drowsiness, confusion and, eventually, coma. Treatment in the majority of cases is supportive therapy to allow the liver to recover from the acute damage. This may include intravenous fluids and nutrition, renal support with haemofiltration, antibiotics for secondary infective episodes, sedation and ventilation for the development of hepatic coma, and mannitol for cerebral oedema. The overall mortality for acute liver failure is approximately 50 per cent, even with the best the supportive therapy. Liver transplantation is appropriate for some patients with acute liver failure, although the overall results are poor in comparison to liver transplantation for chronic liver disease. Indications for orthotopic (OLT) liver transplantation, based on the King’s College London transplant experience, are given in Table 52.4.

Chronic liver disease

Because of the many diverse functions of the liver, patients with chronic liver disease may present in many different ways. Lethargy and weakness are common features irrespective of the underlying cause. Often this precedes clinical jaundice which indicates the liver’s inability to metabolise bilirubin. The serum level reflects the severity of the underlying liver disease. Progressive deterioration in liver function is associated with a hyperdynamic circulation involving a high cardiac output, large pulse volume, low blood pressure and flushed warm extremities. Fever is a common feature which may be related to underlying inflammation and cytokine release from the diseased liver or due to bacterial infection to which patients with chronic liver disease are predisposed. Skin changes may be evident, including spider naevi, cutaneous vascular abnormalities which blanch on pressure, palmar erythema and white nails (leuconychia). Endocrine abnormalities are responsible for hypogonadism and gynaecomastia. The mental derangement associated with chronic liver disease is termed ‘hepatic encephalopathy’. This is associated with memory impairment, confusion, personality changes, altered sleep patterns and slow slurred speech. The most useful clinical sign is the flapping tremor demonstrated by asking the patient to extend his arms and hyperextend the wrist joint. Abdominal distension due to ascites is a common late feature. This may be suggested clinically by the demonstration of a fluid thrill or shifting dullness. Protein catabolism produces loss of muscle bulk and wasting, and a coagulation defect is suggested by the presence of skin bruising. A patient with the typical features of end-stage chronic liver disease is shown in Fig. 52.3. The Child’s classification allows an easy method of describing the severity of liver disease and allows comparison of treatments for patients with chronic liver disease (Table 52.5).
Imaging the liver

The major advances which have taken place over recent years in surgical approaches to the liver and the enormous improvement in the safety of liver surgery are due to the careful individualised planning of surgery which is possible owing to the information obtained by preoperative imaging. The ideal choice of imaging modality is determined by the likely liver pathology and the locally available equipment and radiological expertise.

Ultrasound

This is the first-line test owing to its safety and availability. It is entirely operator dependent. It is useful for determining bile duct dilatation, the presence of gallstones (Fig. 52.4) and the presence of liver turnouts. Doppler ultrasound allows flow in the hepatic artery, portal vein and hepatic veins to be assessed. In some countries it is used as a screening test for the development of primary liver turnouts in a high-risk population. Ultrasound is useful in guiding the percutaneous biopsy of a liver lesion.

Computerised tomography (CT)

The current ‘gold standard’ for liver imaging is triple-phase spiral CT. This provides fine detail of liver lesions down to less than 1 cm in diameter and gives information on their nature (Fig. 52.5). Oral contrast enhancement allows visualisation of the stomach and duodenum in relation to the liver hilum. The early arterial phase of the intravenous contrast vascular enhancement is particularly useful for detecting small liver turnouts owing to their preferential arterial blood supply. The venous phase maps the branches of the portal vein within the liver and the drainage via the hepatic veins. Inflammatory liver lesions often exhibit rim enhancement with intravenous contrast, whereas the common haemangioma characteristically shows late venous enhancement. The density of any liver lesion can be measured, which can be useful in establishing the presence of a cystic lesion.

Magnetic resonance imaging (MRI)

MRI (Fig. 52.6) would appear to be as effective an imaging modality as CT in the majority of patients with liver disease. It does, however, offer several advantages. First, many patients are precluded from iodine-containing intravenous contrast agents because of a history of allergy. These patients should be offered MRI rather than contrast CT. Second, magnetic resonance cholangiopancreatography (MRCP) can produce excellent quality imaging of the biliary tract noninvasively. The image quality is currently below that available from endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) but this is rapidly improving. Currently, it should be considered for diagnostic questions where ERCP has failed or is impossible due to previous surgery. Magnetic resonance angiography (MRA) similarly provides high-quality images of the hepatic artery and portal vein without the need for arterial cannulation. It is used as an alternative to selective hepatic angiography for diagnosis. It is particularly useful in patients with chronic liver disease and a coagulopathy in whom the patency of the portal vein and its branches is in question.

Endoscopic retrograde cholangiopancreatography

ERCP (Fig. 52.7) is required in patients with an obstructive pattern of liver function tests or in whom imaging has suggested an abnormality of the biliary tract. A preoperative check of coagulation is essential, along with prophylactic antibiotics and an explanation of the main complications which include pancreatitis, cholangitis and bleeding or perforation of the duodenum related to sphincterotomy. Endoluminal ultrasound of the biliary tract is possible using a ‘baby’ scope, and may provide additional information on the extent of hilar tumours. Therapeutic interventions are also possible at the time of ERCP and include stone retrieval, balloon dilatation of strictures, endoprosthesis insertion and brush cytology of turnouts to provide a tissue diagnosis.

Percutaneous transhepatic cholangiography

PTC is indicated where endoscopic cholangiography has failed or is impossible, as in patients with previous Polya gastrectomy. It is often required in patients with hilar bile duct turnouts where endoscopic cholangiography fails to visualise the intrahepatic bile ducts (Fig. 52.7).

Angiography

Selective visceral angiography (Fig. 52.1) may be required both for diagnostic purposes and for therapeutic intervention. Prior to liver resection it may be used to visualise the anatomy of the hepatic artery to the right and left sides of the liver and to confirm patency of the portal vein. It can also provide additional information on the nature of a liver nodule, primary liver turnouts having a well-developed arterial blood supply. Therapeutic interventions include the occlusion of arteriovenous malformations, embolisation of bleeding sites in the liver and the treatment of liver turnouts (chemoembolisation).

Nuclear medicine scanning

Radioisotope scanning can provide diagnostic information which cannot be obtained by other imaging modalities. Iodidea is a technetium-99m (99mTc)labelled radionuclide which is administered intravenously, removed from the circulation by the liver, processed by hepatocytes and excreted in the bile. Imaging under a gamma camera allows uptake and excretion to be monitored in real time. These data are particularly useful where a bile leak or biliary obstruction is suspected and a noninvasive screening test is required. A sulphur colloid liver scan allows the liver’s Kupffer cell activity to be determined. This may be particularly useful to confirm the nature of a liver lesion, adenomas and haemangiomas having a lack of Kupffer cells and hence no uptake of sulphur colloid.

Laparoscopy and laparoscopic ultrasound

Laparoscopy is useful for the staging of hepatopancreatobiliary cancers. Lesions which have failed to be detected by conventional imaging are mainly peritoneal metastases and superficial liver tumours. Approximately 30 per cent of patients may have additional lesions detected by laparoscopy which have not been shown on good-quality planar imaging by CT or MRI. Laparoscopic ultrasound may increase this figure and provides additional information with liver tumours on their proximity to the major vessels and bile duct branches.

Fluorodeoxyglucose—position emission tomography

(FDG—PET)

This new imaging modality depends on the avid uptake of glucose by cancerous tissue in comparison to benign or inflammatory tissue. At
present it is mainly used to determine the nature of a mass lesion demonstrated on another form of imaging. Deoxyglucose is labelled with the positron emitter fluorine-18 ($^{18}$FDG) and this is administered to the patient prior to imaging by positron emission tomography (PET). A three-dimensional image of the whole body is obtained, highlighting areas of increased glucose metabolism (Fig. 52.8).
Liver trauma

**General**

Liver injuries are fortunately uncommon because of the liver’s position under the diaphragm protected by the chest wall. However, when they do occur they are serious injuries associated with a significant morbidity and mortality, even with prompt and appropriate management. Liver trauma will be divided into blunt trauma injuries which produce contusions, lacerations and avulsion injuries to the liver, and penetrating injuries, such as stab and gunshot wounds. The liver is typically one of many organs to be damaged, the chest or pericardium often being involved with penetrating injuries and the spleen or kidney with blunt trauma.

**Diagnosis of liver injury**

The liver is an extremely well-vascularised organ and blood loss is therefore the major early complication of liver injuries. Clinical suspicion of a possible liver injury is essential as a laparotomy by an inexperienced surgeon with inadequate preparation preoperatively is doomed to failure. All lower chest and upper abdominal stab wounds should be suspect, especially if considerable blood volume replacement has been required. Similarly, severe crushing injuries to the lower chest or upper abdomen often combine rib fractures, haemothorax and damage to the spleen and/or liver. Patients with a pene-trating wound will require a laparotomy and/or thoracotomy once active resuscitation is underway. Owing to the opportunity for massive ongoing blood loss and the rapid development of a coagulopathy, the patient should be directly transferred to the operating suite whilst blood products are obtained and volume replacement is ongoing. Patients with blunt trauma who are haemodynamically stable but have objective clinical signs, such as upper abdominal tenderness and guarding, should have an oral and intravenous contrast enhanced CT scan of the chest and abdomen. This will demonstrate evidence of parenchymal damage to the liver or spleen as well as associated traumatic injuries to their feeding vessels. Free fluid can also be clearly established and a diagnostic aspirate performed. The chest scan will help to exclude injuries to the great vessels and demonstrate damage to the lung parenchyma. Additional investigations which may be of value include peritoneal lavage, which can confirm the presence of haemoperitoneum, and laparoscopy, which can demonstrate an associated diaphragmatic rupture.

**Initial management of liver injuries**

**Penetrating**

The initial management of a patient with an upper abdominal penetrating injury is the basis of resuscitation. The initial survey assesses the patients airway patency, breathing pattern and circulation. Peripheral venous access is gained with two large-bore cannulae and blood sent for cross match of 10 units of blood, full blood count, urea and electrolytes, liver function tests, clotting screen, glucose and amylase. Initial volume replacement should be with colloid or 0-negative blood if necessary. Arterial blood gases should be obtained and the patient intubated and ventilated if the gas exchange is inadequate. Intercostal chest drains should be inserted if associated pneumothorax or haemothorax is suspected. Once initial resuscitation has been commenced the patient should be transferred to the operating theatre with further resuscitation being performed on the operating table. The necessity for fresh frozen plasma and cryoprecipitate should be discussed with the blood transfusion service immediately the patient arrives, as these patients rapidly develop irreversible coagulopathies due to a lack of fibrinogen and clotting factors. Standard coagulation profiles are inadequate to evaluate this acute loss of clotting factors, and factors should be given empirically, aided by the results of thromboelastography (TEG), if available (Fig. 52.9).

**Blunt trauma**

With severe blunt injuries the plan for resuscitation and management is as outlined above for penetrating injuries. For the patient whose vital signs are normal, imaging may be performed to evaluate further the nature of the injury. The basic surgical management differs between penetrating and blunt injuries thought to involve the liver. Penetrating injuries should be explored, whereas blunt injuries can be treated conservatively. The indication for discontinuing conservative treatment for blunt trauma would be evidence of ongoing blood loss despite correction of any underlying coagulopathy and the development of signs of generalised peritonitis.

**The surgical approach to liver trauma**

The surgical approach is partly dictated by the nature of the suspected injury. Good access is vital. A rooftop incision gives excellent visualisation of the liver and spleen and, if necessary, can be extended upwards for a median sternotomy. A stab incision in the liver can be sutured with a fine absorbable monofilament suture. If necessary, this can be facilitated by producing vascular inflow occlusion by placing an atraumatic bulldog clamp on the proximal vessel prior to repair with 5/0 or 6/0 Prolene suture. If unavoidable the hepatic artery may be ligated, although parenchymal necrosis and abscess formation will result in some individuals. Portal vein injuries should be repaired with 5/0 Prolene, again with exposure of the vessel being facilitated by the placement of an atraumatic vascular clamp. The blunt trauma of deceleration injuries often produces lacerations of the liver parenchyma adjacent to the anchoring ligaments of the liver. These may be amenable to suture with an absorbable monofilament suture. Again, inflow occlusion may facilitate this suturing and, if necessary, the sutures can be buttressed to prevent them cutting through the liver parenchyma. With more severe deceleration injuries a portion of the liver may be avulsed from anterior to posterior. These injuries are more complex as they are associated with a devitalised portion of the liver and often major injuries to the hepatic veins and IVC. The initial management of liver injuries is to pack the liver to produce haemostasis. This is effective for the majority of liver injuries if the liver is packed against the natural contour of the diaphragm by packing from below. Large abdominal packs should be used to ease their removal, and the abdomen closed to facilitate compression of the parenchyma. Care should be taken to avoid over-zealous packing as this may produce pressure necrosis on the liver parenchyma. Crush injuries to the liver often result in large parenchymal haematomas and diffuse capsular lacerations. Suturing is usually ineffective, and packing is the most useful method of providing haemostasis. Necrotic tissue should be removed, but poorly perfused but viable liver left in situ. If packing is necessary the patient should have the packs removed after 48 hours, and commonly no further surgical intervention is required. Antibiotic cover is advisable and full reversal of any coagulopathy is essential. If a major liver vascular injury was suspected at the time of the initial laparotomy then referral to a specialist centre should be considered. A common surgical approach under these circumstances would be to place the patient on vena-venous bypass using cannulae in the femoral vein via a long saphenous cutdown and being returned, via a roller pump, to the superior vena cava (SVC) via an internal jugular line. Veno-venous bypass allows the IVC to be safely clamped to facilitate caval or hepatic vein repair. A rapid-infuser blood transfusion machine facilitates the delivery of a large volume of blood instantaneously. Once prepared, the patient is re-laparotomised via the rooftop incision with a midline extension to the xiphisternum. The liver is mobilised by division of the supporting ligaments, and complete vascular isolation of the liver achieved by occluding the hilar inflow and the IVC above the renal veins and at the level of the diaphragm with atraumatic vascular clamps. Venous return is provided by the vena-venous bypass. Warm ischaemia of the liver is tolerated for up to 45 minutes, allowing sufficient time in a blood-free field for repair of injuries to the IVC or hepatic veins.

**Other complications of liver trauma**

By far the most important complication of blunt or penetrating trauma to the liver is sudden massive blood loss. There are, however, other
presentations and complications which require specific investigation and treatment. A subcapsular or intrahepatic haematoma requires no specific intervention and should be allowed to resolve spontaneously. Attempts to aspirate these lesions may result in the development of a liver abscess due to contamination. Abscesses may also form as a result of secondary infection of an area of extensive parenchymal ischaemia, especially after penetrating trauma. Treatment under these circumstances is with appropriate systemic antibiotics and aspiration under ultrasound guidance once the necrotic tissue has liquefied. Biliary fistulae are a rare but important complication of liver trauma and may be difficult to control. The main aspects to management are to drain any intraperitoneal bile collections externally by percutaneous drainage under ultrasound guidance. This is followed by endoscopic or percutaneous cholangiography to determine the site of the biliary fistula and decompress the biliary tree by nasobiliary drainage or endoprosthesis insertion. If this fails to control the fistula the affected portion of the liver may require to be resected. Late vascular complications include hepatic artery aneurysms and arteriovenous and arteriobiliary fistulae (Figure 52.10). These are best treated nonsurgically by a specialist hepatobiliary interventional radiologist. The feeding vessel can be embolised transarterially. Evidence of liver failure may be seen with extensive liver trauma. If the blood supply and biliary drainage of the liver are intact this will usually reverse with conservative supportive treatment.

Long-term outcome of liver trauma

The capacity of the liver to recover from extensive trauma is remarkable, and parenchymal regeneration occurs rapidly. Late complications are rare but the development of biliary tract strictures many years after recovery from liver trauma has been reported. The treatment depends on the mode of presentation and the extent and site of stricturing. A segmental or lobar stricture associated with atrophy of the corresponding area of liver parenchyma and compensatory hypertrophy of the other liver lobe may be treated expectantly. A dominant extra hepatic bile duct stricture associated with obstructive jaundice may be treated initially with endo-biliary balloon dilatation or stenting but will usually require surgical correction using a Roux-en-Y hepatodocho-jejunostomy.
Portal hypertension

An elevation in portal pressure is most commonly found accompanying liver cirrhosis, although it may be present in patients with extra hepatic portal vein occlusion, intrahepatic veno-occlusive disease or occlusion of the main hepatic veins [Budd—Chiari syndrome (BCS)]. As portal hypertension produces no symptoms it is usually diagnosed following presentation with decompensated chronic liver disease and encephalopathy, ascites or variceal bleeding.

Management of bleeding varices

General resuscitation

Varices usually present with the acute onset of a large volume haematemesis, the lower oesophagus being the most common site for variceal bleeding. The diagnosis may be suspected if the patient is known to have liver cirrhosis but needs to be confirmed following initial resuscitation of the patient. This involves obtaining peripheral and subsequently central venous access whilst adequate blood is obtained (initially 10 units). Liver function tests will reveal underlying liver disease and a coagulation profile will reveal any underlying coagulopathy. Vitamin K is administered (10 mg intravenously), but correction of a coagulopathy will require the administration of fresh frozen plasma. An associated thrombocytopenia is usually secondary to hypersplenism due to cirrhosis and is treated if the platelet count falls below 50 x 10^9/litre. Variceal bleeding is often associated with hepatic encephalopathy, and endoscopic evaluation under these circumstances may require sedation and mechanical ventilation. Bronchial aspiration is a frequent complication of variceal bleeding.

If the rate of blood loss prohibits endoscopic evaluation a Sengstaken—Blakemore tube may be inserted to provide temporary haemostasis. This is shown diagrammatically in (Fig. 52.11). Once inserted, the gastric balloon is inflated with 250 ml of air and retracted to the gastric fundus where the varices at the oesophagogastric junction are tamponaded by the subsequent inflation of the oesophageal balloon to a pressure of 40 mmHg. The two remaining channels allow gastric and oesophageal aspiration. An X-ray is used to confirm the position of the tube. The balloons should be temporarily deflated after 12 hours to prevent pressure necrosis of the oesophagus.

Drug treatment for variceal bleeding

Vasopressin has been the most extensively used drug for the initial control of variceal haemorrhage (20 units in 10 ml of 5per cent dextrose intravenously over 10 minutes). Nitro-glycerin (40 micro gram/min) may be as effective. Octreotide, the long-acting somatostatin analogue, has recently been evaluated and may have an important role.

Endoscopic treatment of varices

Initial treatment of oesophageal varices in most centres would be endoscopic sclerotherapy using 5 per cent ethanalamine olate. Banding has recently produced encouraging results and is associated with a lower incidence of oesophageal ulceration. The majority of variceal bleeds will respond to a single course of sclerotherapy. An early re-bleed is less likely to be controlled by further sclerotherapy and a third bleed only rarely.

Transjugular intrahepatic portosystemic stent shunts (TIPSS)

The emergency management of variceal haemorrhage has been revolutionised by the introduction of TIPSS in the early 1990s. Over a short period it has become the main treatment of variceal haemorrhage which has not responded to drug treatment and sclerotherapy. The shunts are inserted under local anesthetic, analgesia and sedation using fluoroscopic guidance and Ultrasoundography. Via the internal jugular vein and SVC a guide wire is inserted into a hepatic vein and through the hepatic parenchyma into a branch of the portal vein. The track through the parenchyma is then dilated with a balloon catheter to allow insertion of a metallic stent which is expanded once a satisfactory position is achieved (Fig. 52.12). A satisfactory drop in portal venous pressure is usually associated with good control of the variceal haemorrhage. The main early complication of this technique is perforation of the liver capsule which can be associated with fatal intraportal neceorrhage. TIPSS occlusion may result in further variceal haemorrhage and occurs more commonly in patients with well-compensated liver disease and good synthetic function. Post shunt encephalopathy is the confusional state caused by the portal blood bypassing the detoxification of the liver. It occurs in about 40 per cent of patients, a similar incidence to that found after surgical shunts. If severe, the lumen of the TIPSS can be reduced by insertion of a smaller stent. The main contraindication to TIPSS is portal vein occlusion. Care must be exercised in the positioning of the TIPS S in patients who may be subsequently considered for liver transplantation. Proximal placement may interfere with the caval anastomosis and too distal a placement may result in difficulty in reconstructing portal inflow to the graft. The main long-term complication to TIPSS is stenosis of the shunt, which is common (approximately 50 per cent at 1 year) and may present as further variceal haemorrhage.

Surgical shunts for variceal haemorrhage

The increasing availability of liver transplantation and TIPSS has greatly reduced the indications for surgical shunts. It is rarely considered for the acute management of variceal haemorrhage as the morbidity and mortality under these circumstances are high. The main current indication for a surgical shunt is a patient with Child’s grade A cirrhosis in whom the initial bleed has been controlled by sclerotherapy. Long-term beta-blocker therapy and chronic sclerotherapy or banding are the main alternatives.

Surgical shunts are an effective method of preventing re-bleeding from oesophageal or gastric varices as they reduce the pressure in the portal circulation by diverting the blood into the low-pressure systemic circulation. Shunts may be divided into selective (e.g. splenorenal) and nonselective (e.g. porto-caval), the former attempting to preserve blood flow to the liver whilst decompressing the left side of the portal circulation responsible for giving rise to the oesophageal and gastric varices. Selective shunts may be associated with a lower incidence of portal systemic encephalopathy (PSE), a confusional state commonly found in patients with chronic liver disease who have undergone radiological or surgical porto-systemic shunts. The different types of surgical shunts are shown in Fig. 52.13. There is no evidence that prophylactic shunting is beneficial in patients with varices who have not bled.

Oesophageal stapled transection

This technique for the management of bleeding oesophageal varices utilised the circular stapling device initially employed for Anastomosis of the rectum for stapling and resecting a ring of the lower oesophagus. As with surgical shunts in the acute situation, it was associated with a high perioperative mortality and has been largely abandoned in centres where TIPSS is available.

Management of varices secondary to splenic or portal vein thrombosis

Accurate angiography is an important aspect of the assessment of patients with suspected extrahepatic portal vein thrombosis. Therapeutic options are limited. Patients with oesophageal and/or gastric varices secondary to splenic or portal vein thrombosis can be effectively treated...
by splenectomy and gastro-oesophageal devascularisation, in which the blood supply to the greater and lesser curve of the stomach and lower oesophagus is divided. Splenic vein thrombosis may be seen secondary to chronic pancreatitis and portal vein thrombosis is a common late complication of liver cirrhosis.

**Variceal bleeding and liver transplantation**

The management of variceal bleeding should always take into account the possibility of liver transplantation where this is available. The patient’s age or associated medical condition may be a contraindication. TIPSS would be the preferred management for bleeds resistant to sclerotherapy as long as placement is optimal. Previous surgical shunts greatly increase the morbidity associated with OLT and probably the mortality.

**Ascites**

The accumulation of free peritoneal fluid is a common feature of advanced liver disease independent of the aetiology. The fluid accumulation is usually associated with abdominal discomfort and a dragging sensation. Development is usually insidious. The aetiology of the ascites must be established. Imaging by CT will confirm the ascites and demonstrate the irregular and shrunken nature of a cirrhotic liver and associated splenomegaly. Intravenous contrast enhancement will allow abdominal varices to be demonstrated and patency of the portal vein, portal vein thrombosis being a common pre-disposing factor to ascites in chronic liver disease. In patients without evidence of liver disease malignancy is a common cause and a possible primary site may also be established on CT. Aspiration of the peritoneal fluid allows analysis for cytology, an amylase estimation to exclude pancreatic ascites, and both microscopy and culture to exclude primary bacterial peritonitis and tuberculous peritonitis. The urinary 24-hour sodium excretion is used as a guide to treatment.

**Treatment of ascites in chronic liver disease**

The initial treatment is to restrict additional salt intake and commence diuretics using either spironolactone or frusemide. This should be combined with advice on avoiding any precipitating factors for impaired liver function, such as alcohol intake in patients with alcoholic cirrhosis. Patients on diuretics should be monitored for the development of hyponatraemia and hypokalaemia.

**Abdominal paracentesis**

Patients failing to respond to diuretic treatment may require repeated percutaneous aspiration of the ascites (abdominal paracentesis) combined with volume replacement using salt-poor or standard human albumin solution dependent on the serum sodium level. This is an unsatisfactory treatment but may provide some short-term symptomatic relief.

**Liver transplantation for ascites**

Diuretic-resistant ascites is an indication for liver transplantation if associated with a deterioration in liver function (rising bilirubin, dropping albumin, prolonged PT). The patient’s age, underlying aetiology of liver disease and associated medical problems will be the major factors determining suitability for liver transplantation. In those considered inappropriate for liver transplantation, management is aimed at symptomatic control of ascites.

**Peritoneovenous shunting**

The Le Veen shunt is designed for the relief of ascites due to chronic liver disease. One end of the silastic tube is inserted into the ascites within the peritoneal cavity and it is then tunnelled subcutaneously to the neck, where it is inserted under direct vision into the internal jugular vein and fed into the SVC. Owing to a one-way valve within the tubing, peritoneal fluid is drawn from the abdomen and drained to the circulation due to the lower pressure in the SVC in comparison to the abdomen during the respiratory cycle. Although often effective when combined with continued diuretic therapy they are prone to occlude and become displaced or infected. In an attempt to prevent the high occlusion rate a further development was the insertion of a chamber placed over the costal margin to allow digital pressure and evacuation of any debris within the peritoneo-venous shunt (Denver shunt).

**TIPSS for ascites**

The procedure and its limitations are as outlined above for the emergency treatment of bleeding varices secondary to portal hypertension. The use of TIPS S for ascites is for symptomatic relief, and the procedure is associated with considerable risks including death from haemorrhage, renal failure or heart failure. Post stent encephalopathy is common (about 40 per cent) and the majority of stents will stenose on long-term follow-up (approximately 50 per cent by 1 year). Although a useful treatment modality, it has not become widely utilised because ascites is not life threatening. More encouraging results have been obtained in those with persistent chylothorax.
**Chronic liver conditions**

There are several chronic liver conditions which, although rare, are important to recognise because they require a specific plan for investigation and treatment, and may present mimicking a more common clinical condition.

**Budd—Chiari syndrome**

This is a condition principally affecting young females in which the venous drainage of the liver is occluded by hepatic venous thrombosis or obstruction from a venous web. As a result of venous outflow obstruction the liver becomes acutely congested with the development of impaired liver function and subsequently portal hypertension, ascites and oesophageal varices. In an acute thrombosis the patient may rapidly progress to fulminant liver failure, but in the majority of cases abdominal discomfort and ascites are the main pre-senting features. If chronic the liver progresses to established cirrhosis. The cause of the venous thrombosis needs to be established and an underlying myeloproliferative disorder or procoagulant state is commonly found, such as antithrombin 3, protein C or protein S deficiency. The diagnosis is com-monly suspected in a patient presenting with ascites in whom CT scan shows a large congested liver (early stage, Fig. 52.14) or a small cirrhotic liver in which there is gross enlargement of segment I (the caudate lobe). This feature is due to preservation and hypertrophy of the segment with direct venous drainage to the IVC in the face of atrophy of the rest of the liver due to venous obstruction (Fig. 52.15). IVC compression or occlusion from the segment I hyper-trophy is also commonly a feature, as is thrombosis of the portal vein. Confirmation of the suspected diagnosis is by hepatic venography via a transjugular approach which demonstrates occlusion of the hepatic veins and may allow a transjugular biopsy. Treatment of BCS must be tailored to the individual patient and, in particular, the stage of disease at presentation. Patients presenting in fulminant liver failure should be considered for liver transplantation, as should those with established cirrhosis and the complications of portal hypertension. Those in whom cirrhosis is not established may be considered for portosystemic shunting by TIPPS, portocaval shunt or mesoaoarial shunting. IVC com-pression may be relieved by the insertion of a retrohepatic expandable metallic stent. If the BCS is treated satisfactorily the prognosis of this patient group is largely dependent on the underlying aetiology and whether this is amenable to treatment. Patients are usually left on life-long anti-coagulation with warfarin.

**Primary sclerosing cholangitis (PSC)**

This condition often presents in young adults with mild non-specific symptoms, and biliary disease is suggested by the finding of abnormal liver function tests. Rarely the first pre-sentation is with jaundice due to biliary obstruction. The dis-ease process results in progressive fibrous stricturing and obliteration of both the intrahepatic and extra hepatic bile ducts. Although the aetiology is unknown, a genetic predisposition is likely owing to its association with chronic ulcerative colitis (UC). In patients with PSC and UC the condition usually progresses even if the diseased colon is removed. The diagnosis is principally based on the findings at cholangiography in which irregular, narrowed bile ducts are demonstrated in both the intrahepatic and extrahepatic biliary tree (Fig. 52.16). If the radiological appearances are equivocal a liver biopsy is required to demonstrate the fibrous obliteration of the biliary tracts. There is no specific treatment which can reverse the ductal changes, and the patients usually slowly progress to progressive cholestasis and death from liver failure. There is a strong predisposition to cholangiocarcinoma and this should be considered in any patient with PSC in whom a new or dominant stricture is demonstrated on cholangiography. Diagnosis of cancers in PSC is greatly facilitated by biliary brush cytology, as imaging rarely shows evidence of a mass lesion even in patients with advanced cancers. Patients with good liver function, no dominant strictures and negative biliary cytology may simply be monitored for disease progression. The only useful treat-ment modality is liver transplantation, which is associated with excellent results if carried out before bile duct cancer has developed. Temporary relief of obstructive jaundice due to a dominant bile duct stricture can be achieved by biliary stenting, although there is considerable risk of cholangitis from the introduction of bacteria to the biliary tract.

**Primary biliary cirrhosis (PBC)**

As with PSC, the presentation of patients with PBC is often hidden with general malaise and lethargy prior to the development of clinical jaundice or the finding of abnormal liver function tests. The condition is largely confined to females. Diagnosis is suggested by the finding of circulating anti-smooth muscle antibodies and, if necessary, is confirmed by liver biopsy. The condition is slowly progressive with deterioration in liver function resulting in lethargy and malaise. It may be complicated by the development of portal hypertension and the secondary complications of ascites and variceal bleeding. The mainstay of treatment is liver trans-plantation, which should be considered when the patient’s general condition starts to deteriorate with inability to lead a normal lifestyle.

**.Carol’s disease**

This is congenital dilatation of the intrahepatic biliary tree which is often complicated by the presence of intrahepatic stone formation. Presentation may be with abdominal pain or sepsis. Imaging is usually diagnostic with the finding on ultrasound or CT of intrahepatic biliary lakes containing stones. Biliary stasis and stone formation combine to predispose to biliary sepsis which may be life threatening. Another well-recognised complication is the development of carcinoma. No specific treatment is available. Acute infective episodes are treated with antibiotics. Obstructed and septic bile ducts may be drained radiologically or surgically with some improvement. Malignant change within the ductal system results in cholangiocarcinoma which may be amenable to resection. Segmental involvement of the liver by Caroli’s disease may be treated by resection of the affected part, although the ductal dilatation is usually diffuse. Transplanta-tion is a radical but definitive treatment for a patient whose liver function is generally well preserved.

**Simple cystic disease**

Liver cysts are a common coincidental finding in patients undergoing abdominal ultrasound. Radiological findings to suggest that a cyst is simple are that it is regular, thin walled, unilocular, with no surrounding tissue response and no variation in density within the cyst cavity. If these criteria are confirmed and the cyst is asymptomatic no further tests or treatment are required. Large cysts may be associated with symptoms of abdominal discomfort, possibly related to stretching of the overlying liver capsule. Aspiration of the cyst contents under radiological guidance provides a sample for culture, microscopy and cytology, and allows the symptomatic response to cyst drainage to be assessed. Aspiration alone is usually associated with cyst and symptom recurrence, in which case more definitive treatment is required. Open or more recently laparoscopic derocking is the treatment of choice for large symptomatic cysts and is associated with good long-term symptomatic relief.

**Polycystic liver disease**

This is a congenital abnormality associated with cyst forma-tion within the liver and often other abdominal organs, principally the pancreas and kidney. Those associated with renal cysts may have autosomal dominant inheritance. The cysts are often asymptomatic and incidental findings on ultrasound. They usually have no effect on organ function and require no specific treatment. Occasionally, multiple liver cysts give rise to liver discomfort. This often responds to treatment with simple analgesics. Severe pain often indicates haemorrhage into a cyst which may be confirmed by ultrasound or CT scan. Cyst discomort which is not adequately controlled by oral analgesics may be treated by open or laparoscopic fenestration of the liver cysts, although the results are less favourable than with simple cysts.
Liver infections

Viral hepatitis is a major world health problem. In addition to the well-recognised acute and chronic liver diseases produced by hepatitis A, B and C, other hepatitis viruses have been isolated including hepatitis D, which is usually detected only in patients with hepatitis B virus (HBV) infection, and hepatitis E, which produces a self-limiting hepatitis due to faecal—oral spread similar to hepatitis A.

Hepatitis A presents with anorexia, weakness and general malaise for several weeks prior to the development of clinical jaundice, often accompanied by tenderness on palpation of an enlarged liver. The condition is spread by the faecal—oral route and often spreads rapidly in closed communities. Liver function tests will be compatible with an acute hepatitis with elevation of bilirubin and transaminases. Diagnosis is confirmed by the antibody titre to hepatitis A. The condition is virtually always self-resolving, although rarely the viral hepatitis can lead to fulminant liver failure. Once the clinical condition resolves the liver tends to recover fully with no functional deficit and no long-term sequelae.

Hepatitis B is a more serious condition in most respects than hepatitis A. Although it can also produce an acute self-resolving hepatitis, the virus is often not cleared and pro-duces long-term liver damage with the development of liver cirrhosis and primary liver cancers. Patients may therefore present acutely with malaise, anorexia, abdominal pain and clinical jaundice due to active hepatitis or may present at a later stage owing to the complications of cirrhosis, most commonly ascites or variceal bleeding. Treatment for acute hepatitis is supportive. In patients with cirrhosis, treatment is initially dictated by the specific complication at presentation (see subsections on the treatment of ascites and variceal bleeding earlier in this chapter). In established cirrhosis, liver transplantation may be considered if viral eradication or suppression can be achieved with antiviral agents (e.g. lamivudine). Without viral suppression death from reinfection of the transplanted liver is common. The hepatitis virus greatly increases the risk of primary liver cancers which usually appear at the stage when the liver parenchyma has become cirrhotic. The assessment and management of HBV cirrhosis with hepatocellular carcinoma (HCC) is discussed in the section on Liver tumours.

Hepatitis C has become one of the commonest causes of chronic liver disease world-wide and in many countries a large percentage of the population has been exposed. One per cent of blood donors world-wide are hepatitis C virus (HCV) positive. Transmission is often related back to blood transfusion and routine screening of blood for HCV has only recently been introduced in many countries. As with hepatitis B, it may present as an acute hepatitis or remain hidden until the development of cirrhosis and the complications of portal hypertension. Acute hepatitis C process to cirrhosis in about 20 per cent of cases. Deterioration in liver function, ascites or bleeding in a patient with known HCV cirrhosis necessitates an urgent assessment for liver transplantation, if available. Although reinfection of the graft is common, generally results in a milder form of disease than the graft and patient fully recover and is associated with a good long-term outcome.

Ascending cholangitis

Ascending bacterial infection of the biliary tract is usually associated with obstruction, and presents with clinical jaundice, rigors and a tender hepatomegaly. The diagnosis is confirmed by the finding of dilated bile ducts on ultrasound, an obstructive picture of liver function tests and the isolation of an organism from the blood on culture. The condition is a medical emergency and delay in appropriate treatment results in organ failure secondary to sepsicaemia. Once the diagnosis has been confirmed the patient should be com-menced on a first-line antibiotic (e.g. third-generation cephalosporin), rehydrated and arrangements made for endoscopic or percutaneous transhepatic drainage of the biliary tree. Biliary stone disease is a common predisposing factor and the causative ductal stones may be removed at the time of endoscopic cholangiography by endoscopic sphincterotomy.

Pyogenic liver abscesses

The aetiology of a pyogenic liver abscess is unexplained in the majority of patients. It has an increased incidence in the elderly, diabetics and the immunosuppressed, who usually present with anorexia, fevers and malaise accompanied by right upper quadrant discomfort. The diagnosis is suggested by the finding of a multiloculated cystic mass on ultrasound or CT scan (Fig. 52.17) and is confirmed by aspiration for culture and sensitivity. The most common organisms are Streptococcus milleri and Escherichia coil but other enteric organisms such as Strepococcus faecalis, Klebsiella and Proteus vulgaris also occur and mixed growths are common. Opportunistic pathogens include Staphylococci. First-line antibiotics would be a penicillin, aminoglycoside and metronidazole or a cephalosporin and metronidazole. Treatment is with intravenous antibiotics guided by ultrasound. Percutaneous drainage without ultrasound guidance should be avoided as an empyema may follow drainage through the pleural space. A source for the liver abscess should be sought, particularly from the colon. Atypical clinical or radiological findings should raise the possibility of a necrotic neoplasm.

Amoebic liver abscesses

Entamoeba histolytica is endemic in many parts of the world. It exists in vegetative form outside the body and is spread by the faecal—oral route. The most common presentation is with dysentery but it may also present with an amoebic abscess, the common sites being paracaecal and in the liver. The amoebic cyst is ingested and develops into the trophozoite form in the colon which passes through the bowel wall and to the liver via the portal blood. Diagnosis is by isolation of the parasite from the liver lesion or the stool and confirming its nature by microscopy. Often patients with clinical signs of an amoebic abscess will be treated empirically with metronidazole (750 mg t.d.s. for 5—10 days) and investigated further only if they do not respond.

Hydatid liver disease

This is a very common condition in countries around the Mediterranean. The causative tapeworm, Echinococcus granulosus, is present in the dog intestine and ova are ingested by humans and pass in the portal blood to the liver. Liver abscesses are often large by the time of presentation with upper abdominal discomfort or may present after minor abdominal trauma as an acute abdomen due to rupture of cyst into the peritoneal cavity. Diagnosis is suggested by the finding of a multiloculated cyst on ultrasound and is further supported by the finding of a floating membrane within the cysts on CT scan (Fig. 52.18). Active cysts contain a large number of smaller daughter cysts (Fig. 52.19) and rupture can result in impregnation and growing within the peritoneal cavity. Liver cysts can also rupture through the diaphragm producing an empyema into the biliary tract producing obstructive jaundice or into the stomach. Clinical and radiological diagnosis can be supported by serology for antibodies to hydatid antigen in the form of an enzyme-linked immunosorbent assay (ELISA). Treatment is indicated to prevent progressive enlargement and rupture of the cysts. In the first instance a course of albendazole or mebendazole may be tried. Failure to respond to medical treatment usually requires surgical intervention, although percutaneous treatments with hypertonic saline and alcohol have been attempted. The surgical options range from liver resection or local excision of the cysts to deroofing with evacuation of the contents. In the peritoneal cavity at the time of surgery with active hydatid daughters should be avoided by continuing drug therapy with albendazole and adding perioperative praziquantel. This should be combined with packing of the peritoneal cavity with 2 N saline-soaked packs and instilling hypertonic (2 N) saline into the cyst before it is opened. A biliary communication should be actively sought and sutured. The residual cavity may become infected and this may be reduced, as may bile leakage, by packing the space with pedicled greater omentum (an omentoplasty). Calcinified cysts may well be dead. If doubt exists as to whether a suspected cyst is active it can be followed on ultrasound, active cysts gradually becoming larger and more superficial in the liver. Rupture of daughter hydatids into the biliary tract may result in obstructive jaundice or acute cholangitis. This may be treated by endoscopic clearance of the daughter cysts prior to cyst removal from the
liver.
Liver tumours

Surgical approaches to resection of liver tumours

Adequate exposure of the liver is an absolute prerequisite to safe liver surgery. A rooftop or transverse abdominal incision provides excellent access to the liver if adequate retraction of the costal margin is employed using a costal margin retractor. Thoracoabdominal incisions are no longer required. The procedure for complete mobilisation of the liver is described, although this will not be necessary in all cases. There are many variations in surgical technique.

Mobilisation of the liver

The falciform ligament is first divided and followed along the anterior surface of the liver towards the suprahepatic IVC. The left triangular ligament is divided, facilitated by placing an abdominal pack in front of the oesophagogastric junction. The right triangular ligament is then divided by retraction of the diaphragm away from the right lobe parenchyma. On exposure of the bare area of the liver the IVC can be seen as it passes behind the liver and this can be suture ligated above the renal veins below the liver and at the level of the main hepatic veins. Mobilisation of the liver is completed by division of the lesser omentum. Removing the liver from the IVC is achieved by lifting the liver anteriorly to expose the multiple small veins passing between the liver parenchyma and the IVC. These should be suture ligated to ensure haemostasis. This proceeds from above the renal veins until the main hepatic veins are reached below the diaphragm.

Dissection of the hilum

The peritoneum overlying the hilar triad is divided. The common bile duct (CBD) is then exposed on the free edge of the lesser omentum, mobilisation being facilitated by ligation and division of the cystic duct and artery followed by removal of the gall bladder. Slinging the CBD with an elastic sling allows exposure of the common hepatic artery and dissection of the main right and left branches. These again may be suture ligated to allow the remaining lymphatic tissue surrounding the portal vein to be ligated and divided. The possibility of an aberrant right hepatic artery should be sought lying posterior to the bile duct and an accessory left hepatic artery from the left gastric artery in the lesser omentum.

Dissection of the hilar bile ducts requires careful retraction on segment IV of the liver, and division of the small vessels and bile duct branches passing between segment IV and the confluence of the right and left hepatic ducts.

Division of the parenchyma

Once the liver has been adequately mobilised and the hilar vessels have been exposed the main inflow vessels and bile duct can be divided to the liver lobe to be resected. The arterial branch may be suture ligated but the bile duct should be transfixed with 4/0 PDS and the portal vein branch with 4/0 Prolene suture. Division of the inflow vessels produces a line of demarcation between the right and left liver passing to the right and parallel with the falciform ligament. The parenchyma is divided along this plane of demarcation commencing by diathermy of the liver capsule. The ultrasound (Cusa) dissector is the most common method used for division of the parenchyma. This allows the parenchyma to be divided leaving the vessels and bile duct branches to be diathermied or ligated depending

Hepatic adenoma (Fig. 52.22)

These are rare benign liver tumours. Imaging by CT demonstrates a well-circumscribed and vascular solid tumour. They usually develop in an otherwise normal liver. Unfortunately, there are no characteristic radiological features to differentiate these lesions from malignant tumours. Angiography will demonstrate a well-developed peripheral arterialisation of the tumour. Confirmation of the nature of these lesions is required by either percutaneous biopsy or resection with histological confirmation. These tumours are thought to have malignant potential and resection is therefore the treatment of choice. Owing to their vascularity, bleeding following percutaneous biopsy is well recognised. An association with sex hormones, including the oral contraceptive pill, is well recognised and regression of symptomatic adenomas on withdrawal of hormone stimulation is well documented.

Focal nodular hyperplasia (FNH)

This is an unusual benign condition of unknown aetiology in which there is a focal overgrowth of functioning liver tissue supported by fibrous stroma. Patients are usually middle-aged females, and there is no association with underlying liver disease. Ultrasound shows a solid tumour mass but does not help in discrimination. Contrast CT may show central scarring and evidence of a well-vascularised lesion. Again, these appearances are not specific for FNH. A sulphur colloid liver scan may be useful. FNH contain both hepatocytes and Kupffer cells. The latter takes up the colloid differentiating FNH from either a benign adenoma or a primary or metastatic cancer, none of which contains a significant number of Kupffer cells.

Surgery for liver metastases

Outcome

The role of surgery in the treatment of colorectal liver metastases is now well established based on prospective data on resected patients compared with unresected patients with a similar stage of disease. The role of resection of liver meta-stases from other primary sites has not been defined. The expected patient survival rate for resection of solitary colorectal metastases is approximately 35 per cent at 5 years with few cancer-related deaths beyond this period. Multiple unilobar and bilobar liver metastases may also be considered for resection, although cure rates are significantly lower.

Staging

This involves defining the extent of the liver involvement with metastases and excluding extrahepatic disease. A stand-and work-up would involve oral and intravenous contrast CT scan of the liver and abdomen, chest CT scan, bone scan and colonoscopy, to look for locally recurrent or synchronous colonic cancers. This information should be taken in parallel with a general medical evaluation before deciding on the suitability for surgery of an individual patient. The typical appearance of colorectal liver metastases on contrast CT is shown in Fig. 52.23. These patients usually have normal liver parenchyma and therefore tolerate a 60—70 per cent resection of liver parenchyma without showing evidence of liver failure.

Surgical approach

The basic surgical approach for liver resection is outlined above. A search for local recurrent disease, peritoneal depo-sits and regional lymph node involvement should be made at the start of the laparotomy. Planar imaging often overlooks peritoneal or superficial liver metastatic deposits. Coeliac node involvement in patients with liver metastases considerably reduces the overall survival whether or not the liver and
nodal disease is resected.

The treatment of unresectable disease

These patients may be offered systemic chemotherapy. First line treatment is with 5-fluouracil and folic acid, which produces a response rate of 30 per cent and may improve the quality of life. Other drug regimes are available and many studies are ongoing evaluating hepatic arterial administration of chemotherapy or radioactive microspheres. Many patients will have undergone previous adjuvant chemotherapy following resection of the large bowel primary. There is no proof as yet regarding further adjuvant treatment following resection of liver metastases.

Hepatocellular carcinoma

Primary liver cancer (HCC) is one of the world’s commonest cancers and its incidence is expected to rise rapidly over the next decade. This rise is due to the association with chronic liver disease, particularly HBV and HCV. Owing to this association many patients who are known to have chronic liver disease are now being screened for the development of HCC by serial ultrasound scans of the liver or serum measurements of alpha fetoprotein (AFP). Patients often present in middle age either because of symptoms of the chronic liver disease (malaise, weakness, jaundice, ascites, variceal bleed, encephalopathy) or with the anorexia and weight loss of an advanced cancer. The surgical treatment options include resection of the tumour and liver trans-plantation. Which option is most appropriate for an individual patient depends on the stage of their underlying liver disease, the size and site of the tumour, the availability of organ transplantation and the management of the immunosuppressed patient.

Staging and clinical assessment of hepatocellular carcinoma

In addition to a general assessment of the patient’s fitness for surgery, crucial information is the severity of the underlying liver disease based on Child’s classification (Table 52.5) and the size and site of the tumour. As chronic liver disease predisposes to these tumours they are often multifocal by the time of diagnosis. Extensive liver resections in patients with advanced cirrhosis are associated with a high mortality due to liver failure and sepsis. In contrast, extensive resections for HCC in a non-cirrhotic liver are associated with a low risk of liver failure, and resection rather than transplantation would be the treatment option of choice. Tumours often metastasise to the lung and bone, and a chest CT scan and bone scan are therefore useful staging investigations. Evidence of intraperitoneal disease is difficult to determine by CT scan, and laparoscopy may be useful for this purpose. The intrahepatic distribution of HCC is equally difficult to determine within the cirrhotic liver.

Ultrasound, early arterial phase enhanced spiral CT scan and CT scan 2 weeks following intrahepatic administration of the contrast agent Lipiodol are the most useful that are currently available (Fig. 52.24).

Surgical approach to HCC

The surgical approach should remove the known cancer with a 1—2 cm margin of unaffected liver tissue. In patients with associated chronic liver disease the volume of liver resected should be minimised to reduce the incidence of postoperative liver failure. Local or segmental resections are preferred to major resections (Fig. 52.21).

Follow-up and adjuvant treatment

There is little evidence that adjuvant chemotherapy will improve the prognosis of patients following resection of HCC, and it may damage the function of the liver in those with underlying chronic liver disease. AFP is a clinically useful tumour marker for follow-up, although its low sensitivity would suggest that imaging should also be employed.

Cholangiocarcinoma

Presentation, pathology and natural history

Bile duct cancers typically present with painless obstructive jaundice. Elderly patients are frequently affected, but patients with primary sclerosing cholangitis (PSC) may develop these tumours at a much earlier age. These tumours are typically slow growing and often arise at the confluence of the right and left hepatic ducts, eventually invading the liver parenchyma. Cancers at this site are usually fibrous and produce tight duct strictures. Distal bile duct cholangio-carcinomas are more frequently polypoidal and obstruct the lumen of the duct. Both invade perineural planes and along lymphatics.

Investigation and staging

The diagnosis should be suspected when ultrasound examination of the jaundiced patient shows dilated intrahepatic but not extrahepatic bile ducts.

Cholangiography will usually show a hilar stricture (Fig. 52.25) and brush cytology will provide a tissue diagnosis in about two-thirds of patients. Polypoidal tumours may closely mimic CBD stones (Fig. 52.26). Spiral CT scan often shows little evidence of a mass lesion unless infiltration into the liver parenchyma has occurred. Regional lymphadenopathy may be apparent but cannot be assumed to be malignant. Evidence of local spread into the portal vein or evidence of hepatic arterial involvement may be obtained by angiography. Distal spread at presentation is unusual, as is peritoneal seeding. Hilar cholangiocarcinomas may be categorised using the system suggested by Bismuth (Fig. 52.27).

Treatment

Surgical resection offers the only possibility of cure and may also be the best form of palliation. Owing to local spread into lymphatics and the perineural space, local resection of a hilar cholangiocarcinoma is rarely curative, although some long-term survivors have been reported. Radical resection of the liver parenchyma associated with the affected bile duct has become the recognised treatment. Those patients in whom the volume of residual liver parenchyma following resection may be inadequate can be considered for transhepatic portal vein embolisation of the branch to the side of the liver to be removed, as described by Nimura and colleagues. This results in compensatory enlargement and functional improvement in the liver parenchyma.

Gall-bladder cancer

The aetiology of gall-bladder cancer is unknown but it almost invariably is associated with the presence of stones in the gall-bladder which may act as a chronic irritant to the gall bladder mucosa. Evidence of a field change in the gall bladder mucosa with areas of dysplasia would support this theory. It is also known to have a very high incidence in patients with gall-bladder wall calcification, the porcelain gall bladder (Fig. 52.28). Presentation is often with symptomatic gallstones where the gall-bladder cancer is an incidental finding. Alternatively, the patient may present...
with pain or obstructive jaundice and in these individuals the tumour is often advanced, having extended outside the liver or towards the hilum of the liver to produce ductal obstruction. Patients in whom the tumour is an incidental finding following cholecystectomy and is limited to the mucosa of the gall bladder have a good prognosis. Those in whom there is transmural spread or those presenting with obstructive jaundice have a poor prognosis. Staging of the tumour will decide the possibilities for management, and includes spiral CT scan of the chest and abdomen, cholangiography, selective hepatic angiography and staging laparoscopy. Radical surgery offers the only hope of cure for gall-bladder cancer and this may involve removing the right lobe liver parenchyma, the biliary tree, along with the hilar lymphatic drainage of the gall bladder by a hilar lymphadenectomy. There is little evidence for chemotherapy either as a sole treatment or in an adjuvant setting. Patients presenting with obstructive jaundice due to an unresectable gall-bladder cancer may have the symptoms relieved by insertion of a biliary endoprosthesis.

Spleen

Anatomy and physiology
The spleen arises by mesenchymal differentiation along the left side of the dorsal mesogastrium in the 8-mm embryo. The weight of the normal adult spleen is between 75 and 150 g. It is shaped like a segment of an orange, its convexity directed backwards and to the left. It lies between the tenth and eleventh ribs posteriorly. It abuts the diaphragm superiorly, anteriorly there is the gastric impression, posteriorly it is in contact with the kidney and the colon lies inferiorly. Within the hilum is the tail of the pancreas and the splenic vessels. It forms the apex of the lesser sac. Within the anterior leaf of the lesser sac the short gastrics pass to the greater curve of the fundus of the stomach. The splenic artery divides at the hilus into branches which run along the trabeculae of the spleen into the white pulp, where they give off branches which are almost perpendicular to the central trunk (Fig. 53.1). This produces a ‘skimming effect’ by which plasma tends to pass down the branches to the white pulp and most of the red cells pass in the trabecular artery to the red pulp. The white pulp has an immune function, whereas the red pulp filters abnormal red cells from the circulation. Phagocytosis of blood-borne particles occurs in both areas. On cutting the spleen areas of red pulp, within which can be seen pale ovoid nodules of white, are apparent.

The white pulp consists of a central trabecular artery surrounded by nodules with germinal centres and periartrial lymphatic sheaths which provide a framework filled with lymphocytes and macrophages. At the edge of the white pulp is the marginal zone into which pass arteries from both the central artery and from the peripheral ‘penicillar’ arteries. Plasma-rich blood which has passed through the central lymphatic nodules is filtered as it passes through the sinuses within the marginal zone, and particles are phagocytosed. Immunoglobulins produced in the lymphatic nodules enter the circulation through the sinuses in the marginal zone. Beyond the marginal zone is the red pulp which consists of cords and sinuses. Cell-concentrated blood passes in the trabecular artery through the centre of the white pulp to the red pulp cords. To pass from the cords to the sinuses, the red cell must elongate and become thinner. This filters abnormally shaped or rigid cells out of the circulation.

Ninety per cent of blood passing through the spleen moves through an open circulation in which blood flows from arteries to cords and thence to sinuses. Thus, splenic pulp pressure reflects pressure throughout the portal venous system. The remaining 10 per cent bypasses the cords and sinuses by direct arteriovenous connections. The overall flow rate through the spleen is about 300 ml/minute.

Functions of the spleen
In the past the spleen was considered dispensable because it was found not to be essential to life. The surgeon therefore sacrificed the spleen with impunity. Increasing knowledge of the untoward effects of splenectomy has led to conservatism in the management of the spleen. Indeed, when splenectomy is performed as part of another operation, such as total gastrectomy, the incidence of complications increases and the mortality rises. For this reason the surgeon now tries to preserve the spleen and maintain the following functions.

**Immune function** — the spleen processes foreign antigen and is a major site of specific immunoglobulin M (IgM) production. The nonspecific opsonins tuftin and properdin are synthesised. These antibodies are of both B- and T-cell origin, and react with bacteria and fungi to make them more susceptible to phagocytosis.

**Filter function** — macrophages in the reticulum capture cellular and noncellular material from the blood and plasma; this material includes bacteria, especially pneumococci.

**Removal of effete, platelets and red cells** — this process is called ‘culling’.

**Pitting** — this is the process of removing particulate inclusions from red cells and returning the repaired red cell to the circulation. Red blood cell nuclei or malarial parasites can be removed by this process without destroying the cell.

**Iron reutilisation** — the phagocytic reticular cells remove iron from ingested degraded haemoglobin during red cell culling and return the iron to the plasma.

**Pooling** — up to 30—40 per cent of blood platelets are sequestered within the spleen. In splenomegaly up to 80 per cent of the platelet pool can be sequestered in the spleen and this, together with accelerated platelet destruction, can result in thrombocytopenia.

**Reservoir function** — in animals, especially the dog, up to one-third of the blood volume may be sequestered in the spleen during sleeping and returned to the circulation on waking. This does not occur in humans.

**Haematopoesis** — this only occurs up to the fifth intra-uterine month and thereafter in certain disease states.

Investigation of the spleen
Conditions that cause splenomegaly can be diagnosed by his-tory, physical signs and laboratory examination. For instance in haemolytic anaemia a full blood count, reticulocyte count and tests for haemolysis will determine the type of anaemia. Similarly, splenomegaly associated with portal hypertension caused by hepatic cirrhosis is diagnosed by the physical signs of liver dysfunction, abnormal liver function tests and evidence of oesophageal varices. Many conditions that cause splenomegaly also cause lymphadenopathy. The cause of the splenomegaly should then be determined from investigations for diseases known to cause lymphadenopathy and splenomegaly. A lymph node biopsy can be helpful in this respect.

**Plain radiography**
This plays little part in investigation now, although calcification in the spleen may suggest an old infarct or hydatid disease. Multiple areas of calcification would suggest splenic tuberculosis.

**Imaging**

**Ultrasoundography** of the spleen (Fig. 53.2) is of value in determining its size and consistency, and whether or not cysts are present. It can be used for diagnosis of a ruptured spleen. However, in this case a computerised tomography (CT) scan is more usually undertaken to exclude other intra-abdominal problems. Similarly, a spiral CT scan with contrast enhancement will be preferable in the diagnosis of splenomegaly to determine both the extent of the disease and the associated problems such as the extent of lymphadenopathy.

**Radioisotope scans**
Technetium-99m (99mTc)-labelled colloid can provide information about the position and size of the spleen and, with appropriately labelled red cells, the life and place of their destruction can be determined.
Congenital abnormalities of the spleen

Absence of the spleen is rare, and when it occurs is often associated with congenital heart disease. Patients without a spleen are occasionally subject to fatal infection.

Splenunculi

These are single or multiple accessory spleens which are found near the hilum of the spleen in 50 per cent, related to the splenic vessels and behind the tail of the pancreas in 30 per cent, or in the splenic ligaments and mesocolon in the remainder. Up to 20 per cent of people have such splenunculi and most are no larger than 2 cm in diameter. Their importance lies in the fact that if not removed at the time of splenectomy they will undergo hyperplasia and may well be the site of persistent disease.

Hamartoma

Rarely, these are found in the spleen, usually being found incidentally at post-mortem examination. They vary in size from less than 1 cm in diameter to masses large enough to produce abdominal swelling. There are two varieties: one mainly lymphoid resembling the white pulp and the other resembling the red pulp. They are occasionally seen incidentally on CT scanning.

Splenic cysts

Nonparasitic cysts of the spleen are rare. They consist of true cysts formed from embryonal rests and include dermoids and mesenchymal inclusion cysts, or false cysts resulting from trauma which contain serous or haemorrhagic fluid. They can be clearly demarcated on scanning, punctured, drained and sclerosed. Operative removal is rarely, if ever, indicated.
Rupture of the spleen

Splenic rupture should be suspected after any trauma, but particularly if there has been direct injury to the left upper quadrant of the abdomen from any angle. Occasionally a fall without direct trauma to the trunk can rupture the spleen, especially if it is diseased or enlarged, for example in infectious mononucleosis or malaria. Advantage was once taken of the fragility of the enlarged spleen in Far Eastern countries where malaria is endemic. Murderers would achieve their purpose by digging a victim beneath the left ribs with a weapon known as the ‘larang’; the enlarged malarial spleen would rupture. A splenic injury should be suspected if there are fractures of the overlying ribs. Iatrogenic rupture remains common and is a reminder of the need for care when dissecting in the left upper quadrant of the abdomen, especially if adhesions are present.

Cases of ruptured spleen may be divided into three groups.

• The patient succumbs rapidly from massive haemorrhage — this type rarely occurs in the normal spleen but is a reminder that a slipped pedicle suture can lead to rapid exsanguination.

• Initial shock, recovery and signs of bleeding — the initial shock is due to the blood loss, tamponade occurs and then further bleeding takes place. General signs of internal haemorrhage are variable but local signs show upper abdominal guarding and, later, local bruising and abdominal distension. Pain referred to the left shoulder is known as Kehr’s sign. There may be hyperaesthesia in this area. The sign can often be demonstrated 15 minutes after elevation of the foot of the bed. It is due to blood in contact with the undersurface of the diaphragm, the pain being mediated through afferent fibres in the phrenic nerve. Shifting dullness may be present in the flanks and on rectal examination fullness in the pelvis is present. The elicitation of these difficult signs should give way to appropriate ultrasonography or CT scanning to determine the site from which the bleeding is occurring.

• The delayed case — after initial signs have passed off and the concern about a serious intra-abdominal bleed has been postponed, late rupture can occur. Such cases should now be rare as scanning should delineate such patients and a haematoma around a spleen should be an indication for either laparotomy or, at the minimum, close observation.

If ultrasonography cannot be performed and reliance has to be made on a plain X-ray of the abdomen it is important to ensure a high-quality soft-tissue X-ray so that the following signs can be elicited:
— obliteration of the splenic outline;
— obliteration of the psoas shadow;
— indentation of the left side of the gastric air bubble;
— fracture of one or more lower ribs of the left side;
— elevation of the left hemidiaphragm;
— free fluid between gas-filled intestinal coils.

Treatment of rupture of the spleen

Previously, immediate laparotomy has been the only reliable course. With better understanding of the problems associated with splenectomy, particularly in countries where malaria is common, splenic preservation should be undertaken where possible. Blood is evacuated and the spleen inspected. If by careful compression of the spleen the bleeding can be con-trolled a vicryl mesh bag can be constructed and the spleen placed in the bag which is then tightened to compress the spleen and to stop the bleeding. This manoeuvre is invaluable in children who are most at risk from splenectomy.

Rupture of a malarial spleen

As has been mentioned, in tropical countries this is not an infrequent catastrophe. The delayed type of rupture (following ‘trivial’ injury) is also very common and the patient is admitted with a perisplenic haematoma. If splenectomy can be performed before the haematoma bursts into the general peritoneal cavity, the prognosis is less grave. Enlarged spleens from any cause can rupture spontaneously or with mild trauma.

The operation is considerably more difficult than in the case of a ruptured normal spleen. Surgeons with tropical experience have surmounted these difficulties by ligating the splenic vessels as they run along the superior border of the body of the pancreas before disturbing the haematoma.
Aneurysm and infarction

Aneurysm of the splenic artery

This is an uncommon condition; estimates of its incidence at post-mortem examination vary between 0.04 and 1 per cent. Whereas aneurysms of other arteries are more common in men, in the splenic artery they are about twice as common in women. They are usually single and situated in the main trunk of the splenic artery (Fig. 53.3), but more than one are found in a quarter of cases.

The aneurysm is symptomless unless it ruptures. Occasionally it is palpable in the epigastrium or associated with a bruit over the left hypochondrium. It may be discovered accidentally, on plain radiograph of the upper abdomen, as a calcified ring situated to the left of the first lumbar vertebra. Rupture of the aneurysm is unsuspected in about half of all cases; it bursts into the peritoneal cavity and the symptoms resemble those of splenic rupture. Nearly half of all cases of rupture occur in patients less than 45 years of age, and a quarter of all cases are in pregnant women (usually in the third trimester of pregnancy or actually in labour).

The treatment of choice is splenectomy and removal of the length of artery bearing the aneurysm. If the aneurysm has eroded into the pancreas or is close to the origin of the splenic artery, then proximal and distal ligation of the sac is usually followed by thrombosis in the aneurysm. In younger patients, particularly women, with an asymptomatic splenic artery aneurysm, surgery is indicated after the diagnosis has been confirmed by selective coeliac arteriography. The maternal mortality rate for surgery at the time of rupture, in late pregnancy, is over 70 per cent. In elderly patients, particularly men, where an asymptomatic calcified aneurysm is detected on plain radiograph, there is less risk of rupture and surgery is not indicated.

Infarction of the spleen (Fig. 53.4)

This occurs in patients with massive spleens resulting from myeloproliferative syndrome, or with vascular occlusion produced by sickle cell disease or an embolus from an infected heart valve in bacterial endocarditis. The infarct may be asymptomatic or may cause left upper quadrant abdominal pain radiating to the left shoulder with splinting of the hemidiaphragm and guarding and, at times, a friction rub may be heard over the splenic area. Sedation and bed rest are sufficient except rarely when a septic infarct causes an abscess necessitating splenectomy.
Enlargement of the spleen

The spleen is a meeting place of medicine and surgery. Table 53.1 summarises the many causes of enlargement of the organ. In connection with Table 53.1, the following points should be noted. In idiopathic thrombocytopenic purpura (ITP) the spleen, although somewhat enlarged, is seldom palpable. In psittacosis the enlarged spleen can be palpated regularly after the first few days of the illness; this enlargement is helpful to differentiate the condition from other varieties of pneumonia. In portal hypertension the spleen is enlarged sec-ondary to hepatic cirrhosis or portal vein thrombosis (Chapter 52). As emphasised in Table 53.1, not all causes of splenomegaly will require splenectomy as part of their treatment. Efficacious splenectomy is required to treat haematological disease with medically uncontrolled hypersplenism, occasionally to stage and diagnose lymphoma, to treat splenic cysts, turnouts and abscesses, and for the relief of the discomfort associated with splenomegaly.

Idiopathic thrombocytopenic purpura

Purpura

Not all cases of purpura (purpura = porphyra (Greek)= purple) benefit from splenectomy. Purpura is defined as local haemorrhage into the skin. A history of purpura and evidence of it on examination should be sought before any surgical procedure is undertaken. Purpura may result from the following.

1. Increased capillary fragility, as in steroid-induced or Henoch—Schönlein purpura.
2. Defective platelets (thrombocytopathies), for example, after taking aspirin which inhibits thromboxane and prostaglandin, and reduces their property of making the platelet adhesive.
3. A reduced number of normal platelets (thrombocyto-penia). This can be a consequence of:

(a) decreased platelet production by marrow megakaryocytes; for example, because of marrow suppression by cytotoxic chemotherapy or in aplastic anaemia;
(b) increased platelet consumption, as seen in disseminated intravascular coagulation where the clotting cascade is triggered by sepsicaemia and platelets adhere to vascular endothelium, or in a large haemangioma in which platelets adhere to the abnormal endothelium;
(c) increased platelet destruction by the spleen. This may be associated with autoimmune disease (e.g. systemic lupus erythematosus); with drug reactions, for example, to quinine; and with certain infections (e.g. mononucleosis). Alternatively, as in ITP, the platelet destruction may not be associated with any other condition;
(d) increased splenic sequestration of platelets. This can be associated with any condition that produces gross splenic enlargement, e.g. portal hypertension.

Splenectomy may sometimes be helpful in purpura associated with splenic destruction or sequestration (points 3c and 3d, above). It is most reliably of use in the management of ITP.

Aetiology of idiopathic thrombocytopenic purpura

In most cases the low platelet count in ITP is due to the development of antibodies which damage the patient’s own platelets (the normal blood platelet count is 250 x 10⁹/litre). Transfused platelets have a short survival time after transfusion into patients with ITP, and the children born to mothers with ITP may have temporary maternal antibody-induced thrombocytopenia after birth.

Clinical features

Purpuric patches (ecchymoses) occur in the skin and mucous membranes which tend to be more prominent in dependent areas because of a higher, gravity aided, intravascular pres-ure. A tendency to spontaneous bleeding from mucous membranes (e.g. epistaxis), and in women to menorrhagia, and prolonged bleeding of minor wounds is common. Urinary and gastrointestinal haemorrhage and haemarthrosis are rare. Intracranial haemorrhage is also rare, but is the most frequent cause of death. Cutaneous ecchymoses may be found on examination and the tourniquet test is positive. The spleen is palpable in only 25 per cent of cases, and gross splenic enlargement suggests that the diagnosis is not ITP.

Investigations

The bleeding time is increased, but the clotting and pro-thrombin times are normal. The platelet count in the peri-pher al blood film is reduced (usually less than 60 x 10⁹/litre). Bone marrow biopsy reveals a plentiful supply of platelet-producing megakaryocytes (the giant cells of bone marrow give origin to blood platelets).

Treatment

The behaviour of the disease is different in children and adults. In children, the disease regresses spontaneously in 75 per cent of cases after one attack. Short courses of cortico-steroids or occasionally azothiaprine are usually followed by recovery. Splenectomy is reserved for severe cases which have relapsed or girls approaching menarche. In adults, the initial attack is less severe than in children, but the disease relapses and becomes more severe. Splenectomy is indicated where the ITP has persisted for more than 6—9 months.

Sixty per cent of patients can be regarded as cured, 20 per cent will be improved and 15 per cent or more will derive no benefit from the splenectomy. It is often, although not invariable, that a response to steroids predicts a good response to splenectomy. If severe bleeding has not been controlled by steroids, fresh blood transfusion or transfusion with platelet concentrates before operation is often necessary. Splenectomy is contraindicated during the acute phase of ITP; the disease should first be controlled by medical treatment. Occasionally, in resistant cases, the antplatelet immune response can temporarily be blocked by IgG transfusion to saturate the splenic Fe binding sites and reduce platelet destruction to allow the platelet count to rise at the time of surgery.

Splenectomy for other causes of thrombocytopenic purpura

Occasionally, splenectomy is of benefit in thrombocytopenia due to systemic lupus erythematosus and in hypersplenism; also in purpura...
associated with points 3c and 3d above.
The haemolytic anaemias

There are five causes of haemolytic anaemia which are amenable to splenectomy:

• hereditary spherocytosis;
• acquired autoimmune haemolytic anaemia;
• thalassaemia;
• hereditary elliptocytosis;
• pyruvate kinase deficiency.

Hereditary spherocytosis

The essential lesion is an increase in permeability of the red cell membrane to sodium. As the sodium leaks into the red cell its osmotic pressure rises, it swells and becomes more spherical, and in consequence more fragile. The mechanism by which the cells rid itself of sodium — the sodium pump — has to work harder. This has two consequences: (1) there is greater loss of membrane phospholipid and so a weakening of the membrane which thus becomes more fragile; and (2) the energy and the oxygen requirements increase. These requirements are particularly difficult to satisfy in the spleen where there is deficiency of both glucose and oxygen. Thus, a large number of red cells is destroyed in the spleen, and splenectomy reduces this cell destruction. Splenectomy does not, of course, cure the congenital red cell membrane defect, but it lessens the anaemia and makes the red cell survival time normal. The defect is transmitted by either parent as a Mendelian autosomal dominant (in 1866 Mendel described ‘dominant’ and ‘recessive’ traits in hybrids; his work passed unnoticed for 35 years). Males and females are equally affected. The circulating bilirubin is not conjugated with glucoronic acid. It is attached to albumin and is not excreted in the urine (acholicural jaundice). Although there is excessive breakdown of red cells with transformation of liberated haemoglobin to bilirubin, the bilirubin compound so produced is excreted by the liver and not the kidneys, thus favouring the formation of pigment gallstones.

Clinical features

Once the disease manifests itself, spontaneous remissions are almost unknown. As a rule the patient is pale and has jaundice. In established cases lassitude and undue fatigue are present, but they vary with the degree of haemolysis.

Sometimes the patient is born jaundiced or becomes so early in life. In certain families the disease is characterised by severe crises of red blood cell destruction; thus, with the onset of a crisis, an erythrocyte count may fall from 4.5 x 10^6 to 1.5 x 10^6 in less than a week. Such crises are characterised by the onset of pyrexia, abdominal pain, nausea, vomiting and extreme pallor, followed by increased jaundice. These crises may be precipitated by acute infection, and can be so severe as to cause death in infancy or childhood. More usually the jaundice, although variable, is very mild and may not appear until adolescence or even adult life. In adult cases there is often a history of attacks of biliary colic; indeed, 68 per cent of untreated patients over the age of 10 years have pigment stones in their gall bladder. Every child with gall-stones should be investigated for hereditary spherocytosis, and enquiry should be made among relatives of patients with spherocytosis for evidence of similar disease.

On examination the spleen is large and, in thin patients, can be palpated easily. Sometimes the liver is also palpable. Chronic leg ulcers can occur in adults with the disease.

Haematological investigations

The fragility test. Increased fragility of erythrocytes characterises this disease. Normally, erythrocytes begin to haemolyse in 0.47 per cent saline solution. In this condition haemolysis occurs in 0.6 per cent or in even stronger solutions.

The reticulocyte count. To compensate for the loss of erythrocytes by haemolysis, the bone marrow discharges into the circulation immature red cells which differ from adult cells by possessing a reticulum.

Faecal urobilinogen. Faecal urobilinogen is increased, as most of the urobilinogen is excreted by this route.

Use of radioactive chromium. Labelling the patient’s own red cells with 51Cr will demonstrate the severity of red cell destruction, and if this is accompanied by daily scanning over the spleen it will show the degree of red cell sequestration by the spleen. If splenic radioactivity is high, splenectomy will be of value.

Treatment

All patients who have hereditary spherocytosis should be treated by splenectomy. In juvenile cases the age at which operation is recommended has been decreasing. If it is not imperative before, the optimum time seems to be about 7 years of age, before gallstones have had time to form but subsequent vulnerability to infection is reduced. Ultrasonography should be performed preoperatively to determine the presence or absence of gallstones.

Acquired autoimmune haemolytic anaemia

This may be due to a drug reaction (e.g. to alpha-methyldopa), to another disease (e.g. systemic lupus erythematosus) or its cause may be unknown. Red cell survival is reduced because of an immune reaction triggered by immunoglobulins or complement on the red cell surface. The red cell surface is damaged as a result of the binding of the Fc portion of the red cell antibody to a macrophage Fc receptor in the spleen. The red cell is thus rendered vulnerable to ‘culling’ within the red cell pulp.

Clinical features

Autoimmune haemolytic anaemias are more common after the age of 50 years and in women. The spleen is enlarged in 50 per cent and pigment gallstones are present in 20 per cent of cases.

Investigations

Anaemia is invariably present and may be associated with spherocytosis because of red cell membrane damage. The Coombs’ test is usually, but not invariably, positive.

Treatment
Usually the disease has an acute, self-limiting course, and no treatment is necessary. Splenectomy should, however, be considered if:

- corticosteroids are ineffective;
- the patient is developing complications from long-term steroid treatment;
- corticosteroids are contraindicated, for example because of a history of peptic ulcer.

Eighty per cent of patients respond to splenectomy.

Thalassaemia (syn. Cooley's anaemia; Mediterranean anaemia)

Thalassaemia is the result of a defect in haemoglobin peptide chain synthesis which is transmitted as a dominant trait. The disease is really a group of related diseases alpha beta and gamma, depending on the haemoglobin peptide chain whose rate of synthesis is reduced. Most patients suffer from beta-thalassaemia in which a reduction in the rate of beta-chain synthesis results in a decrease in haemoglobin A. In addition to a decrease in haemoglobin, intracellular precipitates (Heinz bodies) contribute to premature red cell destruction. The disease is no longer thought to be confined to those living around the Mediterranean.

Clinical features

Graduations of the disease range from heterozygous thalas-saemia minor to homozygous thalassaemia major which is associated with chronic anaemia, jaundice and splenomegaly. Patients with homozygous thalassaemia major frequently develop clinical signs within the first year of life: retarded growth, enlarged head with slanting eyes and depressed nose, leg ulcers, jaundice and abdominal distension (due to splenomegaly).

Investigations

Red cells are small, thin and misshapen, and have a character-istic resistance to osmotic lysis. In the more severe forms nucleated red cells and other immature blood cells are seen. The final diagnosis is by haemoglobin electrophoresis.

Treatment

Blood transfusion may be necessary to correct profound anaemia. Splenectomy is occasionally of benefit in patients who require frequent blood transfusion — particularly if they have developed haemolytic antibodies from repeated trans-fusion — and where the bulky spleen is uncomfortable or painful.

Sickle cell disease

Sickle cell disease is a hereditary haemolytic anaemia, occurring mainly among those of African origin, in which the normal haemoglobin A is replaced by haemoglobin S (HbS). The HbS molecule crystallises when the blood oxygen tension is reduced and this distorts and elongates the red cell. This increases blood viscosity and obstructs flow of blood through both the ‘open’ and ‘closed’ circulations in the spleen, and through other blood vessels. Splenic micro-infarcts, splenomegaly and, later, autosplenectomy develop. This is associated with reduced antibody production and a reduced ability to filter bacteria — especially Streptococcus pneumoniae — in the spleen.

Clinical features

The sickle cell trait can be detected in 9 per cent of those of African origin but most are asymptomatic; sickle cell disease occurs in about 1 per cent of Africans. Depending on the vessels affected by the vascular occlusion, patients may have bone or joint pain, priapism, neurological abnormalities, skin ulcers or abdominal pain due to visceral blood stasis.

Investigations

Characteristic sickle-shaped cells can be seen in a blood film, but this has been replaced by haemoglobin electrophoresis.

Treatment

Hypoxia, which provokes a sickling crisis, should be avoided, and particular care taken in patients with sickle cell anaemia undergoing general anaesthesia. Adequate hydration and partial exchange transfusion may help in a crisis. Splenectomy is of benefit in a few patients where excessive splenic sequestration of red cells aggravates the anaemia. This hypersplenism may be chronic, which usually occurs in late childhood or adolescence, or acute, which occurs in the first 5 years of life and may be precipitated by Streptococcus pneumoniae infection. Acute attacks of hypersplenism can usually be treated with packed red cell transfusion, but occasionally splenectomy is of benefit.

Hypersplenism

This is an indefinite term which includes splenic enlargement, any combination of anaemia, leucopenia or thrombocyto-penia, compensatory bone marrow hyperplasia and improve-ment after splenectomy. The vagueness of the definition implies careful clinical judgement between surgeon and haematologist to determine when long- and short-term risks of splenectomy are less than those of continued conservative management.
Splenomegaly

Schistosomiasis

This is prevalent in Africa (particularly around the Nile delta), Asia and South America. It is caused by infection with *Schistosoma mansoni* in nearly 75 per cent of cases and by *Schistosoma haematobium* in the remainder. Splenic enlargement is produced by hyperplasia which is induced by phagocytosis of disintegrated worms, ova and toxins, and by portal hypertension which is the result of hepatic fibrosis.

Clinical features

Splenomegaly arising from schistosomiasis can occur at any age and is more prevalent in males. The degree of splenic enlargement reflects the extent of hepatic fibrosis and may be massive.

Investigations

The urine and faeces are examined for ova. Liver function tests reveal a varying degree of hepatic impairment. A hypochromic anaemia is always present.

Treatment

Successful medical treatment of established cases does not result in regression of the splenomegaly. Removal of the painful and bulky spleen is indicated where there is no evidence of hepatic or renal insufficiency. If ascites is present, a portosystemic shunt should be combined with splenectomy.

Tropical splenomegaly

Massive enlargement of the spleen occurs frequently in the tropics, for example in malaria (especially in children), kala-azar and schistosomiasis (see above). In parts of Africa and New Guinea splenomegaly cannot be fully attributed to these diseases because tropical splenomegaly is restricted to only a few adults in areas where malaria is endemic. The most likely explanation is an abnormal immune response to malaria or unusual species of plasmodia. Malnutrition may also be a factor and there is a high incidence in lactating women.

The spleen is grossly enlarged (2000—4000 g). This is associated with anaemia due to shortened red cell life and thrombocytopenia due to splenic sequestration of platelets, which respond to splenectomy. Splenectomy is indicated for those disabled by anaemia or by the weight of an enormous spleen. Splenectomy reduces immunity to malaria and there-for antimalarial chemotherapy (e.g. proguanil) should follow splenectomy in malaria endemic areas and be maintained for life.

Hypersplenism due to portal hypertension

Splenomegaly invariably accompanies portal hypertension. This splenic enlargement results in thrombocytopenia (due to splenic sequestration of platelets) and granulocytopenia. These are permanently relieved when splenectomy accom-panies operation for the relief of portal hypertension. Shunt surgery alone does not have the same effect.

Felty’s syndrome

A moderate number of patients with chronic rheumatoid arthritis develops mild leucopenia; in a few of these, neutropenia becomes extreme and is usually associated with enlargement of the spleen; this combination is referred to as ‘Felty’s syndrome’. A remarkable characteristic of this syndrome is that the leucopenia and splenic enlargement are apparently unrelated to the severity of the arthritic changes; indeed, in some instances the arthritis has begun to improve or has become quiescent by the time the low white cell count and the splenomegaly become unmistakable. In those cases in which the arthritis is slight but the splenic enlargement and blood changes are much in evidence, a diagnosis of primary splenic neutropenia is sometimes made. The results of splenectomy are variable. Usually there is an improvement in the blood picture with increased neutrophils, but this improvement is not maintained. However, the liability to infections seems to be decreased in many cases and rheuma-toid arthritis that has become resistant to steroid therapy may, once again, react favourably to the administration of steroids.

Tuberculosis

Tuberculosis of the spleen is not so uncommon as is some-times believed. It occurs chiefly in adults between 20 and 40 years of age. When a patient has splenomegaly with asthenia, loss of weight and an evening fever, it is well to bear in mind the possibility that the enlargement of the spleen may be due to tuberculosis. Too often the signs lead to erroneous diagnosis of leukaemia or some other disorder for which splenectomy is not indicated. Occasionally tuber-culos of the spleen produces portal hypertension. Another form is cold abscess, which is very rare. Splenic puncture followed by culture or guinea-pig inoculation will yield positive results. A therapeutic test with antituberculous drugs (Chapter 8) brings about some improvement, and there is less danger of dissemination of the tubercle bacilli if splenectomy is undertaken. The operation, which is usually rendered difficult because of adhesions, is contraindicated only if other active tuberculous lesions are found to be present. Other-wise, the results of splenectomy in the treatment of tuberculosis of the spleen are excellent.

Neoplasms

The most common benign tumour of the spleen is the haemangioma which may, on occasion, develop into a haemangiosarcoma. Splenectomy may be necessary. The commonest cause of neoplastic enlargement of the spleen is lymphoma. Splenectomy may play a part in the management of these conditions (Chapter 17), but the role is now limited.

Porphyria

Porphyria is a hereditary error of catabolism of haemoglobin in which porphyriuria occurs. The abdominal crises, which are characterised by violent intestinal colic with constipation, are liable to be precipitated by the administration of barbiturates, for which these patients have an idiosyncrasy. The patient is anaemic, frequently suffers from photosensitivity and, in advanced stages of the disease, neurological or mental symptoms (from damage to the brain) are commonly present. On examination, the spleen will be found to be enlarged. On a number of occasions the splenic enlargement, which is usually well marked, has been overlooked and the abdomen has been opened on the presumptive diagnosis of intestinal or appendicular colic, with negative findings. Another manifestation of acute porphyria is spasmodic abdominal pain followed by jaundice.

Two methods of establishing the diagnosis are available.
• The urine is sometimes normal in colour —usually it is orange (often dismissed as ‘concentrated’). If a urine specimen is left exposed to daylight for a few hours it develops a port wine colour, particularly near the surface where it is exposed to the air. There are several conclusive laboratory tests for porphyrinuria.

• Radiography of the abdomen —serial radiographs show areas of intestinal spasm causing short segments of gaseous dilatation of the small and large intestine, and especially of the caecum.

**Treatment**

Often there is a striking decrease in the serum sodium level and the patient is improved considerably by the infusion of isotonic saline solution with careful control of electrolyte balance. Methadone is the best drug to relieve the abdominal pain. If a sedative is required, one of the phenothiazines (e.g. chlorpromazine) should be given. Splenectomy is not of value except in the uncommon erythropoietic type with splenomegaly.

**Gaucher’s disease**

As mentioned, the spleen may take an active part in the storage of abnormal lipoids, as does the remainder of the reticuloendothelial system. In the case of Gaucher’s disease the lipoid in question is glucocerebroside. Gaucher’s disease, which is rare, is characterised by enormous enlargement of the spleen, which may weigh 8 or 9 lbs (3.6—4.1 kg). In most cases the splenic enlargement begins in early childhood, often before the age of 12 years, although the patient rarely seeks advice before adult life. Until the splenic enlargement becomes massive the symptoms are few. There is anaemia, a yellowish-brown discoloration of the skin of the hands and face, and a curious conjunctival thickening (pinguecula) that helps to clinch the clinical diagnosis. Slavonic and Jewish races appear to be more prone to the disease than other races. The diagnosis is confirmed by finding Gaucher’s cells in the bone marrow.

**Treatment**

Splenectomy rids the patient of a large abdominal swelling, but the operation is difficult because of perisplenitis and friability of the splenic pulp. It does not greatly influence the course of the disease, but because it reduces the hyper-splenism (anaemia, leucopenia and thrombocytopenia) and makes the patient more comfortable, the procedure may be indicated.

**Leukaemia**

Leukaemia is one of the conditions to be considered in the differential diagnosis of splenomegaly. The diagnosis can be made by examination of a blood or marrow film. The main treatment is chemotherapy or radiotherapy; occasionally marrow transplantation may be necessary. Splenectomy during the chronic phase of chronic granulocytic leukaemia will not reduce the incidence of blast transformation or improve survival. The procedure should be reserved for hypersplenism occurring during the chronic phase, or for when bone marrow transplantation might be necessary. In rare instances the removal of a symptomatic enlarged spleen during the blastic phase produces relief, but the period of relief is brief and the operation hazardous.

Splenectomy is occasionally indicated for palliation of a painful bulky spleen in chronic lymphocytic leukaemia, but only after consultation with an experienced haematologist.

**Abscess of the spleen**

If a splenic embolus is infected, and the primary condition does not prove fatal, a splenic abscess may be expected to follow. Other sources of metastatic abscess of the spleen are typhoid and paratyphoid fever, osteomyelitis, otitis media and puerperal sepsis. An abscess in the right upper pole of the spleen may rupture and form a left subdiaphragmatic abscess. If the abscess is in the lower pole, rupture results in diffuse peritonitis.

**Treatment**

As a rule, owing to dense adhesions, drainage of the abscess is the only course. Very rarely, splenectomy may be possible with the abscess in situ. The drainage may be performed percutaneously, under ultrasonic or CT guidance, so avoiding the need for operative intervention.
Adynamic obstruction

Paralytic ileus

This may be defined as a state in which there is failure of transmission of peristaltic waves secondary to neuro-muscular failure [i.e. in the myenteric (Auerbach) and the submucous (Meissner) plexuses]. The resultant stasis leads to accumulation of fluid and gas within the bowel with associated distension, vomiting, absence of bowel sounds and absolute constipation.

Varieties

The following varieties are recognised.

• Postoperative — a degree of ileus usually occurs after any abdominal procedure and is self-limiting with a variable duration of 24—72 hours. Postoperative ileus may be prolonged in the presence of hypoproteinaemia or metabolic abnormality (vide in infra).

• Infection — intra-abdominal sepsis may give rise to localized or generalised ileus. Resultant adhesions may contribute a mechanical element to the initial neurogenic aetiology.

• Reflex ileus — may occur following fractures of the spine or ribs, retroperitoneal haemorrhage or even the application of a plaster jacket.

• Metabolic — uraemia and hypokalaemia are the commonest contributory factors.

Clinical features

Paralytic ileus takes a clinical significance if 72 hours after laparotomy:

• there has been no return of bowel sound on auscultation;

• there has been no passage of flatus.

Abdominal distension becomes more marked and tympanitic. Pain is not a feature. In the absence of gastric aspiration, effortless vomiting may occur. Radiologically, the abdomen shows gas-filled loops of intestine with multiple fluid levels.

Management

The essence of treatment is prevention, with the use of nasogastric suction and restriction of oral intake until bowel sounds and the passage of flatus return. Electrolyte balance must be maintained.

Specific treatment is directed towards the cause, but the following general principles apply:

• the primary cause must be removed;

• gastrointestinal distension must be relieved by decompression;

• close attention to fluid and electrolyte balance is essential;

• there is no place for routine use of peristaltic stimulants. Rarely, medical therapy with the adrenergic blocking agent in association with cholinergic stimulation, e.g. neostigmine (the Catchpole regime), may be used in resistant cases provided that an intraperitoneal cause has been excluded;

• if paralytic ileus is prolonged and threatens life, a laparotomy should be considered to exclude a hidden cause and facilitate bowel decompression.

Pseudo-obstruction

This condition describes an obstruction, usually of the colon, in the absence of a mechanical cause or acute intra-abdominal disease. It is associated with a variety of syndromes where there is an underlying neuropathy and/or myopathy. A variety of causes has been described (Table 58.7).

Small intestinal pseudo-obstruction

This condition may be primary (i.e. idiopathic or associated with familial visceral myopathy) or secondary. The clinical picture consists of recurrent subacute obstruction. The diagnosis is made by the exclusion of a mechanical cause. Treatment consists of initial correction of any underlying disorder. Metoclopramide and erythromycin may be of use but cisapride, which increases the local concentration of acetylcholine with the smooth muscle, is the drug of choice.

Colonic pseudo-obstruction

This may occur in an acute or a chronic form. The former, also known as Ogilvie syndrome, presents as acute large bowel obstruction. Abdominal radiographs show evidence of colonic obstruction with marked caecal distension being a common feature. Indeed, caecal perforation is a well-recognised complication. The absence of a mechanical cause requires urgent confirmation by colonoscopy or a single contrast water-soluble barium enema. Once confirmed, pseudo-obstruction should be treated by colonoscopic decompression. This may recur in 25 per cent of cases requiring further colonoscopy with simultaneous placement of a flatus tube. When colonoscopy fails or is unavailable, a tube caecostomy may be required. The chronic form may respond to cisapride but continued symptoms may benefit from surgical intervention with subtotal colectomy and ileorectal anastomosis.

Acute mesenteric ischaemia

Mesenteric vascular disease may be classified as acute intestinal ischaemia — with or without occlusion — venous, chronic arterial, central or peripheral. The superior mesenteric vessels are likeliest of the visceral vessels to be affected by embolisation or thrombosis, with the former being most common. Occlusion at the origin of the superior mesenteric artery (SMA) is almost invariably the result of thrombosis, whilst embol
lodge at the origin of the middle colic artery. Inferior mesenteric involvement is usually clinically silent owing to a better collateral circulation.

Possible sources for the embolisation of the SMA include the left atrium associated with fibrillation, a mural myocardial infarct, an atheromatous plaque from an aortic aneurysm and a mitral valve vegetation associated with endocarditis.

Primary thrombosis is associated with atherosclerosis or thromboangiitis obliterans.

Primary thrombosis of the superior mesenteric veins may occur in association with factor V leiden, portal hypertension, portal pyaemia, sickle cell disease and in women taking the contraceptive pill.

Irrespective of whether the occlusion is arterial or venous, haemorrhagic infarction occurs. The mucosa is the only layer of the intestinal wall to have little resistance to ischaemic injury. The intestine and its mesentery become swollen and oedematous. Blood-stained fluid exudes into the peritoneal cavity and bowel lumen. If the main trunk of the SMA is involved the infarction covers an area from just distal to the duodenojejunal flexure to the splenic flexure. Usually a branch of the main trunk is implicated and the area of infarction is less.

**Clinical features**

The most important clue to an early diagnosis is the sudden onset of severe abdominal pain in a patient with atrial fibrillation or atherosclerosis. The pain is typically central and out of all proportion to physical findings. Persistent vomiting and defecation occur early with the subsequent passage of altered blood. Hypovolaemic shock rapidly ensues. Abdominal tenderness may be mild initially with rigidity being a late feature.

Investigation will usually reveal a profound neutrophil leucocytosis with an absence of gas in the thickened small intestine on abdominal radiograph. The presence of gas bubbles in the mesenteric veins is rare but pathognomonic.

Treatment needs to be tailored to the individual. In conjunction with full resuscitation, in early embolic cases embolectomy via the ileo-colic artery or revascularisation of the SMA may be considered. The majority of cases, however, is diagnosed late. In the young all affected bowel should be resected, whilst in the elderly or infirm the situation may be deemed incurable. Anticoagulations should be implemented early in the postoperative period.

After extensive enterectomy it is usual for patients to require intravenous alimentation. The young, however, may sometimes develop sufficient intestinal digestive and absorptive function to lead relatively normal lives. In selected cases, consideration may be given to small bowel transplantation, but at present this must be considered experimental.

Infarction of the large intestine alone is relatively rare. Involvement of the middle colic artery territory should be treated by transverse colectomy and exteriorisation of both ends, with an extended right hemicolectomy in selected cases.

Ischaemic colitis describes the structural changes which occur in the colon as a result of the deprivation of blood. They are commonest in the splenic flexure whose blood supply is particularly tenuous. They have been classified by Marston into gangrenous, stricturing and transient forms. Acute presentation is with lower abdominal pain and the passage of blood per rectum. The differential diagnosis is usually from a carcinoma, Crohn’s disease or ulcerative colitis. In those patients without evidence of peritonism, most cases resolves spontaneously. In a few, a permanent stricture develops requiring elective resection.

Surgical anatomy and physiology

The gall bladder is pear-shaped, 7.5—12 cm long, with a normal capacity of about 50 ml, but capable of considerable distension in certain pathological conditions. The anatomical divisions are a fundus, a body and a neck that terminates in a narrow infundibulum. The muscle fibres in the wall of the gall bladder are arranged in a criss-cross manner, being particularly well developed in its neck. The mucous membrane contains indentations of the mucosa that sink into the muscle coat; these are the crypts of Luschka.

The cystic duct is about 3 cm in length but variable. Its lumen is usually 1—3 mm in diameter. The mucosa of the cystic duct is arranged in spiral folds known as the valves of Heister. Its wall is surrounded by a sphincteric structure called the sphincter of Lutkins. While the cystic duct joins the common hepatic duct in its supraduodenal segment in 80 per cent of cases, it may extend down into the retroduodenal or even retropancreatic part of the bile duct before joining. Occasionally the cystic duct may join the right hepatic duct or even a right hepatic sectorial duct.

The common hepatic duct is usually less than 2.5 cm long and is formed by the union of the right and left hepatic ducts. The common bile duct is about 7.5 cm long and formed by the junction of the cystic and common hepatic ducts. It is divided into four parts:

• the supraduodenal portion, about 2.5 cm long, running in the free edge of the lesser omentum;

• the retroduodenal portion;

• the infraduodenal portion lies in a groove, but at times in a tunnel, on the posterior surface of the pancreas;

• the intraduodenal portion passes obliquely through the wall of the second part of the duodenum where it is surrounded by the sphincter of Oddi. It terminates by opening on the summit of the papilla of Vater.

The arterial supply of the gall bladder is critical. It is proposed that arterial damage during cholecystectomy may cause ischaemia and result in postoperative bileduct stricture. The cystic artery, a branch of the right hepatic artery, is usually given off behind the common hepatic duct (Fig. 54.1). Occasionally, an accessory cystic artery arises from the gastroduodenal artery. In 15 per cent of cases the right hepatic artery and/or the cystic artery cross in front of the common hepatic duct and the cystic duct. The most dan-gerous anomalies are where the hepatic artery takes a torturous course on the front of the origin of the cystic duct, or the right hepatic artery is torturous and the cystic artery short. The tortuosity is known as the ‘caterpillar turn’ or ‘Moynihan’s hump’ (Fig. 54.2). This variation is the cause of many problems during a difficult cholecystectomy with inflammation in the region of the cystic duct. Inadvertent damage to the right hepatic artery is most difficult to control laparoscopically.

Lymphatics

The lymphatic vessels of the gall bladder (subserosal and submucosal) drain into the cystic lymph node of Lund (the sentinel lymph node), which lies in the fork created by the junction of the cystic and common hepatic ducts. Efferent vessels from this lymph node go to the hilum of the liver, and to the coeliac lymph nodes. The subserosal lymphatic vessels of the gall bladder also connect with the subcapsular lymph channels of the liver, and this accounts for the frequent spread of carcinoma of the gall bladder to the liver.

Surgical physiology

Bile, as it leaves the liver, is composed of 97 per cent water, 1—2 per cent bile salts, and 1 per cent pigments, cholesterol and fatty acids. The liver excretes bile at a rate estimated to be approximately 40 ml/hour. The rate of bile secretion is controlled by cholecystokinin which is released from the duodenal mucosa. With feeding there is increased production of bile.

Functions of the gall bladder

The gall bladder is a reservoir for bile. During fasting resistance to flow through the sphincter is high, and bile excreted by the liver is diverted to the gall bladder. After feeding the resistance to flow through the sphincter of Oddi is reduced, the gall bladder contracts and the bile enters the duodenum. These motor responses of the biliary tract are in part effected by the hormone cholecystokinin.

The second main function of the gall bladder is concentration of bile by active absorption of water, sodium chloride and bicarbonate by the mucous membrane of the gall bladder. The hepatic bile which enters the gall bladder becomes concentrated 5—10 times, with a corresponding increase in the pro-portion of bile salts, bile pigments, cholesterol and calcium.

The third function of the gall bladder is the secretion of mucus — approximately 20 ml is produced per day. With total obstruction of the cystic duct in a healthy gall bladder, a mucocele develops on account of this function of the mucosa of the gall bladder.
Investigation of the biliary tract

Plain radiograph
The skilfully taken plain X-ray of the gall bladder will show radio-opaque gallstones in 10 per cent of patients (Fig. 54.3). It will also show the rare cases of calcification of the gall bladder, a so-called ‘porcelain’ gall bladder (Fig. 54.4). The importance of this appearance is that it is premalignant and an indication for cholecystectomy. Limey bile is a curiosity and is frequently related to multiple small stones (Fig. 54.5). This lesion is not a premalignant lesion.

Oral cholecystography (Graham—Cole test) (Figs 54.6 and 54.7)
Lipoanionic BP is taken in tablets or in liquid form as a suspension or an emulsion, but by far the commonest method is to combine water-soluble contrast medium in a single dose with a capsule of the drug. A control radiograph is taken before the tablets are given, and a series of X-rays is taken on the following day, with further films after a fatty meal. The fatty meal stimulates gall-bladder contraction and reveals the adequacy of gall-bladder function.

This investigation has been discarded by most hospitals because of its inaccuracy except to show diverticulae and polyps, and to assess function; adequate films depend on the patient taking the tablets, and the tablets being absorbed, secreted by the liver and concentrated in the bile ducts. Thus, a cholecystogram which shows no concentration of contrast can result from many causes and it is not diagnostic of gallstone disease.

Intravenous cholangiography
Intravenous cholangiography (biligram—meglimine ioglycamate) permits radiological visualisation of the bile ducts. The drug is given intravenously and is rapidly secreted by the liver into the biliary tree. Careful radiography with or without tomography can clearly define the ducts and the gall bladder delineating the presence of stone disease. The contrast agent can cause allergic reactions such that this test has been discarded in most units.

Ultrasonography (Figs 54.8, 54.9, 54.10, 54.11, 54.12 and 54.13) is noninvasive and is now the standard initial imaging technique for the investigation of the patient suspected of having a gallstone, and is also the prime investigation for the patient presenting with jaundice. It will demonstrate biliary calculi, the size of the gall bladder, the thickness of the gall-bladder wall, the presence of inflammation around the gall bladder, the size of the common bile duct and, occasionally, the presence of stones within the biliary tree. It may even show a carcinoma of the pancreas occluding the common bile duct.

Radioisotope scanning
Technetium-99m (99mTc)-labelled derivatives of imino-diacectic acid (HIDA, PIPIDA) are excreted in the bile and are used to visualise the biliary tree. In acute cholecystitis the gall bladder is not seen. The technique is used when biliary enteric anastomosis are functioning inadequately as it will show the extent of obstruction at the anastomosis and indicate the delay in excretion.

Computerised tomography (CT)
CT is not a useful technique in investigating the biliary tree. Its only value is in the investigation of patients who may have a cancer of the gall bladder or bile ducts, and in these patients will define its extent, the presence of lymphadenopathy and the presence of metastases.

Magnetic resonance cholangiopancreatography (MRCP)
MRCP is now the standard technique for investigation of the biliary tree. Contrast is not necessary and, with appropriate computing, a clear outline of the biliary tree can be achieved with a sensitive and specific diagnosis of bile-duct stones. This technique will replace alternative diagnostic aids as the appropriate magnets with the specific software become more widely available (Fig. 54.14).

Endoscopic retrograde cholangiopancreatography (ERCP)
The ampulla of Vater can be cannulated with the aid of a fibre-optic duodenoscope. The bile ducts are visualised after injecting water-soluble contrast. Bile can be sent for cytological and microbiological examination, and brushings can be taken from strictures for cytological studies. Acute cholangitis may follow ERCP when contrast fills a dilated and obstructed duct; antibiotics are given as prophylaxis, and if obstruction is encountered relief of that obstruction by the placement of a stent must be undertaken. If drainage cannot be achieved then percutaneous transhepatic drainage should be performed. Diagnostic ERCP is now less commonly performed, but its value is its ability to remove stones and stent strictures, thus becoming a therapeutic rather than a diagnostic technique (Figs 54.15, 54.16, 54.17, 54.18, 54.19 and 54.20).

This investigation is only undertaken once a bleeding tendency has been excluded and the patient’s prothrombin time is normal. Antibiotics should be given prior to the procedure. Under fluoroscopic control, a needle (the Chiba or Okuda needle) 15 cm long and 0.7 mm in diameter is advanced into the liver through the eighth intercostal space in the mid-axillary line to a point about 2 cm short of the right margin of the vertebral column. The stilette is then removed and while injecting contrast (e.g. meglumine iothalamate 60 per cent, w/v) the needle is slowly withdrawn until contrast is seen entering a bile radical. Addition to this technique enables placement of a catheter into the bile ducts to provide external biliary drainage or the insertion of indwelling stents. The scope of this procedure can be further extended by leaving the drainage catheter in situ for a number of days and then dilating the track sufficiently for a fine flexible choledochoscope to be passed into the intrahepatic biliary tree in order to diagnose strictures, take biopsies and remove stones.

Percutaneous cholangiography
During cholecystectomy a catheter can be placed in the cystic duct and contrast injected into the biliary tree. The technique defines the anatomy and excludes the presence of stones. With improved preoperative imaging and a more careful operative approach the value of this technique is debatable. The limitation of the technique using single plates can be overcome by an X-ray image intensifier with a television monitor which enables a much more accurate diagnosis of biliary pathology (Figs 54.23, 54.24, 54.25).

Operative biliary endoscopy (choledochoscopy)
At operation a flexible fibre-optic endoscope can be passed down the cystic duct into the common bile duct enabling stone identification and removal under direct vision. The technique can be combined with an X-ray image intensifier to ensure complete clearance of the biliary tree.

After exploration of the bile duct, a tube can be left in the cystic duct remnant or in the common bile duct (a T-tube) and drainage of the biliary tree established. After 7—10 days, a track will be established. This track can be used for the passage of a choledochoscope to remove residual stones in the awake patient in an endoscopy suite. This technique is invaluable in the management of difficult stone disease and prevents the excessive prolongation of an operative exploration of the common bile duct.
Congenital abnormalities of the gall bladder and bile ducts

Embryology

The hepatic diverticulum arises from the ventral wall of the foregut and elongates into a stalk to form the choledochus. A lateral bud is given off which is destined to become the gall bladder and cystic duct. The embryonic hepatic duct sends out many branches which join up the canaliculi between the liver cells. As is usual with embryonic tubular structures, hyperplasia obliterates the lumina of this ductal system; normally recanalisation subsequently occurs and bile begins to flow. During early foetal life the gall bladder is entirely intrahepatic.

Absence of the gall bladder

Occasionally the gall bladder is absent. Failure to visualise the gall bladder is not necessarily a pathological problem.

The Phrygian cap

The Phrygian cap (Fig. 54.26) is present in 2—6 per cent of cholecystograms and may be mistaken for a pathological deformity of the organ. ‘Phrygian cap’ refers to hats worn by people of Phrygia, an ancient country of Asia Minor; it was rather like a liberte’ cap of the French Revolution.

Floating gall bladder

The organ may hang on a mesentery which makes it liable to undergo torsion.

Double gall bladder

Rarely, the gall bladder is twinned. One of the twins may be intrahepatic.

Absence of the cystic duct

This is usually a pathological, as opposed to an anatomical anomaly and indicates the recent passage of a stone or the presence of a stone at the lower end of the cystic duct which is ulcerating into the common bile duct. The main danger at surgery is damage to the bile duct, and particular care to identify the correct anatomy is essential before division of any duct.

Low insertion of the cystic duct

The cystic duct opens into the common bile duct near the ampulla. All variations of this anomaly can occur. At operation they are not important. Dissection of a cystic duct which is inserted low in the bile duct should be avoided as removal will damage the blood supply to the common bile duct and can lead to stricture formation.

An accessory cholecystohepatic duct

Ducts passing directly into the gall bladder from the liver do occur and are probably not uncommon. Nevertheless, larger ducts should be closed but before doing so the precise anatomy should be carefully ascertained (Fig. 54.27).

Extrahepatic biliary atresia

A etiology and pathology

Atresia is present in one per 14 000 live births, and affects male and females equally. The extrahepatic bile ducts are progressively destroyed by an inflammatory process which starts around the time of birth. Intrahepatic changes also occur and eventually result in biliary cirrhosis and portal hypertension. The untreated child dies before the age of 3 years of liver failure or haemorrhage.

The inflammatory destruction of the bile ducts has been classified into three main types (Fig. 54.28):

- type I — atresia restricted to the common bile duct;
- type II — atresia of the common hepatic duct;
- type III — atresia of the right and left hepatic ducts.

Associated anomalies include, in about 20 per cent of cases, cardiac lesions, polysplenia, situs inversus, absent vena cava and a pre duodenal portal vein.

Clinical features

About one-third of cases are jaundiced at birth. In all, how-ever, jaundice is present by the end of the first week and deep-ens progressively. The meconium may be a little bile stained but later the stools are pale and the urine is dark. Prolonged steatorrhoea gives rise to osteomalacia (biliary rickets). Pruritis is severe. Clubbing and skin xanthomas, probably related to a raised serum cholesterol, may be present.

Differential diagnosis

This includes any form of jaundice in a neonate giving a cholestatic picture. Examples are alpha-1-antitrypsin deficiency, cholestasis associated with intravenous feeding, choledochal cyst and inspissated bile syndrome. Neonatal hepatitis is the most difficult to differentiate. Both extrahepatic biliary atre-sia and neonatal hepatitis are associated with giant cell transformation of the hepatocytes. Liver biopsy and radio-nuclide excretion scans are essential.

Treatment

Patent segments of proximal bile duct are found in 10 per cent of type I lesions. A direct Roux-en-Y anastomosis will achieve bile flow in 75 per cent, but progressive fibrosis results in disappointing long-term results. Type II and III are treated by the Kasai procedure, in which radical excision of all bile-duct tissue up to the liver capsule is performed. A Roux-en-Y loop of jejunum is anastomosed to the exposed area of liver capsule above the bifurcation of the portal vein. The chances of achieving effective bile drainage after porto-enterostomy are maximal when the...
operation is performed before the age of 8 weeks, and approximately 90 per cent of children whose bilirubin falls to within the normal range can be expected to survive for 10 years or more. Early referral for surgery is critical.

Postoperative complications include bacterial cholangitis, which occurs in 40 per cent. Repeated attacks lead to hepatic fibrosis and 50 per cent of long-term survivors develop portal hypertension, with one-third having variceal bleeding. Liver transplantation may be considered in the failures.

**Congenital dilatation of the intrahepatic ducts (Carolii’s disease)**

This rare, congenital, nonfamilial condition is characterised by multiple irregular sacular dilatations of the intrahepatic ducts separated by segments of normal or stenotic ducts. Biliary stasis leads to stone formation and cholangitis. The patients present in childhood or in early adult life. Associated conditions include congenital hepatic fibrosis, medullary sponge kidney and, rarely, cholangiocarcinoma. The main-stays of treatment are antibiotics for the cholangitis and the removal of calculi. As the condition can be limited to one lobe of the liver, lobectomy may be indicated.

**Choledochal cyst**

Choledochal cyst is due to a specific weakness in a part of or the whole of the wall of the common bile duct. Anomalous junctions of the biliary pancreatic junction are frequently observed and long common channels result in high levels of biliary amylase in 80 per cent of cases. Common pancreato-biliary channels may be associated with repeated attacks of pancreatitis (Fig. 54.29). The patient may present at any age with attacks of jaundice of obstructive type, cholangitis and abdominal signs. In some patients a swelling may be detected in the upper abdomen. Ultrasonography will confirm the presence of an abnormal cyst and a magnetic resonance imaging (MRI) scan will reveal the anatomy; in particular, the relationship between the lower end of the bile duct and the pancreatic duct. It appears that the anomaly is premalignant; carcinoma of the biliary tract is a well-recognised complication and carries a poor prognosis, and therefore excision is the appropriate management.

Radical excision of the cyst is the treatment of choice with reconstruction of the biliary tract using a Roux-en-Y loop of jejunum. Other procedures have been shown to be ineffective and associated with recurrent attacks of cholangitis.

**Trauma**

Injuries to the gall bladder and extrahepatic biliary tree are rare. They occur as a result of a penetrating wound or a crush injury. Operative trauma is perhaps more frequent than external trauma. The physical signs are those of an acute abdomen. The treatment is cholecystectomy for gall bladder injuries and if the bile duct is damaged then drainage using a T-tube to the bile duct and a drain to the site of damage is appropriate. Many will stricture and these can be secondarily be repaired by a Roux-en-Y anastomosis.

**Torsion of the gall bladder**

This is very rare and relies on a long mesentery which often occurs in an older patient with a large mucocele of the gall bladder. The patient presents with extreme pain and an acute abdomen. Immediate exploration is indicated with cholecystectomy as the only treatment.
Gallstones (cholelithiasis)

Gallstones are the most common biliary pathology. Indeed, cholecystectomy is the commonest surgical procedure in the abdomen in the Western world. Gallstones are classified according to their chemical composition into cholesterol stones, mixed stones and pigment stones. Cholesterol stones consist almost entirely of cholesterol and are often solitary (cholesterol solitaire). Mixed stones account for 90 per cent of gallstones. Cholesterol is the major component. Other components include calcium bilirubinate, calcium phosphate, calcium carbonate, calcium palmitate and proteins. Usually they are multiple, and they are often faceted. Pigment stones are most common in the Far East and are composed almost entirely of calcium bilirubinate. They are mostly small and multiple. Some are hard and coral-like, whereas others are soft and really concretions of sludge rather than stones (Fig. 54.30).

Gas in gallstones

Rarely the centre of a stone may contain radiolucent gas in a triradiate or biradiate fissure and this gives rise to charac-teristic dark shapes on a radiograph — the ‘Mercedes Benz’ or ‘seagull’ signs.

Limey bile

‘Lime-water’ bile is revealed on a plain radiograph (Fig. 54.5) more clearly than if the gall bladder has been visualised by cholecystography. The opacity is the result of the gall bladder becoming filled with a mixture of calcium carbonate and calcium phosphate, usually the consistency of toothpaste. The condition tends to occur when there is a gradual obstruction of the cystic or common bile duct, for example due to chronic pancreatitis or carcinoma of the pancreas. Organisms are rarely grown from the emulsion.

Incidence of gallstones

A ‘fat, fertile, flatulent, female of fifty’ is the classical sufferer from symptomatic gallstones. Useful as this clinical memorandum is, it should be tempered with the knowledge that cholelithiasis occurs in both sexes from childhood to the centenarian. In men the disease tends to occur in the older age groups at which point the incidence is equal to that of women. Stones are rarer in Africa and in southern India, but not in north India.

Causal factors in gallstone formation

The aetiology of gallstones is probably multifactorial. Factors implicated are: (1) metabolic; (2) infective; and (3) bile stasis.

Cholesterol and mixed stones

Metabolic

Cholesterol, insoluble in water, is held in solution by a detergent action of bile salts and phospholipids with which it forms micelles (Fig. 54.31). Bile containing cholesterol stones has an excess of cholesterol relative to bile salts and phospholipids, thus allowing cholesterol crystals to form. Such bile is termed ‘supersaturated’ or ‘lithogenic’. Bile cholesterol increases with age and is raised in women, particularly those taking the contraceptive pill, in obesity and by clofibrate — a drug used in the treatment of certain hyperlipoproteinaemias. The concentration of bile salts in bile is reduced by oestrogens, and also by factors which interrupt the intrahepatic circulation of bile salts (e.g. ileal disease, resection or bypass and choleystamine therapy). These conditions are all associated with an increased incidence of stones, but there are still some people with cholesterol supersaturation who remain free of stones, suggesting that there are other factors of importance.

Infection

The role of infection in causing stones is unclear. Often bile from patients with gallstones is sterile, but organisms have been cultured from the centres of gallstones: the radiolucent centre of many gallstones may represent mucus plugs originally formed around bacteria (Moynihan’s aphorism: ‘A gall-stone is a tombstone erected to the memory of the organism within it’).

Pigment stones are seen in patients with haemolysis in which bilirubin production is increased. Examples are hereditary spherocytosis, sickle cell anaemia, thalassaemia, malar-ia and mechanical destruction of red cells by prosthetic heart valves. Pigment stones are found in the ducts of patients with benign and malignant bile duct strictures. Pigment stones in Oriental countries are associated with infestations of the biliary tree by Clonorchis sinensis and Ascaris lumbricoide. Escherichia coli is often found in the bile of these patients. This bacterium produces the enzyme i3-glucuronidase which converts the bilirubin into its unconjugated insoluble form. These stones are often present throughout the biliary tree including the intrahepatic ducts.

The effects and complications of gallstones

Stones are found throughout the biliary tract and their compli-cations relate to obstruction of the cystic duct, of the intra-hepatic radicals or of the ampulla of Vater. Obstructive complications may be aggravated by the presence of infection leading to cholangitis and abscess formation. Nevertheless, gallstones can be asymptomatic; it is estimated that between 85 and 90 per cent of patients who have gallstones remain asymptomatic. In the UK the prevalence of gallstones at the time of death is estimated to be 17 per cent and possibly increasing. Thus, the mere presence of gallstones is not an indication for a surgical approach. For this reason symptoms must be analysed with care. A typical patient may fulfil Saint’s triad having gallstones, diverticulosis of the colon and a hiatus hernia, yet with symptoms that cannot be directly contributed to any of these. When considering management of a patient with gastrointestinal symptoms it is important to take a specific history and consider whether or not the pain from which the patient suffers is typical or not of biliary tract disease.

Effects and complications of gallstones

- In the gall bladder:
  - Silent stones
  - Chronic cholecystitis
  - Acute cholecystitis
— Gangrene
— Perforation
— Empyema
— Mucocele
— Carcinoma

• *In the bile ducts:*
  — Obstructive jaundice
  — Cholangitis
  — Acute pancreatitis

• *In the intestine:*
  — Acute intestinal obstruction (‘gallstone ileus)
Cholecystitis

It is probably inappropriate, although classical, to subdivide chronic and acute calculous cholecystitis. They are part of the same spectrum of disease and are related to inflammation within the gall bladder secondary to obstruction of the cystic duct by stones. With stones in a gall bladder it appears that there is always some degree of inflammatory change, but there is insufficient evidence to suggest that this is a cause of symptoms. The concept of 'flatulent dyspepsia' being caused by gallstones in the absence of the classic symptoms of biliary colic is probably inappropriate. Nevertheless, some patients do complain of right hypochondrial pain of varying severity in association with nausea and occasional vomiting, and some tenderness in the right subcostal region. Flatulent dyspepsia is common in such patients yet many will not be relieved by cholecystectomy. Numerous investigations have been performed to determine whether those with symptoms of dyspepsia will benefit from cholecystectomy; all have proved ineffective and thus the surgeon must rely on clinical judgment.

Clinical features

The patient has specific episodes of right subcostal pain radiating to the back and to the shoulder. Occasionally the pain starts on the left subcostal side or even in the epigastrum, but at its most severe it is invariably on the right side. Pain may radiate to the chest. The pain is usually severe and may last for minutes or even several hours. Frequently, the pain starts during the night and wakes the patient. Minor episodes of the same discomfort may occur intermittently during the day. Dyspeptic symptoms may coexist and be worse after such an attack. As the pain resolves the patient improves and is able to eat and drink again, often only to suffer further episodes. It is of interest that the patient may have several episodes of this nature over a period of a few weeks and then no more trouble for some months.

If the pain does not resolve the patient will become more systemically unwell as infection supervenes. This is associated with a continuous pain, nausea, vomiting and pyrexia. On examination the patient will be tender in the right subcostal area and may develop guarding, even rigidity, and later a mass may be palpable as the omentum walls off an inflamed gall bladder.

Fortunately, this process is limited by the stone slipping back into the body of the gall bladder and the contents of the gall bladder escaping by way of the cystic duct. This achieves adequate drainage of the gall bladder and enables the inflammation to resolve.

If resolution does not occur the gall bladder may perforate with the development of localised peritonitis or an abscess may form; the abscess may then perforate into the peritoneal cavity with a septic peritonitis — this is uncommon, however, because the gall bladder is usually localised by omentum around the perforation.

When examining a patient with acute cholecystitis it should be noted whether the patient is pyrexial, is jaundiced or dehydrated. His or her respiration should be noted to determine whether there is pain on deep inspiration. On examining the abdomen it is important to determine whether the movement is normal or shallow breathing is present with intestinal distension. The abdomen should be palpated gently, working towards the subcostal area where tenderness with guarding may be noted. In some patients a mass may be palpable. Bowel sounds are usually present but reduced.

Differential diagnosis

Conditions commonly presenting similarly to acute cholecystitis are appendicitis, perforated peptic ulcer and acute pancreatitis. Occasionally acute pyelonephritis of the right kidney, myocardial infarction and right lower lobe pneumonia may lead to confusion. The diagnosis is confirmed by ultrasonography which should show the presence of stones in an inflamed gall bladder with oedema around the gall bladder wall (Fig. 54.32). The stone can often be observed impacted in the infundibulum. A serum amylase estimation should be performed to exclude pancreatitis, and liver functions tests performed to determine whether or not jaundice is present. A mild elevation of the bilirubin can merely be due to oedema around the portahepatis or obstruction of the biliary tree by a stone escaping into the common bile duct. The distended bile duct should be noted on ultrasonography. A chest X-ray will exclude pneumonia, and if there is doubt concerning a cardiac origin then an electrocardiogram should be performed. Renal disease can be excluded by sending the urine for microscopy and culture.

Treatment

Conservative treatment followed by cholecystectomy

Experience shows that in more than 90 per cent of cases the symptoms of acute cholecystitis subside with conservative measures. Nonoperative treatment is based on four principles:

• nasogastric aspiration and intravenous fluid administration;
• administration of analgesics;
• administration of antibiotics — as the cystic duct is blocked in most instances, the concentration of antibiotic in the serum is more important than its concentration in bile. A broad-spectrum antibiotic effective against Gram-negative aerobes is most appropriate (e.g. cephalixin, cefuroxime or gentamycin);
• subsequent management — when the temperature, pulse and other physical signs show that the inflammation is subsiding, the nasogastric tube is removed and oral fluids followed by a fat-free diet are given. Ultrasonography is performed to ensure that no local complications have developed, that the bile duct is of a normal size and that no stones are contained in the bile duct. Cholecystectomy may either be performed on the next available list, or the patient is allowed home to return later when the inflammation has completely resolved.

Conservative treatment is not advised when there is uncertainty about the diagnosis and the possibility of a high retrocaecal appendix or a perforated duodenal ulcer cannot be excluded.

Conservative treatment must be abandoned if the pain and tenderness increase; in this case a percutaneous cholecystostomy performed by the radiologist under ultrasound control will rapidly relieve symptoms. Subsequent cholecystectomy will be required.

Routine early operations

Some surgeons advocate urgent operation as a routine measure in cases of acute cholecystitis. Provided that the operation is undertaken within 48 hours of the onset of the attack, the surgeon is experienced and excellent operating facilities are available, good results are claimed. Nevertheless, the conversion rate in laparoscopic cholecystectomy is five times higher in acute than in elective surgery.

Mucocele of the gall bladder
This occurs when the neck of the gall bladder becomes obstructed by a stone but the contents remain sterile. The bile is absorbed and replaced by mucous secreted by the gall bladder epithelium. The gall bladder may be palpable. Enormous sizes and shapes have been encountered. A mucocele also occurs in those cases of malignancy which occlude the cystic duct, for instance a cholangiocarcinoma.

**Empyema of the gall bladder**

The gall bladder appears to be filled with pus but, surprisingly in over half of cases, bacteria cannot be cultured from this pus. It may be a sequel of acute cholecystitis or the result of a mucocele becoming infected. The treatment is drainage and, later, cholecystectomy (Fig. 54.33).

**Acalculous cholecystitis**

Acute and chronic inflammation of the gall bladder can occur in the absence of stones and give rise to a clinical picture similar to calculous cholecystitis. Some patients have non-specific inflammation of the gall bladder, whereas others have one of the cholecystoses. Oral cholecystography is more useful than ultrasonography in the diagnosis of those patients presenting with chronic symptoms, and radioisotope scanning in those presenting acutely. The identification of cholesterol crystals in a duodenal aspirate may also help. Acute acalculous cholecystitis is particularly seen in patients recovering from major surgery, trauma and burns. In these patients the diagnosis is often missed and the mortality rate is 20 per cent.

**The cholecystoses (cholesterosis, polyposis, adenomyomatosis and cholecystitis glandularis proliferans)**

This is a not uncommon group of conditions affecting the gall bladder in which there are chronic inflammatory changes with hyperplasia of all tissue elements.

**Cholesterosis ('strawberry gall bladder')**

In the fresh state the interior of the gall bladder looks something like a strawberry; the yellow specks (submucous aggregations of cholesterol crystals and cholesterol esters) correspond to the seeds (Fig. 54.34). It may be associated with cholesterol stones.

**Cholesterol polyposis of the gall bladder**

Cholecystography shows negative shadows in a functioning gall bladder, or on ultrasound there is a well-defined polyp present. These are either cholesterol polyposis or adenomatous change. With improving ultrasonography they are seen more frequently and surgery advised only if they change in size. Figure 54.35 summarises the varieties of this condition. A polyp of the mucous membrane is fleshy and granulomatous. All layers of the gall bladder wall may be thickened but some-times an incomplete septum forms which separates the hyperplastic from the normal. Intraparietal 'mixed' calculi may be present. These can be complicated by an intramural, and later extramural, abscess. If symptomatic, the patient is treated by cholecystectomy.

**Diverticulosis of the gall bladder**

Diverticulosis of the gall bladder is usually manifest as black pigment stones impacted in the out-pouchings of the lacunae of Luschka. Diverticulosis of the gall bladder may be demonstrated by cholecystography, especially when the gall bladder contracts after a fatty meal. There are small dots of contrast medium just outside the gall bladder (Fig. 54.36). A septum may also be present (to be distinguished from the Phrygian cap — Fig. 54.26) and the treatment is cholecystectomy.

**Typhoid gall bladder**

Salmonella typhi ('Typhoid Mary', a cook-general who passed Salmonella typhi in her faeces and urine, was responsible for nearly a score of epidemics of typhoid in and around New York City) or, occasionally, Salmonella typhimurium can infect the gall bladder. Acute cholecystitis can occur. More frequently, chronic cholecystitis occurs, the patient being a typhoid carrier excreting the bacteria in the bile. Gallstones may be present (surgeons should not give patients their stones after their operation if there is any suspicion of typhoid!). It is debatable whether the stones are secondary to the salmonella cholecystitis or whether pre-existing stones predispose the gall bladder to chronic infection. Salmonellae can, however, frequently be cultured from these stones. Ampicillin and cholecystectomy are indicated.
Cholecystectomy

Preparation for operation

After appropriate history taking and assessment of the patient’s fitness for the procedure, which will include investi-gation of the cardiovascular and respiratory systems if history suggests these to be a risk factor, a full blood count and biochemical profile are done to exclude abnormal liver function tests or anaemia. Blood coagulation is checked if there is a history of jaundice. The patient is given prophylactic anti-biotics either with the premedication intramuscularly, or intravenously at the time of induction. A second-generation cephalosporin is appropriate. Subcutaneous heparin or antiembolus stockings are prescribed. A consent form is signed ensuring that the patient is fully aware of the procedure being undertaken, the risks involved and complications that may occur.

Laparotomy

A short right upper transverse incision is made centred over the lateral border of the rectus muscle. A full laparotomy, inspecting all abdominal organs, is undertaken and the diagnosis of gallstones confirmed. The gall bladder is appropriately exposed and packs are placed on the hepatic flexure of the colon, the duodenum and the lesser omentum to ensure a clear view of the anatomy of the porta hepatitis. These packs may be retracted using the hand of the assistant ("It is the left hand of the assistant that does all the work —Moynihan) or a stabilised ring retractor used to keep the packs in position (Fig. 54.37). An artery forceps is placed on the infundibulum of the gall bladder and the peritoneum overlying Calot’s triangle is placed on a stretch. The peritoneum is then divided close to the wall of the gall bladder and the fat in the triangle of Calot carefully dissected away to expose the cystic artery and the cystic duct. The cystic duct is cleaned down to the common bile duct whose position is clearly ascertained. The cystic artery is tied and divided. The whole of the triangle of Calot is displayed to ensure that the anatomy of the ducts is clear and the cystic duct is then divided between ligatures. The gall bladder is then dissected away from the gall-bladder bed.

Some golden rules in case of difficulty.

• When the anatomy of the triangle of Calot is unclear, blind dissection should stop.

• Bleeding adjacent to the triangle of Calot should be controlled by pressure and not by blind clipping or clamping.

• When there is doubt about the anatomy a ‘fundus-first’ cholecystectomy dissecting on the gall-bladder wall down to the cystic duct can be helpful.

• If the cystic duct is densely adherent to the common bile duct and there is the possibility of a Mirizzi syndrome (the stone ulcerating through into the common duct), the infundibulum of the gall bladder should be opened, the stone removed and the infundibulum oversewn.

• A cholecystostomy is almost never indicated, but if it has to be done as many stones as possible should be extracted and a large Foley catheter (14 French) placed in the fundus of the gall bladder with a direct track externally. By so doing, should stones be left behind in the gall bladder, these can be extracted with a choledochoscope.

The technique of open cholecystectomy has largely been superseded by laparoscopic cholecystectomy. Nevertheless, no surgeon undertaking laparoscopic cholecystectomy should lose the different technique of undertaking an open cholecystectomy as this may be required when difficulties are encountered laparoscopically.

Laparoscopic cholecystectomy

The preparation and indications for cholecystectomy are the same whether it is performed by laparoscopy or by open techniques. However, a laparoscopic cholecystectomy should only be performed by a surgeon who is frequently undertaking laparoscopic procedures as the skills are different from those required in undertaking an open cholecystectomy.

The patient is positioned either in a Lloyd-Davies position or flat on the table depending on whether the French or American approach is used by the surgeon. A pneumoperitoneum is created and four ports are placed in the abdomen, usually at the umbilicus and the epigastrium, with two 5-mm ports laterally. The triangle of Calot is laid widely open by dividing the peritoneum on the posterior and on the anterior aspect. The cystic duct is carefully defined as is the cystic artery which is divided. Once the triangle of Calot has been laid widely open the cystic duct is clipped and divided. The gall bladder is then removed from the gall bladder bed and once free removed via the umbilicus (Fig. 54.40).

Indications for choledochotomy

In an environment where the modern diagnostic armamentarium described at the beginning of this chapter is not available and neither is perioperative cholangiography, it is well to rehearse the traditional indications for choledochotomy, which are: (1) palpable duct stones; (2) there is jaundice or a history of jaundice or cholangitis; (3) the common bile duct is dilated; and (4) the liver function tests are abnormal, in particular, the alkaline phosphatase is raised.

In centres where adequate facilities are available it is probably inadvisable to do a choledochotomy laparoscopically, but rather to rely on endoscopic techniques unless particular expertise has been achieved in laparoscopic exploration of the bile duct. The incidence of symptomatic stones in the bile duct varies from 5 to 8 per cent. These can, in the main, be dealt with endoscopically without resort to opening the duct. However, current trials suggest that in experienced hands the morbidity of the two techniques is identical.

Symptoms persisting after cholecystectomy

In 15 per cent of patients cholecystectomy fails to relieve the symptoms for which the operation was performed. Such patients may be considered to have a ‘postcholecystectomy’ syndrome. However, such problems are usually related to the preoperative symptoms and are merely a continuation of those symptoms. Full investigation should be undertaken to exclude the presence of a stone in the bile duct, a stone in the cystic duct stump or operative damage to the biliary tree. This is best performed by an MRCP or an ERCP which has the added advantage that if a stone remains it can be removed.
Management of bile-duct obstruction

Patients with symptoms after a cholecystectomy, particularly if jaundice is present, demand urgent investigation. Any patient who does not make an uneventful recovery following gall-bladder surgery should be investigated by ultrasound scanning as a matter of immediacy. If jaundice (either biochemical or clinical) is present emergency measures are required.

The first step in management is to undertake an immediate ultrasound scan. If there is evidence of fluid in the subhepatic space or obstruction of the biliary tree as shown by bile-duct dilatation then an immediate ERCP should be performed to ascertain whether a stone is present or there is obstruction of the common bile duct due to damage at the time of surgery (Fig. 54.41).

If a stone is present immediate removal endoscopically is indicated. If the common bile duct is obstructed by clips or there is leakage from the biliary tree due to a cystic duct leak then a drain should be placed in the subhepatic space percutaneously and a stent placed in the bile duct where possible. Small leaks will usually resolve spontaneously. Should the common bile duct be damaged the patient should be referred to an appropriate expert for reconstruction of the duct.
Stones in the bile duct

Duct stones may occur many years after a cholecystectomy or be related to the development of new pathology, such as infection of the biliary tree or infestation by *Ascaris lumbricoides* or *Clonorchis sinensis*. Any obstruction to the flow of bile can give rise to stasis with the formation of stones within the duct. The consequences of duct stones are either obstruction to bile flow or infection-cholangitis. Stones in the bile ducts are more often associated with infected bile (80 per cent) than are stones in the gall bladder.

**Symptoms**

The patient may be asymptomatic but usually has bouts of pain, jaundice and fever. The patient is often ill and feels unwell. The term ‘cholangitis’ is given to the triad of pain, jaundice and fevers sometimes known as ‘Charcot's triad’.

**Signs**

Tenderness may be elicited in the epigastrium and the right hypochondrium. In the jaundiced patient it is useful to remember Couvouzier’s law — ‘in obstruction of the common bile duct due to a stone, distension of the gall bladder seldom occurs; the organ usually is already shrivelled’. In obstruction from other causes distension is common by comparison. However, if there is no disease in the gall bladder and the obstruction is due to a cancer of the ampulla, pancreas or bile duct, then the gall bladder may well be distended.

**Management**

It is essential to determine whether the jaundice is due to liver disease, disease within the duct such as sclerosing cholangitis or obstruction. Ultrasound scanning, liver function tests, liver biopsy if the ducts are not dilated, and MRI or ERCP will demarcate the nature of the obstruction.

The patient may be ill. Pus may be present within the biliary tree and liver abscesses may be developing. Full supportive measures are required with rehydration, attention to clotting, exclusion of diabetes and starting the appropriate broad-spectrum antibiotics. As soon as resuscitation has taken place, relief of the obstruction is essential. Endoscopic papillotomy is the preferred first technique with a sphincterotomy, removal of the stones using a Dormia basket (Fig. 54.42) or the placement of a stent if stone removal is not possible. If this technique fails, a percutaneous transhepatic cholangiogram can be performed to provide drainage and subsequent percutaneous choledochoscopy. Surgery, in the form of choledocho-tomy, is now rarely used for this situation as most patients can be managed by minimally invasive techniques (Fig. 54.43).

**Choledochotomy**

If a stone (or stones) is present in the common bile duct, removal should have priority over cholecystectomy. Should the patient be unfit for cholecystectomy, or even cholecystostomy, the gall bladder should be removed on a future occasion (‘a living problem is better than a dead “cert”’ — Grey Turner). In particular, this may be the case in suppurative cholangitis. Recent evidence suggests that sub-acute cholecystectomy may not be necessary. After endoscopic removal of stones, only 10 per cent of patients will have subsequent problems with their gall bladder.

**Supraduodenal choledochotomy**

Most stones in the common bile duct can be removed by this route. If, as is often the case, a stone can be felt, an attempt is made to manoeuvre it into a position midway between the entrance of the cystic duct and the superior border of the duodenum. The stone is steadied between the finger and thumb. The duct is opened longitudinally directly on to the stone, enabling it to be removed by a malleable scoop or Desjardin’s gallstone forceps. The interior of the duct is then explored upwards and downwards with the scoop for further stones.

When the stone cannot be felt, or cannot be manipulated into the optimum position just described, 2 cm of the common bile duct is exposed, two stay sutures are placed in the duct and a longitudinal incision into the duct is made between them. Escaping bile is mopped up or removed by suction. Through this opening it may be possible to identify the stones and remove them with a scoop or forceps (Fig. 54.44). A balloon catheter, similar to that used for embolec-tomy, and irrigation of the ducts with saline are useful additional methods. Choledochoscopy may be employed to confirm that all calculi have been removed. Usually drainage of the common bile duct is carried out by means of a T-tube (Fig. 54.45); T-tubes should be made of latex or rubber and used only once — plastic tubes are hardened by the bile and are difficult to remove. Latex and rubber stimulate fibrinous adhesion of the omentum to liver and colon to form a safe track. There is very little reaction to a plastic tube and there-fore the risk of biliary peritonitis is greater. The transverse limb, shortened if necessary to about 5 cm long, is inserted in the duct which is closed snugly about the vertical limb, using fine catgut on anatraumatic needle. The long limb is brought out through a separate stab wound laterally, as this facilitates the Buhrenne procedure should it subsequently be required for a retained stone. The bile draining from the tube is collected in a plastic bag by the side of the bed, its amount and character being noted. After 10 days the tube may be clamped for increasing periods, and the absence of pain and jaundice and the presence of bile in the stools indicate satisfactory flow into the duodenum. Sodium diatrizoate is injected down the tube to obtain a cholangiogram, and if there are no filling defects in a well-outlined duct, and the increasing periods, and the absence of pain and jaundice and the presence of bile in the stools indicate satisfactory flow into the duodenum.

If this procedure is attempted, it is essential to provide drainage placed in apposition to the common duct.

**Transduodenal sphincterotomy**

Transduodenal sphincterotomy is indicated when a stone is found to be impacted near the ampulla of Vater (Fig. 54.46) and it cannot be retrieved from above. Other indications are when the common bile duct is dilated and contains multiple stones and biliary sludge, and when the papilla is fibrosed and stenosed secondary to the passage of stones through it. Some surgeons prefer the method to supraduodenal choledochotomy to remove all duct stones. If the supraduodenal approach fails to clear the duct, it is preferable to place a large T-tube in the duct (14 or 16 Fr) and close the abdomen. Subsequently, the stone can be removed by the Buhrenne procedure or endoscopically. The combination of a supra-duodenal approach with a transduodenal approach frequent-ly leads to complications.

**Closure of the common duct without a T-tube**

The patient may be ill. Pus may be present within the biliary tree and liver abscesses may be developing. Full supportive measures are required with rehydration, attention to clotting, exclusion of diabetes and starting the appropriate broad-spectrum antibiotics. As soon as resuscitation has taken place, relief of the obstruction is essential. Endoscopic papillotomy is the preferred first technique with a sphincterotomy, removal of the stones using a Dormia basket (Fig. 54.42) or the placement of a stent if stone removal is not possible. If this technique fails, a percutaneous transhepatic cholangiogram can be performed to provide drainage and subsequent percutaneous choledochoscopy. Surgery, in the form of choledocho-tomy, is now rarely used for this situation as most patients can be managed by minimally invasive techniques (Fig. 54.43).

If a stone (or stones) is present in the common bile duct, removal should have priority over cholecystectomy. Should the patient be unfit for cholecystectomy, or even cholecystostomy, the gall bladder should be removed on a future occasion ('a living problem is better than a dead “cert”' — Grey Turner). In particular, this may be the case in suppurative cholangitis. Recent evidence suggests that sub-acute cholecystectomy may not be necessary. After endoscopic removal of stones, only 10 per cent of patients will have subsequent problems with their gall bladder.

**Supraduodenal choledochotomy**

Most stones in the common bile duct can be removed by this route. If, as is often the case, a stone can be felt, an attempt is made to manoeuvre it into a position midway between the entrance of the cystic duct and the superior border of the duodenum. The stone is steadied between the finger and thumb. The duct is opened longitudinally directly on to the stone, enabling it to be removed by a malleable scoop or Desjardin’s gallstone forceps. The interior of the duct is then explored upwards and downwards with the scoop for further stones.

When the stone cannot be felt, or cannot be manipulated into the optimum position just described, 2 cm of the common bile duct is exposed, two stay sutures are placed in the duct and a longitudinal incision into the duct is made between them. Escaping bile is mopped up or removed by suction. Through this opening it may be possible to identify the stones and remove them with a scoop or forceps (Fig. 54.44). A balloon catheter, similar to that used for embolec-tomy, and irrigation of the ducts with saline are useful additional methods. Choledochoscopy may be employed to confirm that all calculi have been removed. Usually drainage of the common bile duct is carried out by means of a T-tube (Fig. 54.45); T-tubes should be made of latex or rubber and used only once — plastic tubes are hardened by the bile and are difficult to remove. Latex and rubber stimulate fibrinous adhesion of the omentum to liver and colon to form a safe track. There is very little reaction to a plastic tube and there-fore the risk of biliary peritonitis is greater. The transverse limb, shortened if necessary to about 5 cm long, is inserted in the duct which is closed snugly about the vertical limb, using fine catgut on anatraumatic needle. The long limb is brought out through a separate stab wound laterally, as this facilitates the Buhrenne procedure should it subsequently be required for a retained stone. The bile draining from the tube is collected in a plastic bag by the side of the bed, its amount and character being noted. After 10 days the tube may be clamped for increasing periods, and the absence of pain and jaundice and the presence of bile in the stools indicate satisfactory flow into the duodenum. Sodium diatrizoate is injected down the tube to obtain a cholangiogram, and if there are no filling defects in a well-outlined duct, and the contrast enters the duodenum freely, the T-tube can be removed. Subsequent bile drainage is minimal and does not usually persist for more than 1 day.

**Closure of the common duct without a T-tube**

If this procedure is attempted, it is essential to provide drainage placed in apposition to the common duct.

**Transduodenal sphincterotomy**

Transduodenal sphincterotomy is indicated when a stone is found to be impacted near the ampulla of Vater (Fig. 54.46) and it cannot be retrieved from above. Other indications are when the common bile duct is dilated and contains multiple stones and biliary sludge, and when the papilla is fibrosed and stenosed secondary to the passage of stones through it. Some surgeons prefer the method to supraduodenal choledochotomy to remove all duct stones. If the supraduodenal approach fails to clear the duct, it is preferable to place a large T-tube in the duct (14 or 16 Fr) and close the abdomen. Subsequently, the stone can be removed by the Buhrenne procedure or endoscopically. The combination of a supra-duodenal approach with a transduodenal approach frequent-ly leads to complications.

The duodenum is opened in its second part between stay sutures and the region of the ampulla brought into the opening by traction using tissue forceps. Removal of the stone or stones requires division of the duodenal papilla and the sphincter. A grooved director is passed through the papillary opening and up into the bile duct where it must be palpated. The papilla and part of the sphincter are now divided at 10 o’clock. If the bile-duct mucosa is sutured to that of the duodenum, the procedure is called a sphincteroplasty. Before sutures are placed in the papilla, it is essential to identify the pancreatic duct.
Choledochoduodenostomy

Choledochoduodenostomy is an alternative to transduodenal sphincterotomy when the common bile duct is dilated and contains multiple stones and sludge, particularly in elderly people (Fig. 54.47). The operation is contraindicated if the common duct is not 15 mm or more in diameter, or it is impossible to make a stoma of 2—3 cm. The convalescence is usually surprisingly placid. It is, indeed, a procedure which has commanded much support.
Stricture of the bile duct

Benign Stricture
(1) Postoperative (80%)
(2) Inflammatory (20%)
Malignant Stricture

Postoperative stricture

Postoperative strictures concern either the common bile duct or the common hepatic duct. In a few cases only the right hepatic duct is implicated. The stricture is the result of a preventable error in technique during the performance of cholecystectomy.

• Blind plunge application of a haemostat to a bleeding cystic or accessory cystic artery, or to the right hepatic artery, is likely to damage the common hepatic duct (Fig. 54.48). The prevention of this tragic happening is standardised. All unexpected haemorrhage in this region should be controlled initially by inserting an index finger into the foramen of Winslow, and pinching the free edge of the gastrohepatic omentum between the finger and thumb. Temporary compression of the hepatic artery in this way allows the bleeding point to be visualised and ligated securely (Hogarth Pringle’s manoeuvre).

• Should cholecystectomy be performed by dissecting from the fundus (fundus-first procedure) too much traction applied to the freed gall bladder may so tent the common bile duct that any forceps intended for the cystic duct grasp the angulated main channel (Fig. 54.49) (forceps should not, in fact, ever be used for grasping the cystic duct prior to ligature — Fig. 54.39).

• Failure to identify the anatomy in Calot’s triangle when there is much inflammation. The common hepatic duct is tied instead of the cystic duct.

• Ignorance of the anatomical anomalies of the bile ducts.

• Laceration of the common bile duct while exploring it for stones.

• In 3 per cent of cases of stricture of the common bile duct, injury occurs during related surgical procedures.

About 15 per cent of injuries to the bile ducts are not recognised at the time of operation. In 85 per cent of cases the injury declares itself postoperatively by: (1) a profuse and persistent leakage of bile if drainage has been provided, or bile peritonitis if such drainage has not been provided; and (2) deepening obstructive jaundice. When the obstruction is incomplete, jaundice is delayed until subsequent fibrosis renders the lumen of the duct inadequate.

Radiological investigation of biliary strictures

• Ultrasonography
• Cholangiography via T-tube, if present
• ERCP
• Transhepatic cholangiography

Treatment

In the debilitated patient, temporary external biliary drainage may be achieved by passing a catheter percutaneously into an intrahepatic duct. Also, stents may be passed through strictures at the time of ERCP and left to drain into the duodenum. When the general condition of the patient has improved, definitive surgery can be undertaken. However, both of these methods may be complicated by cholangitis and are not recommended for all cases. For benign stricture or duct transection, the preferred treatment is immediate Roux-en-Y choledochojunostomy by a surgeon well versed in managing benign postoperative strictures. For a stricture of recent onset through which a guidewire can be passed, balloon dilatation with insertion of a stent is an acceptable alternative provided that the services of an experienced endoscopist are available.

Primary sclerosing cholangitis

This is a chronic fibrosing inflammatory condition of the biliary tree which affects both intrahepatic and extrahepatic ducts, and may involve the gall bladder and pancreas. It is of unknown origin and must be distinguished from secondary sclerosing cholangitis associated with cholelithiasis. It is associated with inflammatory bowel disease, usually ulcerative colitis, in 50—70 per cent of cases, and these patients may be at greater risk of developing a bile-duct carcinoma. The patients are commonly young, being less than 50 years old. They present with a progressive cholestatic disorder and right upper quadrant discomfort, jaundice, pruritis and fever. Investigation reveals a considerable elevation of the alkaline phosphatase, and on cholangiography stricturing and beading of the bile ducts (Fig. 54.50). As the majority of patients has both intrahepatic and extrahepatic biliary tree involvement, surgical treatment is not appropriate. Primarily, these patients are managed with antibiotics, vitamin K, cholestyramine, steroids and azothiaprine, but with little benefit. Repeated dilatation of the strictures is helpful. Many go on to develop cirrhosis due to obstruction. If liver failure supervenes these patients are suitable candidates for liver transplantation.

Parasitic infestation of the biliary tract

Biliary ascariasis

The round worm, *A. lumbricoides*, commonly infests the intestine of inhabitants of Asia, Africa and Central America. It may enter the biliary tree through the ampulla of Vater and cause biliary pain. Complications include strictures, supplicative cholangitis, liver abscesses and empyema of the gall bladder. In the uncomplicated case, antispasmodics can be given to relax the sphincter of Oddi and the worm will return to the small intestine to be dealt with by anthelmintic drugs. Operation may be necessary to remove the worm or deal with complications. Worms can be extracted via the ampulla of Vater by ERCP.

Clonorchiasis (asiatic cholangiohepatitis)

The disease is endemic in the Far East. The fluke, up to 25 mm long and 5 mm wide, inhabits the bile ducts, including the intrahepatic ducts. Fibrous thickening of the duct walls occur. Many cases are asymptomatic. Complications include biliary pain, stones, cholangitis, cirrhosis and
bile-duct carcinoma. Choledochotomy and T-tube drainage and, in some cases, choledocho-duodenostomy are required. Because a process of recurrent stone formation is set up, a choledochojejunostomy with Roux loop affixed to the abdominal parietes is performed in some centres to allow easy subsequent access to the duct system.

**Hydatid disease**

A large hydatid cyst may obstruct the hepatic ducts. Sometimes a cyst will rupture into the biliary tree and its contents cause obstructive jaundice or cholangitis, requiring appropriate surgery (see Chapter 52).
Tumours of the bile duct

Papillomatosis

This rare condition is characterised by the presence of multiple mucous-secreting tumours of the biliary epithelium. These tumours are low-grade papillary carcinomas and should be treated by choledochoscopy with obliteration of the papillary lesions. The malignancy tends to develop over a period of years and may require liver resection. If both lobes are affected then liver transplantation may be required.

Carcinoma of the bile duct

Incidence and aetiology

The incidence of bile-duct carcinoma varies markedly in different parts of the world. It is very rare in the UK, but high rates are found in parts of the world where biliary infection is common. It is associated with the presence of bile-duct stones in a quarter of patients, and is more frequent in patients with sclerosing cholangitis and ulcerative colitis. Anatomical abnormalities, particularly intrahepatic cystic change and choledochal cyst, are also associated with an increased incidence. Clinorchis sinensis is a recognised aetiological factor.

Pathology

Macroscopically, the tumour arises as a small nodule which rapidly encases the bile duct causing jaundice. The tumour invades locally spreading via the nerves, the lymphatics and the portal venous trunk. It may directly invade the portal vein or the surrounding liver. Microscopically, the majority of bile duct tumours are well to poorly differentiated adenocarcinomas.

Clinical features

The patient presents with jaundice. The diagnosis is suspected when obstruction in the biliary tree with a characteristic stricture is demonstrated.

Local spread is frequent and metastases are common at the time of presentation. The diagnosis is confirmed by biopsy, either by the percutaneous transhepatic route or endoscopically, or by cytological brushings taken at endoscopy.

If the patient is under 70 years of age and the tumour is localised either to one lobe of the liver or to the extrahepatic bile duct then resection is possible in 10—20 per cent of patients. Such resections may involve excision of a lobe of the liver and reconstruction of the biliary tree. With the improved techniques associated with modern liver surgery the mortality is now 5 per cent. The median survival is 18 months, with 20 per cent of the patients surviving for 5 years.

Carcinoma of the gall bladder

This is rare in the Western world but there are areas where the incidence is high (in Patna, India, the incidence reaches as high as 9 per cent of biliary tract disease). The tumour is found in less than 1 per cent of gall-bladder operations. In over 90 per cent of instances gallstones are present. The patients are usually in their late 70s, with a female to male ratio of 5:1. The tumour is usually scirrhous, but squamous cell and mixed squamous adenocarcinomas are found. Spread is by direct invasion through the mucosa to the serosa and into the liver, the lymphatics and the veins.

Clinical features

Most present either with an extensive mass in the liver during investigations for jaundice, or at cholecystectomy at the time the histology is received, the tumour being unrecognised by the surgeon.

Treatment and prognosis

Those that are diagnosed at cholecystectomy and confined to the mucosa have a good prognosis. It is debated whether such patients should have a wide excision with resection of adjacent liver and lymph nodes. For those tumours that involve the serosa, the prognosis is poor and chemoradiotherapy is all that can be offered. The survival rate is less than 5 per cent at 5 years and the median survival is 12 months.

Anatomy and physiology

Surgical anatomy

The name ‘pancreas’ is derived from the Greek ‘pan’ (all) and ‘kreas’ (flesh). It was originally thought to act as a cushion for the stomach. The gland weighs approximately 80 g and is situated retroperitoneally. It is divided into a head, which occupies 30 per cent of the gland by mass, and a body and tail which comprises 70 per cent of the whole organ. The head lies within the curve of the duodenum overlying the body of the second lumbar vertebra and the vena cava, with more medially the aorta beneath the neck of the gland. The neck of the pancreas is that part which has the superior mesenteric vessels as a posterior relation. Coming off the side of the pancreatic head and passing to the left and behind the superior mesenteric vein is the uncinate process of the pan-creas. Behind the neck of the pancreas, near its upper border, the superior mesenteric vein joins the splenic vein to form the portal vein (Figs 55.1 and 55.2).

There are nine key processes that occur during pancreatic embryogenesis (Table 55.1).

Malrotation of the ventral bud in the fifth week results in an annular pancreas, while the mode of ductular fusion in the seventh week produces the various possible ductular patterns. Between the 12th and 40th weeks of foetal life, the pancreas differentiates into exocrine and endocrine elements. Of the pancreatic mass, 8—90 per cent is composed of exocrine tissue. The primitive ducts and their ductules are responsible for the lobular arrange-ment of the pancreas. The main pancreatic duct is lined by columnar epithelium which becomes cuboidal in the ductules. Congenital anomalies of the pancreas are varied and arise during the early phase of development (Table 55.2).

Pancreatic acinar tissue is organised into lobules. The main duct ramifies into intralobular and interlobular ducts, ductules and, finally, acini. Acinar cells are clumped around a central lumen to form an acinus which communicates with the duct system. The pancreas thus consists of a network of fine ducts lined by secretory cells. The islets of Langerhans are distributed throughout the pancreas. Islet cells consist of differ-ting cell types: 75 per cent are B cells (producing insulin), 20 per cent A cells (producing glucagon), and the remainder are D cells (producing somatostatin) and a small number of pancreatic polypeptide cells. Within an islet, the B cells form an inner core surrounded by the other cells. Capillaries draining the islet cells drain into the portal vein forming a pancreatic portal system. The pancreatic duct anatomy is variable as a result of the primordial bud development. The dorsal duct is expressed in a variable manner in the adult, as outlined in Fig. 55.3. Approximately 10 per cent of patients will have a significant flow from the main duct through the accessory papilla. The anatomy of the main papilla is also variable (Fig. 55.4) with the outlet of each duct protected by a complex sphincter mechanism (Fig. 55.5). Pancreatic anatomy has an implica-tion on disease, and thus a grasp of the development and variations is important in the assessment of the patient.

Surgical physiology

In response to a meal, the pancreas secretes digestive enzymes in an alkaline (pH 8.4) bicarbonate-rich fluid. Spontaneous secretion is minimal, the hormone secretin which is released from the duodenal mucosa evokes a bicarbonate-rich fluid. Cholecystokinin-pancreozymin (CCK) is released from the duodenal mucosa in response to food: CCK produces no increase in the volume of secretion, but is responsible for enzyme secretion. Vagal stimulation increases volume. Protein is synthesised at a greater rate (per gram of tissue) in the pancreas than in any other tissue, with the possible exception of the lactating mammary gland. About 90 per cent of this protein is exported from the acinar cells as a variety of digestive enzymes. Approximately 6—20 g of diges-tive enzymes enter the duodenum each day. Nascent proteins are synthesised as pre proforms and during their transit through the rough endoplasmic reticulum and Golgi cisterni, the newly synthesised proteins undergo modification in a sequence of steps. The proteins move from the rough endothelial endoplasmic reticulum to the Golgi complex, where lysosomes and maturezymogen storage granules containing proteases are stored, and move to the ductal surface of the cell from which they are extruded by exostosis. During this phase the proteolytic enzymes are in an inactive form, the maintenance of which is important in preventing pancreatitis.
Investigations

It is possible to obtain information about: (1) pancreatic damage by measuring levels of pancreatic enzymes in body fluids; (2) pancreatic function by measuring bicarbonate and enzymes produced in the pancreatic juice; and (3)morpho-logical abnormality of the parenchyma and duct system by ultrasonography, computerised tomography (CT), magnetic resonance imaging (MRI) and endoscopic retrograde cholangiopancreatography (ERCP) (Table 55.3).

Estimation of pancreatic enzymes in body fluids

When the pancreas is damaged, enzymes such as amylase, lipase, trypsin, elastase and chymotrypsin are released into the serum. Measurement of amylase is the most widely used test of pancreatic damage, and none of the other tests shows better specificity or sensitivity. The serum amylase rises with-in a few hours of pancreatic damage and declines over the next 4—8 days. A markedly elevated serum level is highly suspicious of acute pancreatitis. Urinary amylase and amylase—creatinine clearance ratios add little to diagnostic accuracy. If confirmation of the diagnosis is required, CT of the pancreas is of greater value.

Pancreatic function tests

Pancreatic secretion in response to a standardised stimulus can provide an assessment of the functional capacity of the gland. The tests can be divided into those where the stimulus to secretion is indirect — produced by the ingestion of a test meal — and those where secretion is directly stimulated by injection of a hormone. Previously, duodenal intubation with the introduction of a triple lumen tube was performed so that the gastric and duodenal juices could be aspirated, and a nonabsorbable marker such as polyethylene glycol used to assess the completeness of the aspiration. A meal stimulus can be used such as in the Lundh test, or secretin and CCK can be administered intravenously to produce both bicarbonate and enzyme stimulation. These tests have been largely aban-doned because chronic pancreatitis cannot be diagnosed until over 70 per cent of the gland has been destroyed or there is obstruction to the duct. The more practical test is the nitroblue tetrazolium—para-aminobenzoic acid (NBT PABA) test in which the recovery in the urine of PABA is measured after oral administration. The p-aminobenzoic acid is liberated by pancreatic chymotrypsin and excreted in the urine after absorption and liver conjugation. In the pancreolauryl test (PLT), the substrate is represented by fluorescein esterfitted with two molecules of lauric acid. This complex is hydrolysed by a specific pancreatic anly-esterase and the fluo-rescein, liberated into the intestinal lumen, absorbed by the intestinal mucosa and then excreted by the kidneys. This test is cheap, is easy to perform and has a high reliability in recognising severe pancreatic exocrine insufficiency. Careful interpretation of the test results is required in postgastrectomy patients, in patients with extensive intestinal inflam-matory disease, or in patients with gastrointestinal or hepato-biliary disease that markedly alters gastrointestinal transit and intestinal absorptive capacity.

A simpler test now available is one which measures faecal elastase levels. Absence indicates chronic pancreatitis and is specific.

Imaging investigations

Ultrasonography

In the hands of a skilled radiologist, ultrasonography can outline the pancreas with accuracy. However, in patients who are fat and those with much gas or fluid in the bowel, the images of the pancreas are poor and an accurate diagnosis cannot be achieved. In the investigation of jaundice ultrasonography remains the initial preferred investigation. Not only will ultrasound determine whether or not the bile duct is dilated, but it will also define the presence or absence of a mass in the pancreas and the coexistence of gallstones or gross disease within the liver such as metastases (Fig. 55.6).

Computerised tomography (Figs 55.7, 55.8, 55.9, 55.10, 55.11, 55.12)

Pancreatic carcinomas of 1—2 cm in size can usually be demonstrated whether in the head, body or tail of the pancreas. A specific pancreatic protocol should be followed using a spiral CT scanner. Following rapid injection of intra-venous contrast, scanning is performed at 5-mm intervals in the arterial phase and 10-mm intervals during the venous phase. Prior to injection of contrast an unenhanced CT scan is essential to determine the presence of calcification within the pancreas and gall bladder. The stomach and duodenum should be outlined with water and distended to define the duodenal loop. All significant pathologies within the pan-creas can be diagnosed on high-quality spiral CT scans. Endocrine tumours which previously could not be imaged can now be seen with clarity (Fig. 55.12) and this is now probably the preferred technique for defining such tumours. CT scanning is also of value in the therapeutic setting to drain cysts or abscesses, or to guide percutaneous biopsies.

Magnetic resonance imaging

With the recent developments in MRI the pancreas can now be clearly displayed in a manner similar to the best CT image. In addition, clear images of the bile duct and the pancreatic duct, together with fluid collections, can be defined. Magnetic resonance pancreatography and cholangiography may well replace diagnostic endoscopic pancreatography and cho-langiography. MRI is noninvasive and cheaper (Fig. 55.13).

Endoscopic retrograde cholangiopancreatography

By using this technique with a side-viewing fibreoptic duodenoscope the ampulla of Vater can be clearly seen. Images of contrast injected into the biliary and pancreatic ducts can display the anatomy and pathology of these ducts. Changes seen in chronic pancreatitis include pancreatic duct strictures, dilatation of the main pancreatic duct with stones (Figs 55.14, 55.15, 55.16, 55.17, 55.18, 55.19), abnormalities of pancreatic duct side branches, communication of the pancreatic duct with cysts and bile-duct strictures. In pancreatic carcinoma, the main pancreatic duct may be narrowed or completely obstructed at the site of the tumour with dilatation upstream but with a normal duct system downstream. This, in conjunction with bile-duct obstruction or a stricture, results in the so-called' double duct sign’. Collection of bile or pancreatic juice at endoscopy and brushing of these ducts can yield cells which confirm the suspected diagnosis of carcinoma (Fig. 55.20).

Plain X-ray

A chest X-ray should never be forgotten as it may show a complication of pancreatic disease (Fig. 55.21). A plain X-ray before contrast studies is essential to delineate calcification (Fig. 55.22)
Congenital abnormalities

See Table 55.2.

Cystic fibrosis

This is inherited as an autosomal recessive condition. The abnormal genes have been defined and diagnosis of the disorder can now be confirmed by DNA testing. It most frequently occurs among Caucasians, in whom it is the most commonly occurring inherited disorder (incidence one in 1800 live births). Heterozygous carriers of the gene are asymptomatic but can be identified by DNA analysis. Recent reports suggest that such patients may develop pancreatitis later in life. Such findings may give insight into mechanisms of pancreatic disease.

The disorder is the result of a generalised dysfunction of exocrine glands. Glandular secretions have abnormal physio-chemical properties resulting in malabsorption caused by pancreatic insufficiency, chronic pulmonary disease arising from plugging of bronchi and bronchioles, and elevated sodium and chloride ion concentrations in sweat. It is the most common cause of chronic lung disease among children in developed countries.

Secretions precipitate in the lumen of the pancreatic duct causing blockage which results in duct ectasia and fatty replacement of exocrine acinar tissue. The islets of Langerhans usually appear normal, but diabetes mellitus can occur in older patients. Steatorrhoea is usually present from birth resulting in stools which are bulky, oily and offensive. At birth the meconium may set in a sticky mass and produce intestinal obstruction (meconium ileus). Although about 15 per cent of patients do not develop clinical steatorrhoea, most show complete exocrine insufficiency.

The earliest clinical signs of cystic fibrosis are poor growth, poor appetite, rancid greasy stools, abdominal distension, persistent cough, emphysematous chest and finger clubbing. Later the liver may become cirrhotic as a result of bile-duct plugging and signs of portal hypertension may appear; cor pulmonale may develop and the appearance of secondary sexual characteristics may be delayed. The mother may have noticed that the child is salty when kissed — levels of sodium and chloride ions in the sweat above 90 mmol/litre confirm the diagnosis.

Treatment is aimed at control of the secondary consequences of the disease. Malabsorption is treated by administration of pancreatic enzyme preparations, and pulmonary function preserved with aggressive physiotherapy and antibiotics. A suitable diet is low in fat but contains added salt to replace the high losses in the sweat. With optimal treatment 80 per cent of the patients diagnosed early should survive to beyond their 19th year.

Annular pancreas

This is the result of failure of complete rotation of the ventral pancreatic bud during development, so that a ring of pancreatic tissue surrounds the second or third part of the duodenum. It is more prevalent in the Down's syndrome child, and in infants with other congenital gut abnormalities. It is one of the causes of obstructive vomiting in the neonate. The vomiting can be bile stained if the duodenal obstruction is below the ampulla of Vater. Peristaltic waves and upper abdominal distension may be seen, and plain abdominal radiographs show the 'double bubble' sign of the interrupted gastroduodenal shadow produced by the rigid ring of pancreatic tissue. The usual treatment is bypass (duodeno-jejunostomy or duodenoduodenostomy). Attempts at resection of the band may result in a pancreatic fistula. The disease may occur in older life as one of the causes of pancreatitis, in which case resection of the head of the pancreas is preferable to lesser procedures.

Ectopic pancreas

Ectopic pancreas can be found in the submucosa in parts of the stomach, duodenum or small intestine (including Meckel's diverticulae), the gall bladder, adjoining the pancreas, for example in the hilum of the spleen, or in 2 per cent of carefully conducted necropsies, within the liver. Ectopic pancreas in the wall of the intestine may give rise to symptoms and can be a cause of cysts, but this is extremely rare.

Congenital cystic disease of the pancreas

This sometimes accompanies congenital disease of the kidneys and liver, and occurs as part of the von Hippel—Lindau syndrome.
Injuries to the pancreas

External injury (Fig. 55.23)

Presentation and management

The most frequent presentation of blunt pancreatic trauma is epigastric pain which may be minor at first, with the progressive development of more severe pain due to the sequelae of leakage of pancreatic fluid into the surrounding tissues. A rise in pancreatic amylase occurs in 90 per cent of cases. A CT scan of the pancreas or ultrasound scan will delineate the damage that has occurred to the pancreas. Persisting abdominal pain with signs of peritonitis require careful assessment of the patient, and support by intravenous fluids and a nil oral regime should be instituted. Immediate operation is contra-indicated because the bruising associated with the retroperitoneal damage will prevent clear visualisation of the pancreas. It is preferable to manage conservatively, investigate with ultrasound and, once the damage is ascertained, undertake appropriate action. Operation is only indicated if there is disruption of the main pancreatic duct; almost all other patients will resolve with conservative management unless duct stricturing develops leading to recurrent episodes of pancreatitis, in which case the appropriate treatment is resection of the tail of the pancreas up to the site of duct disruption. If the damage is purely confined to the head of the pancreas simple drainage is normally effective; should this fail, however, then a pancreatectoduodenectomy may be necessary.

A pancreatic pseudocyst may develop (Fig. 55.24). If the main duct is intact, the cyst should be drained percutaneously. It is now rarely necessary to undertake a cystgastrostomy (Fig. 55.25). If the cyst develops in the presence of complete disruption of the pancreas, there is no alternative but to undertake a distal resection.

Prognosis

The most common cause of death in the immediate period is bleeding, but once the acute phase has passed the mortality and morbidity should be minimal with a complete return to normal activity. The mortality rate of penetrating injury to the pancreas with associated injuries to the surrounding viscera approaches 50 per cent.

Iatrogenic injury

This can occur in four ways.

- Injury to the tail of the pancreas during splenectomy resulting in a pancreatic fistula.
- Injury to the accessory pancreatic duct (Santorini) which is the main duct in 7 per cent of patients during Billroth II gastrectomy. A pancreateogram performed by cannulating the duct at the time of discovery of such an injury will demonstrate whether it is safe to ligate and divide the duct. If no alternative drainage duct can be demonstrated then the duct should be reanastomosed to the duodenum.
- Attempts at enucleation of islet cell tumours of the pancreas can result in fistulae.
- Duodenal or ampullary bleeding following sphincterotomy. This injury may require duodenotomy to control the bleeding.

Pancreatic fistula

This usually follows operative trauma to the gland, or may occur as a complication of acute or chronic pancreatitis. Management is to define the site of the fistula, the epithelial structure to which it communicates (e.g. external to skin or internal to bowel), and to correct metabolic and electrolyte disturbances. The danger of a pancreatic fistula is that there is digestion of surrounding structures by activated pancreatic enzymes causing local damage, perforation, bleeding and digestion of the skin. Immediate control of the fistula can be obtained by a nil by mouth regime, the use of octreotide and adequate drainage of the fistula with protection of the skin. Investigation of the cause of the fistula is required and, usually, once the cause is determined appropriate remedies can be introduced. Frequently the cause is related to obstruction within the pancreatic duct which can be overcome by the insertion of a stent or catheter endoscopically into the pancreatic duct, and waiting for closure of the fistula while supporting the patient by a conservative regime with parenteral nutritional support and good nursing. As a principle, in the management of any fistula, the underlying cause for the fistula must be treated before closure will be effective.
Pancreatitis

Pancreatitis is primarily due to the intracellular activation of trypsinogen to trypsin by numerous stimuli which, as yet, have not been fully elucidated. The recent discovery that hereditary pancreatitis is related to an abnormal cationic trypsinogen due to an abnormality in the long arm of chromosome 7, in which histidine replaces arginine allowing in certain instances intracellular activation of trypsinogen to trypsin, elucidates in a small way intracellular mechanisms which can occur to cause this disease. In hereditary pancreatitis the same defect can give rise both to acute and to chronic pancreatitis. It is probable that acute pancreatitis is but a phase of chronic pancreatitis; the two are inter-related. For clinical purposes it is useful to divide pancreatitis into acute, which presents as an emergency, and chronic which is a prolonged and frequently life-long disorder resulting from the development of fibrosis within the pancreas.

Acute pancreatitis is defined as an acute condition presenting with abdominal pain and usually associated with raised pancreatic enzyme levels in the blood or urine as a result of inflammatory disease of the pancreas. Acute pancreatitis may recur.

Chronic pancreatitis is defined as a continuing inflammatory disease of the pancreas characterised by irreversible morpho-logical change typically causing pain and/or permanent loss of function. Many patients with chronic pancreatitis have exacerbations, but the condition may be completely painless.

Acute pancreatitis

Incidence

Acute pancreatitis accounts for 3 per cent of all cases of abdominal pain admitted to hospital in the UK. The incidence varies from 21 to 283 cases per million population. In Japan the best estimate is that of 121 cases per million population. The disease may occur at any age, with a peak in the young male and the older female. The mortality has remained unaltered at 10—15 per cent over the past 20 years. About one-third of patients die in the early phase of an attack from multiple organ failure, while deaths occurring after the first week of onset are due to infective complications. Eighty per cent of patients will have a mild attack of pancreatitis in which the mortality is around 1 per cent, while in those who have a severe attack of pancreatitis the mortality varies from 20 to 50 per cent.

Aetiology

The two major causes of acute pancreatitis are biliary calculi, which occurs in 50—70 per cent of patients, and alcohol, which occurs in 25 per cent. The remaining cases may be due to rare causes or be idiopathic (Table 55.4).

The importance of aetiology is that removal of the causative factor can avoid further episodes of pancreatitis. Thus, in a patient who has gallstone pancreatitis, the gallstones should be removed as soon as the patient is fit to undergo surgery and, preferably, before discharge from hospital.

Clinical presentation

There are no pathognomonic symptoms and signs, but pain is usually the cardinal symptom. It characteristically develops quickly, reaching maximum intensity within minutes rather than hours, and persists for hours or even days. The pain is frequently severe or even agonising, it is refractory to the usual doses of analgesics, and constant in nature and intensity. Pain is usually experienced first in the epigastrum but may be localised to either upper quadrant or felt diffusely throughout the abdomen. There is radiation to the back in about 50 per cent of patients and some patients may gain relief by sitting or leaning forwards. The suddenness of onset may simulate a perforated peptic ulcer, while biliary colic or acute cholecystitis can be mimicked if the pain is maximal in the right upper quadrant. Radiation to the chest can simulate myocardial infarction, pneumonia or pleuritic pain. In fact, acute pancreatitis can mimic most causes of the acute abdomen and should seldom be discounted in differential diagnosis. The diagnosis must always be considered in a patient who suddenly develops shock or anuria regardless of whether they have abdominal pain.

Acute pancreatitis should be suspected in the patient who:

- develops marked abdominal pain, fever or unexplained shock following abdominal surgery;
- presents with diabetic coma and shock;
- has clinical features suggesting myocardial infarction with abdominal distension.

Nausea, vomiting and retching are usually marked accompaniments. Vomiting is often frequent and persistent, and retching may persist despite the stomach being kept empty by nasogastric aspiration. Hiccoughs can be troublesome and may be due to gastric distension or irritation of the diaphragm.

On examination the appearance may be that of a patient who is well or, at the other extreme, one who is gravely ill with profound shock, toxicity and confusion. Tachypnoea is common, tachycardia is usual and hypotension may be pre-sent. The body temperature is often normal or even subnormal, but frequently rises as inflammation develops. Mild icterus can be caused by biliary obstruction in gallstone pan-creatitis, and an acute swinging pyrexia suggests cholangitis. Bleeding into the fascial planes can produce blueish discoloration of the flanks (Grey Turner sign) or umbilicus (Cullen’s sign). Neither sign is pathognomonic of acute pancreatitis; in fact Cullen’s sign was first described with rupture of an ectopic pregnancy. Subcutaneous fat necrosis may produce small red tender nodules on the skin of the legs. Abdominal examination may reveal distension due to ileus or, more rarely, ascites with shifting dullness. A mass can develop in the epigastrium due to rupture of an ectopic pregnancy. Subcutaneous fat necrosis can mimic the disease. In hereditary pancreatitis the same defect can give rise both to acute and to chronic pancreatitis. It is probable that acute pancreatitis is but a phase of chronic pancreatitis; the two are inter-related. For clinical purposes it is useful to divide pancreatitis into acute, which presents as an emergency, and chronic which is a prolonged and frequently life-long disorder resulting from the development of fibrosis within the pancreas.

Investigations

A serum amylase four times above normal is indicative of the disease. Plain abdominal X-ray findings include a generalised or local ileus (sentinel loop), a colon “cut-off” sign and a renal “halo” sign. Occasional helpful, but nondiagnostic, signs include calcified gallstones and pancreatic calcification. A chest X-ray may show a spectrum of changes depending on the disease severity. A pleural effusion is present in 20 per cent, and in severe cases a diffuse alveolar interstitial shadowing may suggest an acute respiratory distress syndrome.

Ultrasound scanning. The swollen pancreas may be detected but the gland is poorly visualised in 25—50 per cent of cases. Ultrasound is valuable in detecting free peritoneal fluid, gallstones, dilatation of the common bile duct and, occasionally, other pathologies such as abdominal
Aortic aneurysm.

If doubt remains a CT scan should be performed in order to determine the diagnosis.

Laparotomy. To misdiagnose acute pancreatitis is not uncommon because the presentation is so variable that even the shrewdest clinician can be mistaken. The appearances at laparotomy are characteristic (Fig. 55.26).

Management

On account of the difference in outcome between patients with mild and severe disease it is important to define that group of patients who will develop severe pancreatitis. Various scoring systems have been introduced such as the Ranson and Glasgow scoring systems (Table 55.5). A C-reactive protein level greater than 210 mg/litre in the first 4 days of the attack or 120 mg/litre at the end of the first week has a predictive performance similar to that of the other criteria and has the added benefit of simplicity. Similarly, the Apache II scoring system, well used in intensive care units, can be applied; a score of 9 or more indicates a severe attack but excludes many with a lower score who will develop complications. An Apache score of 6 or more will include 95 per cent of all those who develop a complication.

If after initial assessment a patient is considered to have a mild attack of pancreatitis, a conservative approach is indicated with nil by mouth, intravenous fluid administration and frequent, but noninvasive, observation. However, if the patient develops a severe attack of pancreatitis then a more aggressive approach is required with the patient being admitted to a high-dependency or an intensive care unit. The patient is monitored invasively to ensure homeostasis of the cardiovascular, respiratory and renal systems. In the mild attack antibiotics are not indicated unless there is evidence of infection. There is no indication for pharmacological or therapeutic treatments, and CT scanning is unnecessary unless there is evidence of deterioration. The management of the severe attack involves full resuscitation, and strict asepsis should be observed in the placement of all monitoring lines. If there is evidence of cardiocirculatory compromise then a Swan—Ganz catheter should be inserted in order to measure pulmonary artery wedge pressure, cardiac output and sys-temic resistance (see Chapter 4). Regular arterial blood gas analysis is essential as the onset of hypoxia and acidosis may be detected late by clinical means alone. The techniques evolved in the critical care environment should be applied to the patient with pancreatitis. The patient should be made comfortable, appropriately sedated and adequate analgesics given. Specific therapy such as the administration of aprotinin, somatostatin and platelet-activating factor inhibitors has failed to improve prognosis in numerous clinical trials and should not be given. There is some evidence to support the use of prophylactic antibiotics in the prevention of local and other septic complications. Intravenous cefuroxime or imipenem is advised. If gallstones are the aetiology of severe pancreatitis, an urgent ERCP is indicated to exclude the presence of a stone stuck in the ampulla of Vater if there is no improvement in the general condition of the patient within 48 hours. The presence of cholangitis with abnormal liver function tests is an indication for urgent endoscopic intervention.

Complications

General. Pancreatitis may involve all organs of the body (Tables 55.6 and 55.7) and present demands on the surgeon beyond his or her skills. Those patients who develop systemic complications should be managed by a multidisciplinary team. There is no role for surgery during the initial period of resuscitation and stabilisation. The full care associated with critical care medicine is applied to these patients, and surgical intervention is only contemplated in the patient who deteriorates following successful stabilisation. Once the presence of infected necrosis is suspected and confirmed, an appropriate débridement may be performed. The only other indication for intervention is the presence of cholangitis, in which case an endoscopic sphincterotomy should be performed.

Local. Once the acute phase has been survived, usually by the end of the first week, and major organ failure is under control, then local complications become pre-eminent in the management of these patients. An awareness of these complications is aided by carefully following the course of the patient, and if clinical resolution does not take place a CT scan should be performed to enable definition of any abnormality present. Such abnormalities should be re-imaged at intervals until there is clear evidence of regression. If a fluid collection or abscess persists then drainage, preferably under radiological control, is indicated.

Definitions

Acute fluid collection. This occurs early in the course of acute pancreatitis and is located in or near the pancreas. The wall encompassing the collection is ill defined.

Acute pseudocyst. A collection of pancreatic juice enclosed in a wall of fibrous or granulation tissue that arises following an attack of acute pancreatitis. Formation of a pseudocyst requires 4 weeks or more from the onset of acute pancreatitis (Figs 55.27 and 55.28).

Pancreatic necrosis. A diffuse or focal area of nonviable parenchyma which is typically associated with peri pancreatic fat necrosis. The onset of infection results in infected necrosis which is associated with a trebling of the mortality rate.

Pancreatic abscess. A circumscribed intra-abdominal collection of pus, usually in proximity to the pancreas containing little or no pancreatic necrosis.

Pancreatic effusion. An encapsulated collection of fluid arising as a consequence of acute pancreatitis, typically in the pleural cavity.

Pancreatic ascites. Chronic generalised peritoneal enzyme-rich effusion usually associated with pancreatic duct disruption.

Pseudoaneurysm. Pseudoaneurysm is a false aneurysm of a major peripancreatic vessel confined as a clot by the surrounding parenchyma which is typically associated with peri pancreatic fat necrosis. The onset of infection results in infected necrosis which is associated with a trebling of the mortality rate.

Complications

Complications in pancreatic disease are serious and carry a significant mortality. The prime role in the management of acute pancreatitis is that of the conservative approach. If fluid collections cause symptoms or impair function then percutaneous or transgastric drainage is appropriate. Sterile necrotic material should not be drained. The only indication for operative intervention in acute pancreatitis is the presence of an abscess related to necrosis in or around the pancreas. All other complications can be managed conservatively and, indeed, some authorities suggest that even an infected necrotic pancreas can be managed conservatively with radiological drainage. To determine whether a collection of peripancreatic oedema and fluid is necrotic and infected, a CT scan should be performed and a needle passed into the necrotic area under CT guidance, choosing a path that does not traverse hollow viscera. If the aspirate is infected and the patient’s condition deteriorating, then a laparotomy with débridement of the dead tissue around the pancreas is appropriate. Because the process is progressive further necrotic tissue may form, and the abscess cavity can either be drained and flushed (Beget) (Fig. 55.29) or repeated laparotomies performed until there is a clean granulating cavity (Bradley).

Some of these patients are ill for long periods of time. Nutritional support is essential. During the early phase of disease parenteral nutrition is important and no advantage has yet been shown for early enteral nutrition. However, once the phase of paralytic ileus has been passed it is
appropriate to commence nasojejunal feeding or feeding via a jejunostomy placed in those who have undergone laparotomy. This has the effect of reducing the risk of sepsis from parenteral feeding, and enteral feeding restores the gut mucosal barrier prevent-ing bacterial translocation through the damaged mucosa.

**Prognosis of acute pancreatitis**

For the patient with an acute mild episode the mortality should be less than 1 per cent, while for the patient with a severe attack 20—25 per cent mortality is anticipated. For those who have infected necrosis a mortality of up to 50 per cent can be anticipated. There is a clear responsibility before the patient is discharged to determine the aetiology of the attack of pancreatitis. Gallstones must be treated, and the other causes, listed in Table 55.4, must be excluded. The failure to remove a predisposing factor could lead to a second attack of pancreatitis, which could be fatal.

**Chronic pancreatitis**

Chronic pancreatitis is a chronic inflammatory disease in which there is irreversible progressive destruction of pancreatic tissue. Its clinical course is characterised by a dynamic progressive fibrosis of the pancreas. In the early stages of its evolution it is frequently complicated by attacks of acute pancreatitis that are responsible for recurrent pain which may be the only clinical symptom. The incidence of chronic pancreatitis in a prospective study in Copenhagen was 8.2 new cases per 100 000 population per year, with a prevalence of 27.4 cases per 100 000. The incidence rates in retrospective European, North American and Japanese studies range from two to 10 cases per 100 000 population per year. The disease occurs more frequently in men (male to female ratio of 4:1) and the mean age of onset is about 40 years.

**Pathology and aetiology**

At the onset of the disease when symptoms have developed the pancreas may appear normal. Later the pancreas enlarges and becomes hard as a result of fibrosis. The ducts become distorted and dilated with areas both of stricture formation and of ectasia. Calcified stones weighing from a few milligrams to 200 mg may form within the ducts. The ducts may become occluded with a gelatinous proteinaceous fluid and debris-deformed cysts. Histologically, the lesions affect the lobules producing ductular metaplasia and atrophy of acini, hyperplasia of duct epithelium and interlobular fibrosis. The most frequent cause of chronic pancreatitis is a high alcohol consumption. Other causes are pancreatic duct obstruction resulting from stricture formation after trauma, acute pancreatitis or even occlusion of the duct by pancreatic cancer. Hereditary pancreatitis, infantile malnutrition and a large unexplained idiopathic group make up the remainder. Amongst the idiopathic group there are those who live in warm climates such as Kerala in southern India, and appear to have a high incidence of pancreatitis. Here the pancreatitis begins at a young age, is associated with a high incidence of diabetes mellitus and stone formation is frequent. The impor-tance of hereditary pancreatitis and pancreatitis occurring at a young age is that there is an undoubtedly increased risk of the development of pancreatic cancer, particularly if the patient smokes tobacco heavily.

**Clinical features**

Pain is the outstanding symptom in the majority of patients. The site of pain depends to some extent on the main focus of the disease. If the disease is mainly in the head of the pancreas then epigastric and right subcostal pain is common, while if it is limited to the left side of the pancreas then left subcostal and back pain are the presenting manifestations. In some patients the back pain predominates, while in others the pain is more diffuse. Radiation to the shoulder, usually the left shoulder, occurs. Nausea is common during attacks, and vomiting may occur. The pain is dull and gnawing. The pain is both continuous and episodic, in that severe bouts of pain may occur superimposed on background discomfort. Of the complications of acute pancreatitis can occur with chronic pancreatitis. Because of the pain weight loss is common, in that the patient does not feel like eating. The pain prevents sleep and time off work is frequent. The number of hospital admissions for acute exacerbations is a pointer towards the severity of the disease. Analgesic use—abuse is frequent. This, too, gives an indication of the severity of the disability. The patient’s lifestyle will gradually be destroyed by pain, analgesic dependence, weight loss and inability to work. Complications frequently bring the patient to the attention of the surgeon. Infection is infrequent, possibly related to the increasing incidence of diabetes mellitus with time. Loss of exocrine function will occur leading to steatorrhoea which can be debilitating without supplementation, whilst loss of endocrine function and the development of diabetes are not uncommon, and the incidence increases as the disease progresses.

**Investigation**

Only in the early stages of the disease will there be a rise in serum amylase. Pancreatic function tests merely confirm the presence of pancreatic insufficiency or that more than 70 per cent of the gland has been destroyed. Steatorrhoea affects more than 30 per cent of patients with chronic pancreatitis.

The prime investigation is either an MRI scan or a CT scan which will show the outline of the gland, the main area of damage and the possibilities for surgical correction. An MR cholangiogram will show the presence of biliary obstruction, and an MR pancreatogram the state of the pancreatic duct. An ERCP or a percutaneous pancreatogram (Fig. 55.30) can elucidate the anatomy of the duct and, in conjunction with the whole organ morphology, determine the type of operation required, if operative intervention is indicated.

**Treatment**

A diet low in fat and with no alcohol is advised. Pancreatic enzyme supplementation may reduce the frequency of painful crises. Attention must be paid to nutrition to ensure that the patient gains weight and takes an adequately varied and nutritionally appropriate diet. The use of morphine should be avoided and tobacco smoking curtailed. There is no single therapeutic agent which has been shown to relieve symptoms, although the use of antioxidants to mop up free oxygen radicals has been tried.

The role of surgery is in overcoming obstruction and removing mass lesions. Most patients have a mass in the head of the pancreas, for which a resection of the head of the pancreas either by a pancreaticoduodenectomy or a Beget pro-cedure is appropriate. If the duct is markedly dilated, then a longitudinal pancreatojejunostomy or Frey procedure can be of value (Fig. 55.31). The rare patient with disease limited to the tail will be cured by a distal pancreatectomy.

**Prognosis**

Correctly chosen surgery will relieve symptoms in 75 per cent of patients provided that the aetiological factor is removed. Development of pancreatic cancer is a risk in those who have had the disease more than 20 years. New symptoms or a change in the pattern of symptoms should be investigated and development of cancer excluded.
Carcinoma of the pancreas

Pancreatic cancer is the eighth most common cancer causing death in the UK. The incidence is 10 cases per 100,000 population per year. The incidence has risen steadily over the last 25 years, until 5 years ago when it levelled off. The disease is a disease of ageing, with the average age of death in men being 74 years and that in women 79 years. It affects men and women to the same degree. Predisposing factors are tobacco smoking and chronic pancreatitis. No other relationships have been elucidated.

Pathology

More than 85 per cent of cases are duct cell adenocarcinomas. The remaining tumours are a fascinating variety of pathologies, each with their own characteristics. The more common tumours are listed in Table 55.6. The importance of the pathology is that some tumours have a prolonged natural history, for instance, the cystadenocarcinomas, while those with an ampullary tumour (Fig. 55.32) or a neuroendocrine have an increased survival after resection.

Clinical features

The most frequent symptoms are nonspecific, namely epigastric discomfort, anorexia and weight loss. Often the patient is aware of their digestion for the first time in their life, and such is the mildness of the initial symptoms that they are frequently dismissed both by patient and by doctor. Jaundice is the commonest sign and symptom which brings the patient to the attention of his or her physician. Some 85 per cent of patients present with this symptom. It is characteristically painless jaundice but may be associated with nausea and epigastric discomfort. Change of bowel habit is rare.

On examination there is frequently evidence of weight loss, a palpable liver, a palpable gall bladder and even metastatic lymph nodes in the neck. Courvoisier first drew attention to the association of an enlarged gall bladder and a pancreatic tumour in 1890, when he stated that when the common duct is obstructed by a stone dilatation is rare; when the duct is obstructed in some other way, dilatation is common. In those days dilatation of the duct could not be determined and the dilatation, thus, refers to the gall bladder. Other signs of intra abdominal malignancy should be looked for with care, such as a mass, ascites and tumour deposits in the pelvis.

Investigation

If the patient is jaundiced, the usual blood tests and ultrasound scan should be performed. This will determine whether or not the bile duct is dilated. If it is and there is a genuine suspicion of a tumour in the head of the pancreas, the preferred test is now a contrast enhanced spiral CT scan specific for the pancreas. The next investigation is that of an endoscopic examination to determine whether the jaundice can be relieved endoscopically. If it can, a stent should be inserted through the stricture to relieve the jaundice. Attention should be paid to the coagulation to ensure that no bleeding occurs during this process. If the ERCP shows the characteristic features of a tumour and the CT scan shows that the tumour is small (less than 4 cm), and confined to the head of the pancreas without evidence of distant spread or vascular invasion, then the patient should be considered for operative intervention and their state of general fitness assessed. More accurate information can be obtained by endoscopic ultrasound in which the ultrasound probe on the end of an endoscope is used to obtain images of the tumour via the duodenum, giving good definition of the tumour and its extent. Unfortunately, lymphadenopathy is not well shown by this technique, but its possible to determine with accuracy whether or not the portal vein is involved.

Management

At the time of presentation, 90—95 per cent of patients are unsuitable for resection because of either local spread into the superior mesenteric vein, para aortic or mesenteric lymphadenopathy, or hepatic metastases. In some patients age precludes major operative intervention. For those patients who are inoperable palliative treatment should be offered. Jaundice is relieved by stenting. Obstruction of the duode-num occurs in approximately 15 per cent; if this occurs early in the course of the disease surgical bypass by gastrojejunostomy is appropriate, but if its late in the course of the disease then the use of expanding metal stents inserted endoscopically is preferred as many of these patients have prolonged delayed gastric emptying following surgery. If the patient is not a suitable candidate for endoscopic biliary stenting a percutaneous transhepatic stent can be placed. In younger patients who may have a better prognosis a laparotomy to assess the tumour can be appropriate; if the tumour is proved inoperable a choledochoduodenostomy and gastro-jejunostomy is the preferred approach, but the simpler chole-cystjejunostomy (Fig. 55.33) is more frequently performed. The disadvantage of the latter technique is that bile must drain through the cystic duct which is narrow, and if the cystic duct is inserted low into the bile duct it is vulnerable to occlusion by tumour growth. Any patient who has had palliative treatment should have a biopsy performed to obtain histological verification. If operation is undertaken this can be done at the time of the operation, but if no operative procedure is undertaken a percutaneous trucut biopsy of the tumour should be performed.

The role of chemotherapy in the management of pancreatic cancer remains ill defined. If the tumour is a lymphoma then benefit is without doubt. Lymphomas of the pancreas are rare, however, comprising less than 3 per cent of the total number of pancreatic cancers. For the duct cell adenocarcinoma, 5-fluorouracil (5FU) or gemcitabine will produce a remission in 15—25 per cent of patients, whilst the remainder will have no benefit from the therapy. In those that have a remission prognosis is extended by approximately 6 months. No long-term cures have been described with oncological agents.

Surgical resection

If a cystic tumour is encountered, no matter how large, most of these can be removed surgically with a reasonable chance of cure and with low operative mortality. Tumours of the ampulla have a good prognosis and should, if at all possible, be resected. Some of the rare tumours and the neuroendocrine lesions should also be resected if at all possible. Patients with duct cell cancers which are less than 4 cm in diameter, not involving the superior mesenteric or portal veins and with no evidence of multiple enlarged nodes or distant spread, should be considered for a resection. The appropriate resection is that of a pylorus-preserving pancreatoduodenectomy with a local lymphadenectomy. Extended resections have not been shown to be beneficial in improving survival and are associated with an increased morbidity.

The operation can now be performed safely with a mortality of 3—5 per cent. The morbidity remains high with some 40 per cent of patients developing a complication in the postoperative period. These complications are usually infec-tive, but a leak from the pancreatic duct is known to occur in at least 10 per cent of patients and this may give rise to major complications. The role of adjuvant radiotherapy and chemotherapy with resection has not been elucidated.

Pancreatoduodenectomy—preoperative management. A full assessment of the patient’s general condition should be carried out and a decision made whether or not to relieve the jaundice preoperatively. Occasionally, if the period of jaundice is short (2 weeks), it is safe to proceed to operation, but if the period of jaundice is prolonged and a more detailed preoperative assessment of operability is required then a stent allows more time and relieves the symptoms associated with jaundice. The clotting should be carefully checked pre-operatively and adequate hydration ensured. A full explanation is made to ensure that the patient is aware of the diagnosis, the gravity of the operation and the
risks involved, and consent taken.

Under general anaesthesia with adequate monitoring, the abdomen is explored and operability assessed. If the tumour is localised and without distant spread then resection is appropriate. A cholecystectomy is performed. The bile duct is dissected together with the structures in the porta hepatis, removing the lymphatic tissue in this area. This will expose the hepatic artery and enable division of the gastroduodenal artery which will expose the portal vein. The duodenum and right colon are mobilised from the retroperitoneal tissues and the fourth part of the duodenum is dissected and freed from the ligament of Treitz so that the upper jejunum can be brought into the supracolic compartment. The jejunum is divided and the mesentery of the proximal jejunum detached. The proximal duodenum is divided. The neck of the pancreas is divided and then the uncinate process separated from the superior mesenteric artery and vein working up towards the upper bile duct which is divided releasing the specimen (Fig. 55.34). Retroperitoneal lymph nodes are completely removed with the specimen as are those attached to the superior mesenteric vessels. Reconstruction is carried out as in Fig. 55.35. The operation should take between 3 and 6 hours. Blood loss should be low and transfusion unnecessary. Neither duct is stented and a single drain to the subhepatic space should be kept in situ for 4 days.

**Prognosis**

The overall median survival for patients with pancreatic cancer is 20 weeks. Less than 3 per cent of patients will survive for 5 years. Patients with a carcinoma of the ampulla of Vater who have had a resection will have a 5-year survival rate of 40 per cent, while those with a duct cell carcinoma will have a 5-year survival rate of 20 per cent. More ‘benign’ tumours will, of course, have a better prognosis. Following surgery all patients who have had palliative treatment require regular follow-up in order to care for steatorrhoea with enzyme supplementation, diabetes mellitus, if it develops, with oral hypoglycaemics or insulin as appropriate, and pain with either analgesics or an appropriate nerve block. The procedure of transthoracic splanchnicectomy is now the preferred procedure for relieving the pain and should be considered in preference to a coeliac plexus block.
Endocrine tumours of the pancreas

The islet of Langerhans contain three types of cells: alpha, beta and gamma and of these the beta-cell is most prevalent. Tumours of these endocrine cells comprise 1 per cent of all pancreatic tumours.

Pathology

The actual islet cell lesion may be one of the following: (1) generalised hyperplasia; (2) discrete adenoma; (3) generalised adenomatosis; and (4) carcinoma. In about one-third of cases they are multiple and in one-third they are malignant. As part of the multiple endocrine neoplasia syndrome they may be associated with tumours in other endocrine glands, especially the anterior pituitary, the parathyroids and the adrenal cortex. The neuroendocrine tumours may secrete hormones which give rise to the following conditions: insulinoma (insulin), gastrinoma (gastrin), watery diarrhoea hypokalaemia achlorhydria syndrome (WDHA) (vasoactive intestinal peptide), glucagonoma (glucagon), somatostatinoma (somatostatin), CCKoma (CCK), ectopic adrenocorticotropic hormone syndrome (ACTH), hyperpigmentation syndrome (melanocyte-stimulating hormone), ectopic hyperparathyroidism (para-thyroid hormone-related protein), carcinoid syndrome (5-hydroxytryptamine), pancreatic polypeptidoma (PPoma) (pancreatic polypeptide) and growth hormone secreting factor tumour. The commonest of these is the insulinoma.

Hyperinsulinism

Clinical features

The symptoms are many and varied, but the attacks are always associated with hypoglycaemia and occur at irregular intervals, often with progressively increasing frequency and severity. The symptoms include epigastric discomfort, nervousness, ‘feeling unwell’, trembling, sweating, dizziness, episodes of inarticulate speech and uncoordinated movements and, in extreme cases, fits indistinguishable from epilepsy. The age of the patient is variable.

Diagnosis

Diagnosis is made by the three criteria described by Whipple which consists of the signs and symptoms of hypoglycaemia, serum levels of less than 2.8 mmol/litre and the prompt relief of symptoms by the administration of glucose. The hypoglycaemia should be documented and associated with inappropriate levels of serum insulin (greater than 6 l. micro units/dl) and elevated C-peptide levels. Once the diagnosis has been made, the next step is to localise the tumour. The prime investigation is that of a high-quality CT scan of the pancreas with rapid injection (5—7 ml/second) of intravenous contrast (Fig. 55.12). The diagnosis of the characteristic ‘blush’ noted at the site of the tumour can be confirmed by endoscopic ultrasound. Angiography and selective sampling is no longer indicated. Further information is not required.

Treatment

The only curative treatment is extirpation of the tumour. Appropriate intravenous therapy with glucose and insulin is started preoperatively to maintain the blood sugar between 5 and 8 mmol/litre. The tumour is located usually with ease. Occasionally, the tumour cannot be palpated and then intraoperative ultrasound will invariably localise the tumour if present. Enucleation is the procedure of choice. Resection is rarely necessary unless the tumour is adjacent to the main duct in the head of the pancreas or there are multiple tumours in close proximity. The operative mortality rate is 1 per cent and the symptoms should be relieved in more than 95 per cent of patients.

Zollinger—Ellison syndrome

Diagnosis

The diagnosis should be suspected when peptic ulcer disease occurs at a very young age, there is virulent peptic ulcer disease, peptic ulcer disease occurs in unusual sites such as the jejunum, there is a marginal ulcer, unexplained diarrhoea, coexistent parathyroid disease or a family history of endocrinopathy.

The diagnosis of Zollinger—Ellison syndrome is confirmed by the demonstration of hypergastrinaemia and concurrent gastric hyperacidity. If there is doubt about the diagnosis a confirmatory secretin or calcium infusion test should be performed.

Location and localisation

In 1984 Stabile et al. described the ‘gastrinoma triangle’ (confluence of the cystic duct and common bile duct superiorly, junction of the second and third parts of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially) and suggested that 80—90 per cent of gastrinomas would be found within this triangle. This is, indeed, the case. A high percentage of tumours will be found in the duodenal wall and these are often quite small (4—6 mm). As 50—60 per cent of patients with the Zollinger—Ellison syndrome have malignant tumours, careful investigation should be performed preoperatively to exclude metastatic disease. If there is no metastatic disease exploration should be undertaken.

Treatment

If the tumour is localised then resection of the tumour should be undertaken. Unfortunately, the surgical cure rate is only 30 per cent. Nevertheless, if a single tumour is found and excised the patient is cured. If other problems coexist, the patient can be managed medically with omeprazole and octreotide. Total gastrectomy is advised only if medical therapy fails.
Further reading

The peritoneum

The peritoneal membrane is conveniently divided into two parts — the visceral surrounding the viscera and the parietal lining the other surfaces of the cavity. The peritoneum has a number of functions (Table 56.1). The parietal portion is richly supplied with nerves and, when irritated, causes severe pain accurately localised to the affected area. The visceral peritoneum, in contrast, is poorly supplied with nerves, and its irritation causes vague pain which is usually located to the midline.

The peritoneal cavity is the largest cavity in the body, the surface area of its lining membrane (2 m² in an adult) being nearly equal to that of the skin. The peritoneal membrane is composed of flattened polyhedral cells (mesothelium), one layer thick, resting upon a thin layer of fibroelastic tissue. Beneath the peritoneum, supported by a small amount of areolar tissue, lies a network of lymphatic vessels and rich plexuses of capillary blood vessels from which all absorption and exudation must occur. In health, only a few millilitres of peritoneal fluid is found in the peritoneal cavity. The fluid is pale yellow, somewhat viscid and contains lymphocytes and other leucocytes; it lubricates the viscera allowing easy movement and peristalsis.

In the peritoneal space mobile gas-filled structures float upwards under the influence of posture, as does free air (‘gas’). In the erect position, when free fluid is present in the peritoneal cavity, pressure is reduced in the upper abdomen compared with the lower abdomen. When air is introduced it rises, allowing all of the abdominal contents to sink.

During expiration intra-abdominal pressure is reduced and peritoneal fluid, aided by capillary attraction, travels in an upward direction towards the diaphragm. Experimental evidence shows that particulate matter and bacteria are absorbed within a few minutes into the lymphatic network through a number of ‘pores’ within the diaphragmatic peritoneum. This upward movement of peritoneal fluids is responsible for the occurrence of many subphrenic abscesses.

The peritoneum has the capacity to absorb large volumes of fluid: this ability is used during peritoneal dialysis in the treatment of renal failure. But the peritoneum can also produce an inflammatory exudate when injured (Table 56.2). When a visceral perforation occurs the free fluid which spills into the peritoneal cavity runs downwards, largely directed by the normal peritoneal attachments. For example, spillage from a perforated duodenal ulcer may run down the right paracolic gutter.

When parietal peritoneal defects are created healing occurs, not from the edges, but by the development of new mesothelial cells throughout the surface of the defect. In this way large defects heal as rapidly as small defects.
Acute peritonitis

Most cases of peritonitis are due to an invasion of the peritoneal cavity by bacteria, so that when the term ‘peritonitis’ is used without qualification, bacterial peritonitis is implied. Bacterial peritonitis is usually polymicrobial, both aerobic and anaerobic organisms being present. The exception is primary peritonitis (‘spontaneous’ peritonitis) in which a pure infection with streptococcal, pneumococcal or haemophilus bacteria occurs.

Bacteriology

Bacteria from the gastrointestinal tract. The number of bacteria within the lumen of the gastrointestinal tract is normally low until the distal small bowel is reached, while high concentrations are found in the colon. However, disease (e.g. obstruction, achlorhydria, diverticula) may increase proximal colonisation. The biliary and pancreatic tracts are normally free from bacteria, although they may be infected in disease, e.g. gallstones. Peritoneal infection is usually caused by two or more bacterial strains. The commonest are Escherichia coli, aerobic and anaerobic streptococci, and the bacteriodes. Less frequently Clostridium welchii is found; still less frequently staphylococci or Klebsiella pneumonlae (Friedländer’s bacillus). Gram-negative bacteria contain endotoxins (lipopolysaccharides) in their cell walls which have multiple toxic effects on the host, primarily by causing the release of tumour necrosis factor (TNF) from host leucocytes. Systemic absorption of endotoxin may produce endotoxic shock with hypotension and impaired tissue perfusion. Other bacteria such as C. welchii produce harmful exotoxins.

Bacteroides are commonly found in peritonitis. These Gram-negative, nonsporing organisms, although predominant in the lower intestine, often escape detection because they are strictly anaerobic, and slow to grow on culture media unless there is an adequate carbon dioxide tension in the anaerobic apparatus (Gillespie). In many laboratories, the culture is discarded if there is no growth in 48 hours. These organisms are resistant to penicillin and streptomycin but sensitive to metronidazole, clindamycin, lincomycin and cephalosporin compounds. Since the widespread use of metronidazole (‘Flagyl’) bacteriodes infections have diminished greatly.

Nongastrointestinal causes of peritonitis

Nongastrointestinal causes of peritonitis include chlamydia, gonococcus, beta-haemolytic streptococcus, pneumococcus and Mycobacterium tuberculosis. Since the advent of antibiotics haemolytic streptococcal peritonitis has lost many of its dreaded lethal properties. In young girls and women, pelvic infection via the Fallopian tubes is responsible for a high proportion of ‘nongastrointestinal’ infections but bacteriodes is also found in the female genital tract.

Immunodeficient patients, for example those with human immunodeficiency virus (HIV) infection (the acquired immunodeficiency syndrome — AIDS) or on immunosuppressivetreatment, may present with opportunistic peritoneal infection, e.g. mycobacterium avis intracellulare (MAI).

Route of infection

Infecting organisms may reach the peritoneal cavity via a number of routes (Table 56.3).

Even in patients with nonbacterial peritonitis (e.g. acute pancreatitis, intraperitoneal rupture of the bladder or haemoperitoneum) the peritoneum often becomes infected by transmural spread of organisms from the bowel, and its not long (often a matter of hours) before a bacterial peritonitis develops. Most duodenal perforations are initially sterile for up to several hours, and many gastric perforations are also sterile at first; intestinal perforations are usually infected from the beginning. The proportion of anaerobic to aerobic organisms increases with the passage of time. Mortality reflects:

- the degree and duration of peritoneal contamination;
- the age of the patient;
- the general health of the patient;
- the nature of the underlying cause.

Localised peritonitis

Anatomical, pathological and surgical factors may favour the localisation of peritonitis.

Anatomical

The greater sac of the peritoneum is divided into (a) the subphrenic spaces, (b) the pelvis, and (c) the peritoneal cavity proper. The latter is redivided into a supracolic and an infracolic compartment by the transverse colon and transverse mesocolon, which deters the spread of infection from one to the other. When the supracolic compartment overflows, as is often the case when a peptic ulcer perforates, it does so over the colon into the infracolic compartment, or by way of the right paracolic gutter to the right iliac fossa, and thence to the pelvis. Posture can assist in directing collections into the pelvis, as in the ‘Sherren’ regime for perforated appendicitis.

Pathological

The clinical course is determined in part by the manner in which adhesions form around the affected organ. Inflamed peritoneum loses its glistening appearance and becomes reddened and velvety. Flakes of fibrin appear and cause loops of intestine to become adherent to one another and to the pariectes. There is an outpouring of serous inflammatory exudate rich in leucocytes and plasma proteins that soon becomes turbid; if localisation occurs, the turbid fluid becomes frank pus. Peristalsis is retarded in affected bowel, and this helps in preventing distribution of the infection. The greater omen-turn, by enveloping and becoming adherent to inflamed structures, often forms a substantial barrier to the spread of infection.

Surgical

Drains are frequently placed during operation to assist localisation (and exit) of intra-abdominal collections: their value is disputed. They may act as conduits for exogenous infection. Collections detected postoperatively on ultrasound or computerised tomography (CT) scanning may be drained percutaneously.

Diffuse peritonitis
A number of factors may favour the development of diffuse peritonitis.

Speed of peritoneal contamination is a prime factor in the spread of peritonitis. If an inflamed appendix (Fig. 56.1) or other hollow viscus perforates before localisation has taken place, there is a gush of contents into the peritoneal cavity which may spread over a large area almost instantaneously. Perforation proximal to an obstruction, or from sudden anastomotic separation, is associated with severe generalised peritonitis and a high mortality.

Stimulation of peristalsis by the ingestion of food, or even water, hinders localisation. Violent peristalsis occasioned by the administration of a purgative or an enema may cause the widespread distribution of an infection that would otherwise have remained localised.

The virulence of the infecting organism may be so great as to render the localisation of infection difficult or impossible.

Young children have a small omentum.

Disruption of localised collections may occur with injudicious and rough handling, e.g. appendix mass or pericolic abscess.

Deficient natural resistance (‘immune deficiency’) may result from drugs (e.g. steroids), disease (e.g. AIDS) or old age.

Clinical features

Localised peritonitis

Localised peritonitis is bound up intimately with the causative condition and the initial symptoms and signs are those of that condition. When the peritoneum becomes inflamed the temperature, and especially the pulse rate, rise. Abdominal pain increases and usually there is associated vomition. The most important sign is guarding and rigidity of the abdominal wall over the area of the abdomen which is involved, with a positive ‘release’ sign (rebound tenderness), if inflammation arises under the diaphragm shoulder tip (‘phrenic’) pain may be felt. In cases of pelvic peritonitis arising from an inflamed appendix in the pelvic position or from salpingitis the abdominal signs are often slight, deep tenderness of one or both lower quadrants alone being present, but a rectal or vaginal examination reveals marked tenderness of the pelvic peritoneum. With appropriate treatment localised peritonitis usually resolves. In about 20 per cent of cases an abscess follows. Infrequently, localised peritonitis becomes diffuse. Conversely, in favourable circumstances diffuse peritonitis can become localised, most frequently in the pelvis or at multiple sites within the abdominal cavity. A large collection of bile localised to the subhepatic space can remain dangerously ‘silent’ until a late stage.

Diffuse (generalised) peritonitis

Diffuse (generalised) peritonitis may present in differing ways dependent on the duration of infection.

Early. Abdominal pain is severe and made worse by moving or breathing. It is first experienced at the site of the original lesion, and spreads outwards from this point. Vomiting may occur. The patient usually lies still. Tenderness and rigidity on palpation are typically found when the peritonitis affects the anterior abdominal wall. Abdominal tenderness and rigidity are diminished or absent if the anterior wall is unaffected, as in pelvic peritonitis or, rarely, peritonitis in the lesser sac. Patients with pelvic peritonitis may complain of urinary symptoms; they are tender on rectal or vaginal examination. Infrequent bowel sounds may still be heard for a few hours but they cease with the onset of paralytic ileus. The pulse rises progressively, but if the peritoneum is deluged with irritant fluid, there is a sudden rise. The temperature changes are variable and can be subnormal.

Late. If resolution or localisation of generalised peritonitis does not occur, the abdomen remains silent and increasingly distends. Circulatory failure ensues, with cold, clammy extremities, sunken eyes, dry tongue, thready (irregular) pulse, and drawn and anxious face (Hippocratic facies, Fig 56.2). The patient finally lapses into unconsciousness. With early diagnosis and adequate treatment, this condition is rarely seen in modern surgical practice.

Diagnostic aids

A number of investigations may elucidate a doubtful diagnosis, but the importance of a careful history and repeated examination must not be forgotten

A leucocytosis is usually seen in peritonitis but is often delayed for many hours.

Peritoneal diagnostic aspiration may be helpful but is usually unnecessary. After infiltrating the skin of the abdomen with local anaesthetic, the peritoneum is entered in one or more quadrants with a sterile needle an or intravenous cannula attached to a syringe into which is sucked any free fluid. Bile-stained fluid indicates perforated peptic ulcer or gall bladder, the presence of pus indicates bacterial peri-tonitis; blood is aspirated in a high proportion of patients with intraperitoneal bleeding. When aspiration fails, the introduction of a small quantity of sterile physiological saline, followed after a few minutes by peritoneal aspiration may produce fluid of diagnostic value. Microscopy of the fluid may show neutrophils (indicative of acute inflammation) and bacteria (confirming infection).

An X-ray film of the abdomen may confirm the presence of diluted gas-filled loops of bowel (consistent with a paralytic ileus) or show free gas, although the latter is best shown on an erect chest X-ray (Fig. 56.3). If the patient is too ill for an ‘erect’ film to demonstrate free air collecting under the diaphragm, a lateral decubitus film is just as useful showing gas beneath the abdominal wall. Serum amylase estimation may uphold the diagnosis of acute pancreatitis provided it is remembered that moderately raised values are frequently found following other abdominal catastrophes and operations, e.g. perforated duodenal ulcer.

Ultrasound and CT scanning, when available, may also be helpful in some patients by identifying a cause of peritonitis e.g. perforated appendicitis, acute pancreatitis (Fig. 56.4). Such knowledge may influence operative approach or contraindicate operation.

Treatment

It cannot be stressed too strongly that in any case of doubt, early surgical intervention is to be preferred to a ‘wait and see’ policy; for greater numbers of patients die from delay than from an ‘unnecessary’ laparotomy. This rule is particularly true for postoperative peritonitis.
Treatment consists of:

• general care of the patient;
• specific treatment for the cause;
• peritoneal lavage when appropriate.

**General care of the patient**

Correction of circulating volume and electrolyte imbalance. Patients are frequently hypovolaemic with electrolyte disturbances. The plasma volume must be restored and the plasma electrolyte concentrations corrected. Central venous catheterisation and pressure monitoring may be helpful in correcting fluid and electrolyte balance particularly in patients with concurrent disease. Plasma protein depletion may also need correction as the inflamed peritoneum leaks large amounts of protein. If the patient’s recovery is delayed for more than 7—10 days, intravenous feeding (‘hyper-alimentation’ or ‘total parenteral nutrition’) is required.

Gastrointestinal decompression. A nasogastric tube is passed into the stomach and aspirated. Intermittent aspiration is maintained until the paralytic ileus resulting from peritonitis has recovered. Measured volumes of water are allowed by mouth when only small amounts are being aspirated. If the abdomen is soft and not tender, and bowel sounds return, oral feeding may be progressively introduced. It is important not to prolong the ileus by missing this stage.

**Antibiotic therapy.** Administration of antibiotics prevents the multiplication of bacteria and the release of endotoxins. As the infection is usually a mixed one, initially parenteral broad-spectrum antibiotics active against aerobic and anaerobic bacteria should be given.

A fluid balance chart must be started so that daily output by gastric aspiration and urine is known. Additional losses from the lungs, skin, and in faeces are estimated, so that the intake requirements can be calculated and seen to have been administered. Throughout recovery, the haematocrit and serum electrolytes and urea must be checked regularly.

**Analgesia.** The patient should be nursed in the sitting-up position and must be relieved of pain before and after operation. Once the diagnosis has been made morphine may be given, and continued as necessary. If appropriate expertise is available epidural infusion may provide excellent analgesia. Freedom from pain allows early mobilisation and adequate physiotherapy in the postoperative period which help to prevent basal pulmonary collapse, deep-vein thrombosis and pulmonary embolism.

**Vital system support.** Especially if septic shock is present, special measures may be needed for cardiac, pulmonary and renal support. Administration of oxygen postoperatively can help to prevent and mitigate the effects of septic shock, especially adult respiratory distress syndrome (ARDS) which may require a period of mechanical ventilation. If oliguria persists despite adequate fluid replacement, both diuretics and inotropic agents such as dopamine may be needed.

**Specific treatment of the cause**

If the cause of peritonitis is amenable to surgery, such as in perforated appendicitis, diverticulitis, peptic ulcer, gangrenous cholecystitis or in rare cases of perforation of the small bowel, operation must be carried out as soon as the patient is fit for anaesthesia. This is usually within a few hours. In peritonitis due to pancreatitis or salpingitis, or in cases of primary peritonitis of streptococcal or pneumococcal origin, nonoperative treatment is preferred (if the diagnosis can be made with certainty).

**Peritoneal lavage**

In operations for general peritonitis its essential that after the cause has been dealt with the whole peritoneal cavity should be explored with the sucker and mopped dry, if necessary until all seropurulent exudate is removed. The use of a large volume of saline (1—2 litres) containing dissolved antibiotic (e.g. tetracycline) has been shown to be very effective (Matheson).

**Prognosis**

With modern treatment diffuse peritonitis carries a mortality of about 10 per cent. The systemic complications and lethal factors are listed in Table 56.4.

**Complications of peritonitis**

All of the complications of a severe bacterial infection are possible, but the specific abdominal complications of peritonitis are listed in Table 56.5.

**Acute intestinal obstruction due to peritoneal adhesions**

This usually gives central colicky abdominal pain with evidence of small bowel gas and fluid levels sometimes confined to the proximal intestine on X-ray. Bowel sounds are increased. It is more common with localised peritonitis. It is essential to distinguish this from paralytic ileus.

**Paralytic ileus**

There is usually little pain and gas-filled loops with fluid levels are seen distributed throughout the small and large intestines on abdominal X-ray. In paralytic ileus, bowel sounds are reduced or absent.

**Abscesses**

Abscess formation following local or diffuse peritonitis usually occupies one of the situations shown in Fig. 56.5. The symptoms and signs of a purulent collection may be very vague and consist of nothing more than lassitude, anorexia and failure to thrive; pyrexia (often low-grade), tachycardia, leucocytosis and localised tenderness are also common. Later on a palpable mass may develop. When palpable an intraperitoneal abscess should be monitored by marking out its limitations on the abdominal wall, and meticulous daily examination. More commonly its course is monitored by repeat ultrasound or CT scanning. In the majority of cases with the aid of antibiotic treatment, the abscess or mass becomes smaller and smaller, and finally is undetectable. In others, the abscess fails to resolve, or becomes larger, in which event it must be drained. In many situations, by waiting for a few days the abscess becomes adherent to the abdominal wall, so that it can be drained without opening the general peritoneal cavity; if facilities are available ultrasound or CT-guided drainage may avoid further operation. Open
drainage of an intraperitoneal collection should be carried out by cautious blunt finger exploration to minimise the risk of an intestinal fistula.

**Pelvic abscess**

The pelvis is the commonest site of an intraperitoneal abscess because the vermiform appendix is often pelvic in position and also the Fallopian tubes are frequent sites of infection. A pelvic abscess can also occur as a sequel to any case of diffuse peritonitis and is a common sequel of anastomotic leakage following large bowel and rectal surgery. Pus can accumulate in this area without serious constitutional disturbance and unless the patient is examined carefully from day to day, such abscesses may attain considerable proportions before being recognised. The most characteristic symptoms of a pelvic abscess are diarrhoea and the passage of mucus in the stools. It is no exaggeration to say that the passage of mucus, occurring for the first time in a patient who has, or is recovering from, peritonitis, is pathognomonic of pelvic abscess. Rectal examination reveals a bulging of the anterior rectal wall which, when the abscess is ripe, becomes softly cystic. Left to nature, a proportion of these abscesses bursts into the rectum, after which the patient nearly always recovers rapidly. If this possible happy termination does not readily occur the abscess should be drained deliberately. In women vaginal drainage through the posterior fornix is often chosen. In other cases, where the abscess is definitely pointing into the rectum, rectal drainage (Fig. 56.6) is employed. If any uncertainty exists, the presence of pus can be confirmed by ultrasound or CT scanning or by an aspirating needle introduced through the rectum or abdominal wall into the swelling. Laparotomy is almost never necessary. Rectal drainage of a pelvic abscess is far preferable to suprapubic drainage, which risks exposing the general peritoneal cavity to infection. Drainage tubes can also be inserted percutaneously or via the vagina or rectum under radiological (ultrasonic or CT) guidance (Fig. 56.7).
Subphrenic abscess

Anatomy

The complicated arrangement of the peritoneum results in the formation of four peritoneal and three extraperitoneal spaces in which pus may collect. Three of these spaces are on either side of the body, and one is approximately in the midline (Figs 56.8 and 56.9).

Left superior (anterior) intraperitoneal (‘left subphrenic’) is hounded above by the diaphragm, and behind by the left triangular ligament and the left lobe of the liver, the gastrohepatic omentum and anterior surface of the stomach. To the right is the falciform ligament and to the left the spleen, gastroepiploic omentum and diaphragm. The common cause of an abscess here is an operation on the stomach, the tail of the pancreas, the spleen or the splenic flexure of the colon.

Left inferior (posterior) intraperitoneal (‘left subhepatic’) is another name for the ‘lesser’ sac. The commonest cause of infection here is complicated acute pancreatitis. In practice a perforated gastric ulcer rarely causes a collection here because the potential space is obliterated by adhesions.

Right superior (anterior) intraperitoneal (‘right subphrenic’) lies between the right lobe of the liver and the diaphragm. It is limited posteriorly by the anterior layer of the coronary and the right triangular ligaments, and to the left by the falciform ligament. Common causes here are perforating cholecystitis, a perforated duodenal ulcer, a duodenal cap ‘blew out’ following gastrectomy and appendicitis.

Right inferior (posterior) intraperitoneal (‘right subhepatic’) lies transversely beneath the right lobe of the liver in Rutherford Morison’s pouch. It is bounded on the right by the right lobe of the liver and the diaphragm. To the left is situated the foramen of Winslow and below this lies the duodenum. In front are the liver and the gall bladder, and behind, the upper part of the right kidney and diaphragm. The space is bounded above by the liver, and below by the transverse colon and hepatic flexure. It is the deepest space of the four and the commonest site of a subphrenic abscess which usually arises from appendicitis, cholecystitis, a perforated duodenal ulcer or following upper abdominal surgery.

Extraperitoneal. There are three of these:

• right and left extra peritoneal which are terms given to perinephric abscesses (Chapter 64);
• midline extraperitoneal which is another name for the ‘bare’ area of the liver which may develop an abscess in amoebic hepatitis (the commonest cause) or a pyogenic liver abscess (Chapter 52).

Clinical features

The symptoms and signs of subphrenic infection are frequently nonspecific, and it is well to remember the aphorism, ‘pus somewhere, pus nowhere else, pus under diaphragm’.

Symptoms

A common history is that when some infective focus in the abdominal cavity has been dealt with, the condition of the patient improves temporarily, but after an interval of a few days or weeks, symptoms of toxemia reappear. The condition of the patient steadily, and often rapidly, deteriorates. Sweating, wasting and anorexia are present. There is sometimes epigastric fullness and pain, or pain in the shoulder on the affected side, owing to irritation of sensory fibres in the phrenic nerve, referred along the descending branches of the cervical plexus. Persistent hiccup may be a presenting symptom.

Signs

A swinging pyrexia is usually present, unless antibiotics or drugs (steroids) have interfered. If the abscess is anterior, abdominal examination will reveal some tenderness, rigidity or even a palpable swelling. Sometimes the liver is displaced downwards, but more often its fixed by adhesions. Examination of the chest is important, and in the majority of cases collapse of the lung or evidence of basal effusion or empyema is to be found.

Investigations

Anumber of these may be helpful as follows. Blood count usually shows a leucocytosis.

A plain radiograph sometimes demonstrates the presence of gas or a pleural effusion. On screening, the diaphragm is often seen to be elevated (so-called ‘tented’ diaphragm) and its movements impaired.

Ultrasound or CT scanning is the investigation of choice and permits early detection of subphrenic collections (Fig. 56.10).

Radiolabelled white cell scanning may occasionally prove helpful when other imaging techniques have failed.

Differential diagnosis. Pyelonephritis, amoebic abscess, pulmonary collapse and pleural empyema give rise to most of the diagnostic difficulties.

Treatment

The clinical course of suspected cases is watched, and blood and imaging investigations are made at suitable intervals. If suppuration seems probable, intervention is indicated. If skilled help is available it is possible to insert a percutaneous drainage tube under ultrasound or CT control. The same tube can be used to instil antibiotic solutions or irrigate the abscess cavity. To pass an aspirating needle at the bedside intervention is indicated. If skilled help is available it is possible to insert a percutaneous drainage tube under ultrasound or CT control. The same tube can be used to instil antibiotic solutions or irrigate the abscess cavity.

If an operative approach is necessary and a swelling can be detected in the subcostal region or in the loin, an incision is made over the site of maximum tenderness, or over any area where oedema or redness is discovered. The parieties usually form part of the abscess wall so that contamination of the general peritoneal cavity is unlikely.

If no swelling is apparent, the subphrenic spaces should be explored either by an anterior subcostal approach or from behind after removal of the outer part of the 12th rib according to the position of abscess on imaging. With the posterior approach the pleura must not be opened and after the fibres of the diaphragm have been separated a finger is inserted beneath the diaphragm so as to explore the adjacent area. The aim
with all techniques of drainage to avoid dissemination of pus into the peritoneal or pleural cavities.

When the cavity is reached, all of the fibrinous loculi must be broken down with the finger and one or two drains or drainage tubes must be fully inserted. These drains are withdrawn gradually during the next 10 days and the closure of the cavity is checked by sinograms or scanning. The appropriate antibiotics are also given.
Special forms of peritonitis

Postoperative

The patient is ill, with raised pulse and peripheral circulatory failure. Following an anastomotic dehiscence the general condition of a patient is usually more serious than if the patient had suffered leakage from a perforated peptic ulcer with no preceding operation. Local symptoms and signs are less definite. Abdominal pain may not be prominent and is often difficult to assess because of normal wound pain and postoperative analgesia. The patient’s deterioration may be wrongly attributed to cardiopulmonary collapse which is usually concomitant.

Peritonitis follows abdominal operations more frequently than is realised. The principles of treatment do not differ from those of peritonitis of other origin. Antibiotic therapy alone is inadequate; no antibiotic can stay the onslaught of bacterial peritonitis due to leakage from a suture line, which must be dealt with by operation.

In patients under treatment with steroids

Pain is frequently slight or absent. Physical signs are similarly vague and misleading.

In children

The diagnosis is in some ways more difficult, in other ways easier, than in adults. If a history can be taken its plain and unembroidered. Any physical signs elicited by a gentle, patient and sympathetic examiner are meaningful.

In senile patients

These can be as fractious as children and unable to give a reliable history. Abdominal tenderness is usually well localised, but guarding and rigidity are less marked because the abdominal muscles are thin and weak.

Bile peritonitis

Unless there is reason to suspect that a bile duct was damaged at an operation, it is improbable that bile as a cause of peritonitis will be thought of until the abdomen has been opened and bile is seen therein. The common causes of bile peritonitis are shown in Table 56.6. Unless the bile has extravasated slowly and the collection becomes shut off from the general peritoneal cavity there are signs of diffuse peritonitis. After a few hours a tinge of jaundice is not unusual. Laparotomy (or laparoscopy) should be undertaken with evacuation of the bile and peritoneal lavage. The source of bile leakage should be identified. A leaking gall bladder is excised or a cystic duct ligated. An injury to the bile duct may simply be drained or alternatively intubated; later reconstructive operation is often required. Infected bile is more lethal than sterile bile. A ‘blown’ duodenal stump must be drained as it is too oedematous to repair, but sometimes it can be covered by a jejunal patch. The patient is often jaundiced from absorption of peritoneal bile, but the surgeon must ensure that the abdomen is not closed until any obstruction to a major bile duct has been either excluded or relieved. Post cholecystectomy bile leaks may be dealt with by percutaneous (ultrasound guides) drainage and endoscopic biliary stenting to reduce bile duct pressure. The drain is reduced when dry and the stent at 4—6 weeks.

Meconium peritonitis

Meconium is a sterile mixture of epithelial cells, mucin, salts, fats and bile and is formed when the foetus commences to swallow amniotic fluid. By the third month of intrauterine life the upper third of the small intestine has become filled with meconium; by the fourth month the accumulation has reached the ileocaecal valve; during the remainder of intrauterine life the colon becomes increasingly filled.

Meconium peritonitis is an aseptic peritonitis which develops late in intrauterine life or during, or just after, delivery. Meconium enters the peritoneal cavity through an intestinal perforation and in over 50 percent of cases the perforation is the result of neonatal intestinal obstruction; in the remainder no cause for the perforation is discernible. When meconium, which is sterile, enters the peritoneal cavity an exudate is secreted that organises rapidly; matting of intestinal loops occurs, and in many cases in a matter of weeks the extruded meconium becomes calcified.

Meconium remains sterile until about 3 hours after birth; thereafter, unless the perforation has become sealed, sterile meconium peritonitis gives place to acute bacterial peritonitis which, unless treated promptly, is rapidly fatal.

Clinical features. Meconium peritonitis should always be considered when a baby is born with a tense abdomen. There is vomiting and failure to discharge meconium. The differential diagnosis between neonatal intestinal obstruction and peritonitis is, in many cases, virtually impossible; indeed in half the cases both are present. Free fluid in the peritoneal cavity is often sufficient to give a fluid thrill. Meconium ileus occurs in 5—10 per cent of newborn babies with cystic fibrosis (mucoviscidosis) who have an inherited autosomal recessive abnormality of mucus secretion. This leads to secondary damage to the pancreas, lungs, liver and small bowel. Bronchial obstruction by mucus plugs can cause fatal pneumonia.

Radiography (Fig. 56.11). Free air in the peritoneal cavity, an abundant quantity of abdominal fluid, fluid levels, calcification (often most distinct on the surface of the liver or the spleen and most readily seen in a lateral view) are characteristic findings, all of which are unlikely to be present in every case. Meconium peritonitis has been diagnosed by radiography of the foetus in utero 2 days before birth.

Treatment. The prognosis is bad, but recovery may follow prompt operation. The greatest chance of survival is in those patients who have an intestinal perforation but no intestinal obstruction, in which case closure of the perforation and drainage of the peritoneal cavity are performed expeditiously. Intestinal lavage can prevent reformation of meconium bolus obstruction and supplements of pancreatic exocrine enzymes are often necessary throughout life. If there is an associated pulmonary problem, the condition requires special treatment (e.g. oxygen, bronchial lavage, nebulisers and long-term use of antibiotics).

Pneumococcal peritonitis

There are two forms of this disease: (1) primary, and (2) secondary to pneumonia.

Primary pneumococcal peritonitis is much more common. The patient is often an undernourished girl between 3 and 6 years of age, and it is probable that the infection sometimes occurs via the vagina and Fallopian tubes, for pneumococci have been cultured from patients’ vaginas. At other times, and always in males, the infection is blood-borne from the upper respiratory tract or the middle ear. After the age of 10 years pneumococcal peritonitis is most unusual. Children with nephritis are more liable to this condition than others. During the past 30 years
the instance of pneumococcal peritonitis has declined greatly and the condition is now rare.

**Clinical features.** The onset is sudden and the earliest symptom is pain localised to the lower half of the abdomen. The temperature is raised to 39.8°C or more and there is usually frequent vomiting. After 24—48 hours profuse diarrhoea, occasionally blood-stained, is characteristic. There is usually increased frequency of micturition. The last two symptoms are due to severe pelvic peritonitis. Herpes on the lip or nostril is often present. In acute forms of the disease, even in cases where there is no involvement of a lung, there is a tinge of cyanosis of the lips and cheeks and movement of the alae nasi is often discernible. On examination rigidity is usually bilateral but is less than in most cases of acute appendicitis with peritonitis.

**Differential diagnosis.** A leucocytosis of 30000/mm³ (30 x 10⁹/litre) or more with approximately 90 per cent polymorphs suggests pneumococcal peritonitis rather than appendicitis. Even so, it is often impossible, especially in males to exclude perforated appendicitis. The other condition which is extremely difficult to differentiate from primary peritonitis in its early stage is pneumonia. An unduly high respiratory rate and the absence of abdominal rigidity are the most important signs supporting the diagnosis of pneumonia, which is usually clarified by a chest X-ray.

**Treatment.** Early operation is always required. After starting antibiotic therapy and correcting dehydration and electrolyte imbalance, a short midline incision is made. The peritoneum is incised. Should the exudate be odourless and sticky, the diagnosis of pneumococcal peritonitis is practically certain, but it is essential to perform a routine laparotomy to exclude other lesions. Assuming that no other cause for the peritonitis is discovered some of the exudate is removed with a syringe and sent to the laboratory for culture and sensitivity tests. Thorough peritoneal lavage is carried out and the incision closed. The patient is returned to bed, and antibiotic and fluid replacement therapy continued. Nasogastric suction drainage is essential. Recovery is usual.

**Primary streptococcal peritonitis of infants and children**

Primary streptococcal peritonitis of infants and children is rather more frequent than pneumococcal peritonitis but still uncommon. When a streptococcus is the infecting organism the peritoneal exudate is thin and slightly clouded and contains flecks of fibrin. The clinical presentation and treatment of streptococcal peritonitis in infants and children are similar to those of pneumococcal peritonitis (see above), but the mortality is higher. An intravaginal foreign body should always be looked for in female patients.

**Idiopathic streptococcal and staphylococcal peritonitis in adults**

Idiopathic streptococcal and staphylococcal peritonitis in adults is fortunately rare, for prior to the antibiotic era it was nearly always fatal and the mortality is still very high. Rightly, in early cases the abdomen is opened, usually on a diagnosis of acute appendicitis. In streptococcal peritonitis the peritoneal exudate is odourless, thin, contains some flecks of fibrin and may be blood stained. In these circumstances pus is removed by suction, the abdomen closed with drainage and nonoperative treatment of peritonitis performed. Recently the use of intravaginal tampons has led to an increased incidence of *Staphylococcus aureus* infections: these can be associated with toxic shock syndrome and disseminated intravascular coagulopathy.

**Peritonitis following abortion/patturition**

The abortionist has usually pushed an instrument through the uterine vault and streptococcal peritonitis follows. Peritonitis following puerperal infection is more common after first deliveries. Rigidity is seldom much in evidence; this, at any rate in part, is due to the stretched condition of the abdominal musculature. The lochia may be offensive but not necessarily so. Diarrhoea is common.

**Treatment.** Provided the infection is limited strictly to the pelvis, the correct treatment is to rest the gastrointestinal tract and provide intravenous fluids, the required antibiotics and attention to electrolyte balance. Posterior colpotomy may be necessary if a pelvic abscess forms. If the peritonitis is generalised, the patient is usually extremely ill and drainage is advisable. This may be carried out by making a small suprapubic incision under local anaesthesia and inserting a drain, which can be done with the patient in bed, if necessary.

In the pre antibiotic era the mortality of general peritonitis following parturition or abortion was at least 50 per cent; with antibiotic therapy and timely operation, the mortality has fallen to less than 10 per cent (Brews).

**Familial Mediterranean fever (periodic peritonitis)**

Familial Mediterranean fever (periodic peritonitis) is characterised by abdominal pain and tenderness, mild pyrexia, polymorphonuclear leucocytosis and occasionally pain in the thorax and joints. The duration of an attack is 24—72 hours, when it is followed by complete remission but exacerbations recur at regular intervals. Most of the patients have undergone appendicectomy in childhood. This disease, often familial, is limited principally to Arabs, Armenians and Jews; other races are occasionally affected. The aetiology is unknown. Usually children are affected but it is not rare for the disease to make its first appearance in early adult life when females outnumber males by two to one. Exceptionally the disease becomes manifest in patients over 40 years of age. At laparotomy, which may be necessary to exclude other causes, the peritoneum — particularly in the vicinity of the spleen and the gall bladder — is inflamed. There is no evidence that the interior of these organs is abnormal. Coicidine may prevent recurrent attacks.

**Differential diagnosis.** Patients with abdominal epilepsy do not have positive physical signs of pyrexia and their attacks are usually controlled by anticonvulsive medication.
Tuberculous peritonitis

Acute tuberculous peritonitis

Tuberculous peritonitis sometimes has an onset that resembles so closely acute peritonitis that the abdomen is opened. Straw-coloured fluid escapes and tubercules are seen scattered over the peritoneum and greater omentum.早期 tuberculosis is greyish and translucent. They soon undergo caseation, and appear white or yellow and are then less difficult to distinguish from carcinoma. Occasionally they appear like patchy fat necrosis. On opening the abdomen and finding tuberculous peritonitis the fluid is evacuated, some being retained for bacteriological studies. A portion of the diseased omentum is removed for histological confirmation of the diagnosis and the wound closed without drainage.

At other times, although acute abdominal symptoms arise, the presence of ascites makes diagnosis of acute tuberculous peritonitis reasonably evident.

Chronic tuberculous peritonitis

Although the incidence of tuberculous peritonitis has declined in Britain, in many parts of the world where measures for eradicating tuberculosis (especially the disease in cows) are enforced less strictly, the condition still occurs. The condition presents with abdominal pain (90 per cent of cases), fever (60 per cent), loss of weight (60 per cent), ascites (60 per cent), night sweats (37 per cent) and abdominal mass (26 per cent).

Origin of the infection

Infection originates from:

- tuberculous mesenteric lymph nodes;
- tuberculosis of the ileocaecal region;
- a tuberculous pyo salpinx;
- blood-borne infection from pulmonary tuberculosis, usually the ‘miliary’ but occasionally the ‘cavitating’ form.

Varieties of tuberculous peritonitis

There are four varieties of tuberculous peritonitis: ascitic, encysted, fibrous and purulent.

Ascitic form

The peritoneum is studded with tubercules and the peritoneal cavity becomes filled with pale, straw-coloured fluid. The onset is insidious. There is loss of energy, facial pallor and some loss of weight. The patient is usually brought for advice because of enlargement of the abdomen. Pain is often completely absent; in other cases there is considerable abdominal discomfort which may be associated with constipation or diarrhoea. On inspection, dilated veins can be seen coursing beneath the skin of the abdominal wall. Shifting dullness can be elicited readily. In the male child congenital hydroceles sometimes appear, due to the patent processus vaginales becoming filled with ascitic fluid from the peritoneal cavity. Because of the increased intra-abdominal pres-sture an umbilical hernia commonly occurs. On abdominal palpation a transverse solid mass can often be detected. This is rolled-up greater omentum infiltrated with tubercules.

Diagnosis is seldom difficult except when it occurs in an acute form or when it first appears in an adult, in which case it has to be differentiated from other forms of ascites, especially from malignant secondary deposits. A positive Mantoux test in a child with ascites strongly suggests, and a negative test is good evidence against, tuberculosis. In adults this test is of negligible value. Laparoscopy is useful by allowing inspection of the peritoneal cavity, where the appearance is often diagnostic. Areas of caseation can be biopsied for histology and microbiological studies. The ‘open’ (Hasan) technique of trocar insertion should be used because of the risk of adhesions to the abdominal wall. The diagnosis of tuberculous peritonitis having been made, it is always important to look for tuberculous disease elsewhere. The possibility of tuberculous salpingitis in females should be remembered. A chest X-ray should always be taken before laparoscopy or laparotomy is performed.

The ascitic fluid is pale yellow, usually clear and rich in lymphocytes. The specific gravity is comparatively high, often 1.020 or over. Even after centrifugation, rarely can \textit{M.tuberculosis} be found, but its presence can be demonstrated by culture or by guinea-pig inoculation.

Treatment. See guidelines, Chapter 8. If the general condition is good, the patient can return home and, if an adult, to light work, before the course of chemotherapy has been completed.

Encysted form

Encysted (syn. loculated) form is similar to the above, but one part of the abdominal cavity alone is involved. Thus, a localised intra-abdominal swelling is produced which gives rise to difficulty in diagnosis. In a female above the age of puberty when the swelling is in the pelvis, an ovarian cyst will probably be diagnosed. In the case of a child it is sometimes difficult to distinguish the swelling from a mesenteric cyst. For these reasons laparotomy is often performed, and if an encapsulated collection of fluid is found, it is evacuated and the abdomen is closed. The general treatment already detailed is required, but the response to this treatment is more rapid. Late intestinal obstruction is a possible complication.

Fibrous form

Fibrous (syn. plastic) form is characterised by the production of widespread adhesions, which cause coils of intestine, especially the ileum, to become matted together and distended. These distended coils act as a ‘blind loop’ and give rise to steatorrhoea, wasting and attacks of abdominal pain. On examination, the adherent intestine with omentum attached, together with the thickened mesentery, may give rise to a palpable swelling or swellings. The first intimation of the disease may be subacute or acute intestinal obstruction. Sometimes the cause of the obstruction can be remedied easily by the division of bands. Lateral anastomosis between an obviously dilated loop and a collapsed loop of small intestine should not be done, as the ‘blind loop’ syndrome is a certain out-come. If the adhesions are accompanied by fibrous strictures of the ileum as well it is best to excise the affected bowel, provided not too much of the small intestine needs to be sacrificed. If adhesions only are present a plication may be performed (see Chapter 58). Chemotherapy after adequate surgery will rapidly cure the condition.

Purulent form

The general treatment already detailed is required, but the response to this treatment is more rapid. Late intestinal obstruction is a possible complication.
The purulent form is rare. When it occurs, usually it is secondary to tuberculous salpingitis. Amidst a mass of adherent intestine and omentum, tuberculous pus is present. Sizeable cold abscesses often form, and point on the surface, commonly near the umbilicus, or burst into the bowel. In addition to prolonged general treatment, operative treatment may be necessary for the evacuation of cold abscesses and possibly for intestinal obstruction. If a faecal fistula forms it usually persists because of distal intestinal obstruction. Closure of the fistula must therefore be combined with some form of anastomosis between the segment of intestine above the fistula and an unobstructed area below. The prognosis of this variety of tuberculous peritonitis is relatively poor.

**Peritoneal bands and adhesions**

Congenital bands and membranes. Congenital bands and membranes occur in the peritoneum at various sites as described in textbooks of anatomy. Intestinal obstruction is rarely seen except by an obliterated vitellointestinal duct.

- **Peritoneal adhesions.** Peritoneal adhesions are abnormal deposits of fibrous tissue that form after peritoneal injury. They follow operation or peritonitis and are the commonest cause of small bowel obstruction and secondary female infertility in developed countries. They are discussed in detail in Chapter 58.

- **Talc granuloma.** Talc (silicate of magnesium) should never be used as a lubricant for rubber gloves for it is a cause of peritoneal adhesions and granulomas in the Fallopian tubes. Potassium bitartrate which is completely soluble is free from these serious complications.

- **Starch peritonitis.** Like talc, starch powder has found disfavour as a surgical glove lubricant. In a few starch-sensitive patients it causes a painful ascites, fortunately of limited duration. Should laparotomy be performed any small granulomas in, say, the omentum will be found to contain birefringent starch particles. Starch-free surgical gloves are now widely available
Ascites

Ascites, an excess of serous fluid within the peritoneal cavity, can be recognised clinically only when the amount of fluid present exceeds 1500 ml; in the obese a greater quantity than this is necessary before there is clear evidence of the presence of intraperitoneal fluid. Ultrasound and CT scanning can detect much smaller volumes of ascitic fluid.

Mechanism of ascites

The balanced effects of plasma and peritoneal colloid osmotic and hydrostatic pressures determine the exchange of fluid between the capillaries and the peritoneal fluid. Normal intraperitoneal pressure and normal peritoneal fluid colloid osmotic pressure cannot be measured. Protein rich fluid enters the peritoneal cavity when capillary permeability to protein is increased, as in peritonitis and carcinomatosis peritonei. Capillary pressure may be increased because of generalised water retention, cardiac failure, constrictive pericarditis or vena cava obstruction. Capillary pressure is raised selectively in the portal venous system in the Budd-Chiari syndrome, cirrhosis of the liver or extra-hepatic portal venous obstruction (see Chapter 52). Plasma colloid osmotic pressure may be lowered in patients with reduced nutritional intake, diminished intestinal absorption, abnormal protein losses, or defective protein synthesis as occurs in cirrhosis. Peritoneal lymphatic drainage may be impaired resulting in the accumulation of protein-rich fluid.

Clinical features

The abdomen is distended evenly, with fullness of the flanks, which are dull to percussion. Usually shifting dullness is present, but when there is a very large accumulation of fluid this sign is absent. In such cases, on flicking the abdominal wall, a characteristic fluid thrill is transmitted from one side to the other. In women, ascites must be differentiated from an enormous ovarian cyst. The causes of ascites are listed in Table 56.7.

Congestive heart failure, the commonest cause of ascites, causes increased venous pressure in the vena cava and consequent obstruction to the venous outflow from the liver. This increased pressure can be seen as engorgement of the veins of the neck — a striking sign in this condition. The ascitic fluid is light yellow and of low specific gravity, about 1.010, with a low protein concentration (<25 g/litre). Patients with constrictive pericarditis (syn. Pick’s disease) have both peritoneal and pleural effusions due to engorge-ment of the vena cavae consequent upon the diminished capacity of the right side of the heart.

In cirrhosis there is obstruction to the portal venous system which is caused by oblitative fibrosis of the intrahepatic venous bed. Lymph flow may be increased. In the Budd-Chiari syndrome (Chapter 52), thrombosis or obstruction of the hepatic veins is responsible for obstruction to venous outflow from the liver.

The ascites seen in patients with peritoneal metastases is due to excessive exudation of fluid and lymphatic blockade. The fluid is dark yellow and frequently blood stained. The specific gravity, 1.020 or over, and the protein content (>25 g/litre) are high. Microscopical examination often reveals cancer cells especially if large quantities of fluid are ‘spun-down’ to produce a concentrated deposit for sampling.

Ascites occurs with low plasma albumin concentrations; for example in patients with albuminuria or starvation. The ascites in this instance is due to alterations in the osmotic pressure of the capillary blood, and has a low specific gravity.

Rarely ascites and pleural effusion are associated with solid fibroma of the ovary (Meigs’ syndrome). The effusions disappear when the tumour is excised.

Treatment

Ascites may be tapped (paracentesis abdominis) but unless other measures are taken, the fluid soon reaccumulates and repeated tappings remove valuable protein. Treatment of the specific cause is undertaken whenever possible, for example if portal venous pressure is raised, it may be possible to lower it by treatment of the primary condition (Chapter 52). Dietary sodium restriction to 200 mg per day may be helpful but diuretics are usually required.

Paracentesis abdominis

The bladder having been emptied by a catheter, under local anaesthesia puncture of the peritoneum is carried out with a moderate sized trocar and cannula at one of the points shown in Fig. 56.12. Alternatively a peritoneal drain may be inserted under ultrasound guidance to minimise the risk of visceral injury. In cases where the effusion is due to cardiac failure the fluid must be evacuated slowly. In other circumstances this precaution is unnecessary. If the cannula becomes blocked with fibrin it is cleared with a stylet or the drain is flushed. After the fluid has been evacuated the puncture is sealed and a tight hinder is applied to the abdomen. Some surgeons prefer to perform the ‘tap’ over the liver beneath the costal margin or in the midline beneath the xiphistemum.

Permanent drainage of ascitic fluid

In rare cases where ascites accumulates rapidly after paracentesis and the patient is otherwise fit, permanent drainage of the ascitic fluid via a peritoneovenous shunt (e.g. LeVeen) may render the patient more comfortable. Similar in concept to shunts for hydrocephalus (Chapter 35), a catheter (e.g. of silicone) is constructed with a valve so as to allow one-way flow from the peritoneum to a central vein (e.g. internal jugular). A chamber placed subcutaneously over the chest wall may be included for manual compression. Insertion is relatively simple. The complications include overloading the venous system, cardiac failure and disseminated intravascular coagulopathy. The frequency of these complications may be reduced by evacuating ascitic fluid and partially replacing it with normal saline at the time of shunt insertion. The procedure may also be used for patients with terminal malignant ascites giving improved quality of life, despite the risk of further dissemination of malignant cells.

Chylous ascites

In some patients the ascitic fluid appears milky due to an excess of chylomicrons (triglycerides). Most cases are associated with malignancy, usually lymphomas; other causes are cirrhosis, tuberculosis, filariasis, nephrotic syndrome, abdominal trauma (including surgery), constrictive pericarditis, sarcoidosis and congenital lymphatic abnormality. The condition is rare. The prognosis is poor unless the underlying condition can be cured. In addition to other measures used to treat ascites, patients should be placed on a fat-free diet with medium-chain triglyceride supplements.

Peritoneal loose bodies (peritoneal mice)

Peritoneal loose bodies almost never cause symptoms. One or more may be found in a hernial sac or in the pouch of Douglas. The loose body may come from an appendix epiploica that has undergone axial rotation followed by necrosis of its pedicle and detachment, but they are also
found in those who suffer from subacute attacks of pancreatitis. These hyaline bodies attain the size of a pea or bean, and contain saponified fat surrounded by fibrin.
Neoplasms of the peritoneum

Carcinoma peritonei is a common terminal event in many cases of carcinoma of the stomach, colon, ovary or other abdominal organs and also of the breast and bronchus. The peritoneum, both parietal and visceral, is studded with secondary growths, and the peritoneal cavity becomes filled with clear, straw-coloured or blood-stained ascitic fluid.

The main forms of peritoneal metastases are:

• discrete nodules —by far the most common variety;
• plaques varying in size and colour;
• diffuse adhesions —this form occurs at a late stage of the disease, and gives rise, sometimes, to a ‘frozen pelvis

Gravity probably determines the distribution of free malignant cells within the peritoneal cavity. Cells not caught in peritoneal folds along the attachments of mesenteries gravitate into the pelvic pouches or into a hernial sac, enlargement of which is occasionally the first indication of the condition. Implantation occurs also on the greater omentum, the appendices epiploicae and the inferior surface of the diaphragm. It is remarkable how often patients riddled with intraperitoneal carcinoma preserve their nutrition and look and feel comparatively well until the terminal stage.

Differential diagnosis

Early discrete tubercles common in tuberculous peritonitis are greyish and translucent and closely resemble the discrete nodules of peritoneal carcinomatosis, but the latter feel hard when rolled between the finger and thumb, making the differential diagnosis tolerably simple. Fat necrosis usually can be distinguished from a carcinomatous nodule by its opacity. Peritoneal hydatids can also simulate malignant disease after rupture of a hydatid cyst, with seeding of daughter cysts.

Treatment

Ascites due to carcinomatosis of the peritoneum may respond to systemic chemotherapy. In other cases intraperitoneal chemotherapy with cisplatin, mitomycin C or methotrexate after drainage of ascites may be effective.

Tamoxifen (an oestrogen receptor site competitor) can dramatically reduce ascites due to breast cancers which are oestrogen dependent.

Pseudomyxoma peritonei

This rare condition occurs more frequently in females. The abdomen is filled with a yellow jelly, large quantities of which are oftenmore or less encysted. The condition is associated with bothmucinous cystic tumours of the ovary andappendix. Recent studies suggest that most cases arise from a primary appendiceal tumour with secondary implantation on to one or both ovaries. It is often painless and there is frequently no impairment of general health for a long time. Although an abdomen distended with what seems to be fluid that cannot be made to shift should raise the possibility, the diagnosis is more often suggested by ultrasound and CT scanning or made at operation. At laparotomy masses of jelly are scooped out. The appendix, if present, should be excised together with any ovarian tumour. Unfortunately recurrence is usual. Pseudomyxoma peritonei is locally malignant but does not give rise to extraperitoneal metastases. Occasionally the condition responds to radioactive isotopes or intraperitoneal chemotherapy which may be used in recurrent cases.

Mesothelioma

As in the pleural cavity, this is a highly malignant tumour. Asbestos is a recognised cause. It has a predilection for the pelvic peritoneum, but it is not radiosensitive. Alkylating agents have given remissions. Benign forms are reported. Recent regimens of multiple chemocytotoxic agents have been reported as curative for early forms of malignant mesothelioma.

Desmoid

This is considered under familial adenomatous polyposis (Chapter 57).
Laparoscopy (peritoneoscopy)

Laparoscopic surgery has developed rapidly over recent years (Chapter 70). Previously used largely as a diagnostic procedure, laparoscopy with the aid of modern video technology is now used to perform many ‘minimally invasive operations (Table 56.8).

The primary trocar for laparoscopy is inserted using either the ‘open’ or ‘closed’ technique. In the latter method a ‘pneumopenitoneum’ is created by the insertion of a special needle (e.g. Verres’) through which carbon dioxide is delivered. Once the peritoneal cavity is adequately distended a sharp-ended trocar is inserted ‘blindly’ and the laparoscope then introduced. In the ‘open’ method, which is to be preferred, a small incision (usually subumbilical) is made through the abdominal wall down to the peritoneum which is opened under direct vision. This reduces the risk of visceral injury and eliminates the rare major vascular injuries (iliac, vena caval and aortic) that occur with the ‘closed’ method.

The greater omentum

Rutherford Morison called the greater omentum ‘the abdominal policeman’ [but it has not any feet, i.e. it does not move across the abdomen of its own volition, but passively due to peristalsis, and it may be pushed by the movements of the abdominal wall into an area of immobility (rigidity) where there is local peritoneal irritation]. Relatively larger and structurally more substantial in the adult than in the child, the discharge of its life-saving constabulary duties becomes more effective after puberty, and remains unabated throughout life. The greater omentum attempts, often successfully, to limit intraperitoneal infective and other noxious processes (Fig. 56.13). For instance, an acutely inflamed appendix is often found wrapped in omentum and this saves many patients from developing diffuse peritonitis. Some sufferers of herniae are also greatly indebted to this structure, for it often plugs the neck of a hernial sac and prevents a coil of intestine from entering and becoming strangulated.

Apart from a small portion of it becoming gangrenous while performing the last-mentioned duty (strangulated omentocele) this Good Samaritan of the peritoneal cavity seldom itself becomes diseased; when it does become overwhelmed, as in tuberculous peritonitis and carcinomatosis peritonei, it becomes rolled like a scroll.

Torsion of the omentum. Torsion of the omentum is a rare emergency and consequently is seldom diagnosed correctly. It is usually mistaken for appendicitis with somewhat abnormal signs. It may be primary or secondary to an adhesion of the omentum, to an old focus of infection, or to a hernia. Successive herniations of a portion of the omentum into a hernial sac of irregular bore are credited with giving the necessary stimulus to omental torsion.

The patient is most frequently a middle-aged, obese male. A tender lump may be present in the abdomen. The blood supply having been jeopardised, the twisted mass sometimes becomes gangrenous, in which case bacterial peritonitis soon follows.

Treatment. The abdomen having been opened, the pedicle above the twist is ligated securely and the mass removed.

Omental cyst (see below).
The mesentery

A wound of the mesentery can follow a severe abdominal contusion and is a cause of haemoperitoneum.

Seat-belt syndrome

If a car accident occurs when a seat belt is worn, sudden de-acceleration can result in a torn mesentery. This possibility should be borne in mind particularly as multiple injuries may distract attention from this injury. If there is any bruising of the abdominal wall, or even marks of clothing impressed into the skin, laparotomy may be indicated.

Diagnostic peritoneal lavage

Diagnostic peritoneal lavage may be helpful in this situation (Chapter 4). Under local anaesthetic a subumbilical incision is made down to the peritoneum in a similar way to that used for ‘open’ laparoscopy (see above). A purse-string suture is placed in the peritoneum which is then incised. Free fluid, e.g. blood or intestinal contents, may be found, but if not a peritoneal dialysis catheter is inserted and the purse-string suture tied. A litre of normal saline is run into the peritoneum and then drained off by placing the bag and tubing below the patient’s abdomen. The presence of blood (>100 000 red blood cells/mm³), bile or intestinal contents is an indication for laparotomy. In about 60 per cent of cases, the mesenteric laceration is associated with a rupture of the intestine. If the tear is a large one and especially if it is transverse (Fig. 56.14a), the blood supply to the neighbouring intestine is cut off and a limited resection of gut is imperative. Small wounds and wounds in the long axis (Fig. 56.14b) should be sutured. If extensive damage to the mesenteric arcade of vessels is associated with damage to contiguous intestine, exteriorisation of the damaged segment is preferable to excision and suture.

Torsion of the mesentery

See volvulus neonatorum, and volvulus of the small intestine, Chapter 58.

Embolism and thrombosis of mesenteric vessels

See Chapters 57 and 58.
Acute nonspecific ileocaecal mesenteric adenitis

Aetiology

Nonspecific mesenteric adenitis was so named to distinguish it from specific (tuberculous) mesenteric adenitis. It is now very much more common than the tuberculous variety. Despite much investigation the aetiology often remains unknown although some cases are associated with Yersinia infection of the ileum. In other cases an unidentified virus is blamed. In about 25 per cent of cases a respiratory infection precedes an attack of nonspecific mesenteric adenitis. This self-limiting disease is never fatal but may be recurrent.

Pathology

There is a small increase in the amount of peritoneal fluid. The ileocaecal mesenteric lymph nodes are enlarged and can be seen and felt between the leaves of the mesentery. In very acute cases they are distinctly red and many of them are the size of a walnut. The nodes nearest the attachment of the mesentery are the largest. They are not adherent to their peritoneal coats and if a small incision is made through the overlying peritoneum, a node is extruded easily.

Clinical features

During childhood, acute nonspecific mesenteric adenitis is a common condition. It is unusual after puberty but is some-times seen in teenage girls. The typical history is one of short attacks of central abdominal pain lasting from 10 to 30 min-utes, and associated with circumscribed pallor. They tend to come on when the patient is tired. Vomiting is common but there is no alteration of bowel habit. If vomiting is absent, it is more likely to be a case of mesenteric adenitis than appendicitis.

On examination

There are spasms of general abdominal colic, usually referred to the umbilicus, with intervals of complete freedom, which never appertains in obstructive appendicitis. The patient seldom looks ill. In more than half of the cases the temperature is elevated; in severe examples it exceeds 38.3°C. Abdominal tenderness is greatest along the line of the mesentery. When present, shifting tenderness is a valuable sign for differentiating the condition from appendicitis. After laying the patient on the left side for a few minutes, the maximum tenderness moves to the left of the original site.

The pelvic peritoneum is tender to rectal palpation in 30 per cent of cases. The neck, axillae and groins should be palpated for enlarged lymph nodes — if these nodes are enlarged, brucellosis should come to mind.

Leucocyte count

There is often a leucocytosis of 10000—12000/mm³ (10—12 x 10⁹/litre) or more on the first day of the attack, but this falls on the second day.

Treatment

When the diagnosis can be made with assurance, bed rest for a few days is the only treatment necessary. If at a second examination, an hour or two after confinement to bed, acute appendicitis cannot be excluded, it is safer to perform either appendicectomy or diagnostic laparoscopy.

Tuberculosis of the mesenteric lymph nodes

Tuberculous mesenteric lymphadenitis is considerably less common than acute nonspecific lymphadenitis. Tubercle bacilli, usually, but not necessarily, bovine, are ingested and enter the mesenteric lymph nodes by way of Peyer’s patches. It is possible for one draught of raw milk to start the infection; it is equally possible that a toddler can become infected with human tubercle bacilli by placing one dust-covered small object in its mouth. Sometimes only one lymph node is infected; usually there are several; occasionally massive involvement occurs.

Presentation. Demonstrated radiologically. The shadows cast by one or more calcified tuberculous lymph nodes are seen in a plain radiograph of the abdomen. They must be distinguished from other calcified lesions, e.g. renal or ureteric stones. Their mobility on repeated plain abdominal radiographs can clinch the diagnosis but orography can be employed in doubtful cases. Often the shadow cast by such a lymph node or nodes is situated in the ileocaecal region, but nearly as many are displayed along the line of attachment of the mesentery. Usually, the radiological char-acteristics are unmistakable. Each node is round or oval, not homo-geneous, but mottled, and its outline is not regular, but bosselated like a blackberry. Calcification of these lymph nodes occurs at the earliest in 18 months. It is often assumed, wrongly, that because a tuberculous lymph node is calcified, the infection is necessarily defunct. Especially in children, this assumption may not be valid.

As a cause of general symptoms. The patient, usually a child under 10 years of age, loses appetite, looks pale and there is some loss of weight; sometimes evening pyrexia occurs. In children with these symptoms, especially those who live in the country, if the Mantoux test is negative, brucellosis, the ‘disease of mistakes’ should be thought of and serological studies undertaken.

As a cause of abdominal pain. Sometimes abdominal pain is the cause of the patient being brought for advice; usually this pain is central, not severe but rather a discomfort and is often constant. On examination the abdomen is somewhat protuberant and there is tenderness on deep pressure to the right of the umbilicus. In these circumstances, the condition resembles acute nonspecific mesenteric lymphadenitis. On deep palpation inflamed mesenteric lymph nodes are sometimes palpable as firm, discrete, tender, bean-like objects most frequently to the right of and near the umbilicus. A normal leucocyte count favours tuberculosis and, in a child, a positive Mantoux test is confirmatory evidence of tuberculosis.

Symptoms indistinguishable from those of appendicitis. On occasions the abdominal pain is acute and may be accompanied by vomiting. This, combined with tenderness and some rigidity in the right iliac fossa, makes the diagnosis from appendicitis almost impossible. When, as is sometimes the case, the tuberculosis infection of the mesenteric lymph nodes becomes reactivated in adolescent or adult life, the diagnostic difficulties are even greater. A radiograph may show calcified lymph nodes, but as such a condition can coexist with appendicitis, in some cases laparoscopy or laparotomy is necessary. If the mesentery is found to be in an inflamed state with caseation of some of the lymph nodes, the diagnosis of active tuberculosis is confirmed.

As a cause of intestinal obstruction. Remote, rather than recent, tuberculous mesenteric adenitis can be the cause of intestinal obstruction. For instance, a coil of small intestine becomes adherent to a caseating node, and is thereby angulated, or a free coil may become imprisoned in the tunnel beneath the site of adherence and the mesentery.
As a cause of pseudomesenteric cyst. When tuberculous mesenteric lymph nodes break down, the tuberculous pus may remain confined between the leaves of the mesentery, and a cystic swelling having the characteristics of a mesenteric cyst is found. When such a condition is confirmed at operation, the tuberculous pus should be aspirated without soiling the peritoneal cavity, the wound closed, the sensitivity of the organism should be sought and medical treatment continued until the infection has been overcome.

As ileocaecal nodes. At laparotomy hard, enlarged lymph nodes may be found limited to the ileocaecal mesentery as a result of previous tuberculous infection. If the nodes have a yellow colour, they may well arise from a carcinoid tumour of the appendix or ileum (Chapter 57).

Treatment. Therapy is similar to that of other tuberculous infections (Chapter 8). Most cases subside but from time to time a local abscess forms, usually in the right iliac fossa when the tuberculous pus should be evacuated and the abdomen closed without drainage.

Mesenteric cysts

Mesenteric cysts are classified as:

• chylolymphatic;
• enterogenous;
• urogenital remnant;
• dermoid (teratomatous cyst).

Chylolymphatic cyst, the commonest variety of mesenteric cyst, probably arises in congenitally misplaced lymphatic tissue that has no efferent communication with the lymphatic system; it arises most frequently in the mesentery of the ileum. The thin wall of the cyst, which is composed of connective tissue lined by flat endothelium, is filled with clear lymph or, less frequently, with chyle varying in consistency from watered milk to cream. Occasionally the cyst attains a great size. More often unicellular than multilocular, a chylolymphatic cyst is almost invariably solitary, although there is an extremely rare variety in which myriads of cysts are found in the various mesenteries of the abdomen. A chylolymphatic cyst has a blood supply independent of that of the adjacent intestine, thereby enucleation is possible without the necessity of resection of gut.

Enterogenous cyst is believed to be derived either from a diverticulum of the mesenteric border of the intestine, which has become sequestrated from the intestinal canal during embryonic life, or from a duplication of the intestine. An enterogenous cyst has a thicker wall than a chylolymphatic cyst, and its lined by mucous membrane, sometimes ciliated. The content is mucinous, and is either colourless or yellowish-brown from bygone haemorrhage into the cyst. As can be seen at operation, the muscle in the wall of an enterogenous cyst and the bowel with which it is in contact have a common blood supply; consequently removal of the cyst always entails resection of the related portion of intestine.

Clinical features of a mesenteric cyst. A mesenteric cyst is encountered most frequently in the second decade of life, less often between the ages of 1 and 10 years and, exceptionally, in infants under 1 year.

The patient presents on account of:

• a painless abdominal swelling. A cyst of the mesentery presents
characteristic physical signs:
— there is a fluctuant swelling near the umbilicus (Fig. 56.15a),
— the swelling moves freely in a plane at right angles to the attachment of the mesentery (Fig. 56.15b),
— there is a zone of resonance around and, classically, a belt of resonance across the cyst;
• recurrent attacks of abdominal pain with or without vomiting. The pain results from recurring temporary impaction of a food bolus in a segment of bowel narrowed by the cyst, or possibly from torsion of the mesentery;
• an acute abdominal catastrophe arises as a result of:
— torsion of that portion of the mesentery containing the cyst,
— rupture of the cyst, often due to a comparatively trivial accident,
— haemorrhage into the cyst,
— infection.

Radiography. In most instances, the patient should be submitted to a barium meal and follow through. The hollow viscera will be found to be displaced around the cyst and not infrequently some portion of the lumen of the small intestine will be narrowed. In order to exclude or confirm the diagnosis of a hydronephrosis, an ultrasound examination or a urogram should be performed. In cases of painless enlargement of the abdomen, an ultrasound scan should be undertaken first. Needle aspiration combined with instillation of radio opaque water-soluble contrast media can transform doubt into certainty.

Treatment. As has been indicated already, many chylolymphatic cysts can be enucleated in toto.

When, after aspiration of about half the contents of the cyst, the major portion of the cyst has been dissected free, but one portion abutting on the intestine or a major blood vessel seems too dangerous to remove, this portion can be left attached and its lining destroyed by careful diathermy.

In the case of an enterogenous cyst, enucleation must not be attempted. If a comparatively short segment of the intestine is involved, resection of the cyst with the adherent portion of the intestine, followed by intestinal anastomosis, is the correct course. Should a very large segment of small intestine be implicated, an anastomosis should be made between the apex of the coil of small intestine and the cyst wall.
which, in this instance, holds sutures well.

The older treatment of marsupialisation of a mesenteric cyst has little to recommend it; a fistula or recurrence results. Occasionally, however, on account of its simplicity it is advisable in a poor-risk subject in whom surgery is necessary.

**Omental cysts**

Omental cysts occur nearly as frequently as mesenteric cysts. Preoperative differentiation is possible because a lateral radiograph, ultrasound or CT scan shows the cyst in front of the intestines. Treatment is omentectomy.

**Cyst of the mesocolon**

Cyst of the mesocolon is uncommon and is differentiated from a mesenteric cyst only at operation. The treatment is similar.

**Cysts arising from a urogenital remnant**

Cysts arising from a urogenital (Wolffian or Mullerian) remnant are essentially retroperitoneal, but they are included in the classification because it is not impossible for such a cyst to project forward into the mesentery.

The following, while not being mesenteric cysts in the true meaning of the term, give rise to the same physical signs and, in practice, they are mesenteric cysts:

- *serosanguineous cyst* is probably traumatic in origin, but a history of an accident is seldom obtained;
- *tuberculous abscess of the mesentery*;
- *hydatid cyst of the mesentery*.
Neoplasms of the mesentery

Mesenteric tumours are classified as:
• benign:
  — lipoma,
  — fibroma,
  — fibromyxoma;
• malignant:
  — lymphoma,
  — secondary carcinoma.

Tumours situated in the mesentery give rise to physical signs similar to those of a mesenteric cyst, the sole exception being that they sometimes feel solid.

A benign tumour of the mesentery is excised in the same way as an enterogenous mesenteric cyst, i.e. with resection of the adjacent intestine. When possible, a malignant tumour of the mesentery is subjected to the same treatment. In inoperable cases, radiotherapy can be employed if the biopsy specimen reveals that the growth is radiosensitive.
The retroperitoneal space

Pus or blood in the retroperitoneal space tends to track to the corresponding iliac fossa. If a retroperitoneal abscess develops, it should be evacuated by the nearest route through the abdominal wall, avoiding opening the peritoneum. Should the retroperitoneal collection be found at laparotomy, it must be drained by a counter-incision in the flank. Pus frequently develops from a renal or spinal source and is sometimes tuberculous (‘cold abscess’): tracking can develop alongside the psoas muscle and appear in the groin, where it must be distinguished from other swellings (e.g. hernia, Chapter 62). Retroperitoneal haematoma may be caused by fractured spine, a leaking abdominal aneurysm, acute pancreatitis or a ruptured kidney.

Retroperitoneal cyst

A cyst developing in the retroperitoneal space often attains very large dimensions, and has at first to be distinguished from a hydronephrosis. Even after the latter condition has been eliminated by scanning or orography, a retroperitoneal cyst can seldom be diagnosed with certainty from a retroperitoneal tumour until displayed at operation. The cyst may be unilocular or multilocular. Many of these cysts are believed to be derived from a remnant of the Wolffian duct, in which case they are filled with clear fluid. Others are teratomatous and are filled with sebaceous material.

Excision of these and other retroperitoneal swellings is best performed through a transperitoneal incision.

Idiopathic retroperitoneal fibrosis

This is one of a group of fibromatoses (others being Dupuytren’s contracture and Peyronies disease). Most cases are idiopathic, but many causes are known (Table 56.9). Familial cases are known, involving mediastinal fibrosis, sclerosing cholangitis, Riedel’s thyroiditis and orbital pseudotumour. An autoimmune link has not been demonstrated. Extensive collagen deposition surrounds the ureters, mostly at the level of the pelvic brim or below. Most patients present with ureteric obstruction, often with renal failure (Chapter 64): cases due to malignancy are treated appropriately according to the cause, but the prognosis is often poor.

Primary retroperitoneal neoplasms arising from connective tissues

Retroperitoneal lipoma, in the first instance, is usually mistaken for a hydronephrosis, a diagnosis which is ruled out by ultrasonography, CT scan or orography. Women are more often affected. These swellings sometimes reach an immense size. A retroperitoneal lipoma sometimes undergoes myxomatous degeneration, a complication which does not occur in a lipoma in any other part of the body. Moreover, a retroperitoneal lipoma is often malignant (liposarcoma) (Fig. 56.16) and may increase rapidly in size.

Retroperitoneal sarcoma presents signs similar to a retroperitoneal lipoma. The patient may seek advice on account of a swelling or because of indefinite abdominal pain. On other occasions the tumour, by pressure on the colon, causes symptoms of subacute intestinal obstruction. On examination a smooth fixed mass, which is not tender, is palpated. The most probable original diagnosis is that of a neoplasm of the kidney. This is ruled out by scanning or orography. The ureter, however, is liable to become displaced by the tumour. Exploratory laparotomy should be performed and when possible the tumour is removed. Often it is found widely disseminated in the retroperitoneal space, rendering complete removal impossible, in which case a portion is excised for microscopy. Even when excised at a comparatively early stage, recurrence always takes place, and these tumours must be looked upon as being necessarily fatal. Radiotherapy sometimes keeps recurrences in abeyance for a time.

Removal of a retroperitoneal cyst or neoplasm. After the anterior abdominal wall has been opened and the diagnosis of a retroperitoneal tumour has been confirmed, the incision is extended as necessary. The small intestine is packed away in the upper abdomen or exteriorised and the caecum and the sigmoid colon are relegated to their respective fossae. The posterior peritoneum is then incised throughout its length over the area to be exposed, the incision being parallel to the left border of the aorta. The peritoneum is dissected from the tumour which is removed as completely as possible.
Retroperitoneal tumours arising from specific organs

These may arise from:

• lymph nodes (Chapter 17);
• adrenal gland (Chapter 45);
• kidney and ureter (Chapter 64);
• nervous tissue (Chapter 34).

Abdominal pain

Abdominal pain arising from the alimentary canal is of two types.

1. **Visceral pain.** The alimentary tract is primarily a midline structure with a bilateral nerve supply. Although rotation about the midline occurs during development, nevertheless true visceral pain is referred to the midline as shown in Fig. 57.1. It is dull and poorly localised. For example, an obstructing stenosis of the terminal ileum, which is part of the midgut, would give rise to colicky periumbilical pain.

2. **Peritoneal pain** is of the somatic type and is much more precise, more severe and localised to the site of origin. These components account for the changes in character and site of pain which occur in appendicitis. Once the full thickness of the appendicular wall becomes inflamed the overlying peritoneum becomes involved and the patient has localised right iliac fossa pain (see Chapter 59).

Surgical anatomy

It is of great practical importance to be able to do the following:

1. distinguish various portions of the intestinal tract at sight;

2. know in which part of the abdomen the upper coils, as opposed to the lower coils, of small intestine lie in relationship to the anterior abdominal wall;

3. be able to decide which is the proximal and which is the distal end of any coil under consideration;

4. distinguish irrefutably large from small intestine.

The following are useful tips.

- The mesentery of the jejunum has only two series of arcades of blood vessels, whereas the lower ileum has several series of arcades.

- The mesenteric attachment runs from left to right. Provided that the gut is not twisted, the proximal small bowel lies in the upper part of the abdomen and the lower small bowel lies in the lower part of the abdomen.

- The large intestine can be characterised by its taenia coli and appendices epiploicae.
Malformations and functional abnormalities

Congenital malformations

These malformations are described in the following:
• congenital atresia of the duodenum (see Chapter 58);
• congenital atresia of the small intestine (see Chapter 58);
• volvulus neonatorum (see Chapter 58);
• vascular anomalies (angiodysplasia) (see below);
• malrotation of the colon with failure of descent of the caecum which remains under the right lobe of the liver. This is clearly very important should the patient develop appendicitis (see Chapter 59).
Megacolon and nonmegacolon constipation

There is no single definition of constipation that can be described according to the character of the stools, the frequency of evacuation and the ease of evacuation. Generally speaking a bowel frequency of less than one every 3 days would be considered abnormal. This group of conditions can be divided into:

1. megacolon:
   (a) Hirschsprung’s disease,
   (b) non-Hirschsprung’s megarectum and megacolon;
2. nonmegacolon:
   (a) slow transit,
   (b) normal transit.

Hirschsprung’s disease

Pathology

The major feature of Hirschsprung’s disease is an absence of ganglion cells in the neural plexus of the intestinal wall, together with hyper-trophy of the nerve trunks. This is believed to result from a failure of migration of neuroblasts into the gut from vagal nerve trunks at the end of the first trimester of foetal life.

The loss of ganglion cells extends for a variable distance above the anorectal junction. In about two-thirds of patients the rectum and lower sigmoid colon are involved, but involvement of extremely short segments of the lower rectum or the whole intestinal tract have been described.

The severity of symptoms is not always consistent with the length of the intestinal segment involved and may be related to the number of acetylcholinesterase-positive nerve fibres.

The absence of ganglion cells gives rise to a contracted nonperistaltic segment with a dilated hypertrophied segment of normal colon above it (Fig. 57.2).

Clinical features

Hirschsprung’s disease occurs in approximately one in 4500 live births. It shows a familial tendency and is more common in males than in females. The clinical picture varies from acute intestinal obstruction in neonates to chronic constipation in later life.

1. In neonates the delayed passage of meconium together with mild abdominal distension should alert the paediatrician to the diagnosis of Hirschsprung’s disease. It is often complicated by enterocolitis which may result in perforation and septicaemia, and there is still a high mortality from Hirschsprung’s disease at this age.

2. Chronic constipation starting in the first few weeks of life. The classic picture of gross abdominal distension, chronic constipation and failure to thrive should be rare with a greater awareness of the diagnosis.

3. Severe constipation without soiling in otherwise healthy children and adults can be caused by a short segment of Hirschsprung’s disease. Faecal soiling is not usually a feature of the condition.

Diagnosis

Rectal biopsy. Confirmation of the diagnosis depends on histological demonstration of aganglionosis and hypertrophic nerve fibres in the nerve plexus. The pathologist has to be able to see a representative area of at least one nerve plexus in the biopsy. In children this can be obtained by a suction rectal biopsy or, in adults, by a formal strip, full-thickness, rectal biopsy. Specimens are usually taken from just above the anorectal junction. One is sent for biochemistry and one for histochemistry and histopathology (Fig. 57.3).

Anorectal manometry. This is a useful screening test in the constipated young child or adult who is otherwise fit. The rectosphincteric inhibitory reflex is absent. It should not be carried out in ill neonates because of poor anal tone.

Radiology. Erect and supine abdominal radiographs are useful. If the large intestine is obstructed, they will show distended loops of small and large intestine with fluid levels consistent with a low intestinal obstruction. Intramural gas will indicate enterocolitis, and free peritoneal gas, a perforation.

An enema using a water-soluble contrast medium will often confirm the diagnosis and indicate the length and site of involved intestine. A rectal examination should not be performed before radiology because it may dilate the abnormal segment and modify the radiological features. The contrast is instilled through a fine 5 Fr catheter under screening control with the patient in the lateral position. The coning down of the transition zone, irregularity in the mucosa and abnormal contractions of the intestine are important positive findings.

Treatment

This depends on the age of the patient, the length of the involved segment, the severity of symptoms and the presence of enterocolitis.

In the neonate presenting with obstruction or any child or adult presenting with enterocolitis, an initial colostomy is performed. The site of the colostomy should be as low as possible in the ganglionated segment. A peroperative frozen section biopsy is taken to establish the presence of ganglia. This is important as the transition zone may be difficult to locate precisely.

In the child or adult with constipation alone, the dilated intestine can be evacuated with repeat rectal saline washouts and enemas as a first step. The choice of surgical procedure to follow will depend on the length of the involved segment.

Short segment disease with minimal symptoms may respond to an extended myectomy removing a strip of rectal wall up to the area where normal ganglion cells start.

Long segment disease may be helped by one of the four operations shown below. The definitive operation is preceded by a temporary
colostomy for a few months which allows the proximal distended colon to return to its normal calibre. If a neonate requires a colostomy the
definitive operation is delayed until the child weighs approximately 10 kg when the pelvis is still shallow but wide enough to give good access.
The child will be between 10 months and 1 year of age and toilet training can usually start soon after the operation.

In some older children it may be possible to clear the retained faeces with enemas and laxatives; if so it may be possible to perform a
one-stage operation.

**Duhamel operation**

The aganglionic segment is removed down to the level of the peritoneal reflection over the rectum. The rectum is divided and dosed. The
sacral hollow is opened and the normal colon brought down to the posterior aspect of the rectal stump. With an anal retractor in place a
transverse incision is made from the level in the posterior wall just above the anal sphincter. The normal colon is then grasped and sewn to the
transverse incision in the rectum. The spur between the rectum and normal colon is then divided with a stapler.

**Swenson’s procedure**

The rectum is mobilised from above taking care to dissect immediately outside the fascia propria, preserving autonomic nerves to the bladder
and seminal vesicles. The intestine is transected proximally through normal colon, the presence of ganglion cells having first been checked for
by frozen section biopsy. The mobilised aganglionic segment is then everted out through the anus, the everted rectal mucosa is cleaned, and the
anterior half of the junction between the top of the anal canal and the rectum is opened transversely. The proximal normal colon is then
pulled through this opening and an end-to-end anastomosis made between the colon and anal canal as the aganglionic segment is excised.
Once the anastomosis is complete it is reduced back into the anal canal.

**Colo-rectal anastomosis**

This is usually reserved for older children, teenagers and adults. The rectum is mobilised as before and transected just above the level of the
pelvic floor. The normal colon is then joined to the top of the anal canal either directly with a stapling technique or by a sleeve technique
following a mucosectomy of the upper anal canal and rectum, a procedure described by both Soave and Parks.

**Restorative proctocolectomy**

In cases of Hirichsprung’s disease involving the entire colon, it is possible to reconstruct with an ileoanal pouch procedure (see Chapter 60).

**Idiopathic megarectum and megacolon**

This is a rare condition and the cause is not known although in some it may result from poor toilet training during infancy and in others by a
congenital abnormality of the intestinal myenteric plexus.

**Investigation**

**On clinical examination** there may be a hard faecal mass arising out of the pelvis, and on rectal examination there is a large faecaloma in the
lumen. The anus is usually patulous, perianal soiling is common, and sigmoidoscopy is usually impossible but may show melanosis coli if the
patient has been taking laxatives over many years.

**Radiology.** As there is an enlarged rectum often with distention of the colon over a variable length, a radiograph should be taken without
prior bowel preparation using a small quantity of water-soluble contrast to prevent barium impaction. There is usually gross faecal loading of
the enlarged rectum and colon and, when a contrast examination is carried out, the width of the colon measured at the pelvic brim is usually
more than 6.5 cm (Fig. 57.4).

**Anorectal physiology tests** show abnormally large volumes inflated in the rectum to induce a feeling of rectal fullness, and inhibition of the
internal and external anal sphincters is present but at much larger volumes than normal. Full-thickness rectal biopsy shows normal ganglion
cells which distinguishes this condition from Hirschsprung’s disease.

**Medical treatment**

This is directed at emptying the rectum and keeping it empty with enemas, washouts and sometimes manual evacuation under anaesthesia.
Thereafter the patient is encouraged to develop a regular daily bowel habit with the use of laxatives and repeated enemas as necessary.

**Surgical treatment**

Surgical treatment is necessary sometimes if medical therapy fails. Resection of the dilated rectum and colon (Fig. 57.5) back to normal
diameter colon with normal ganglion cells confirmed by frozen section at the time of surgery is followed by reconstruction with a colo-rectal
anastomosis.

**Nonmegacolon constipation**

Although constipation is often regarded as a trivial symptom some patients are greatly disabled by abdominal pain, distension, reliance on
laxatives and difficulty with defecation. These are usually otherwise healthy individuals who seek help for constipation but eat a normal diet and
have a normal colon on endoscopy and barium enema.

**Investigation**

Whole gut transit time can be measured by asking the patient to stop all laxatives and take a capsule containing radio opaque markers (Fig.
57.6). Retention of more than 80 per cent of the shapes, 120 hours after ingestion, is abnormal.

Defecating proctography may be helpful if the main complaint is difficulty in passing stools.

**Idiopathic slow transit constipation**

This disorder is usually seen in women and results from infrequent bowel actions which may have been present since childhood or may
suddenly follow abdominal or pelvic sur-gery. They have delayed transit using marker studies and may or may not be able to empty the rectum
normally (Fig. 57.6).

This is a difficult condition to treat medically; dietary measures are usually unsuccessful and surgical treatment is only justified after careful studies and when medical treatment has been exhausted. Total colectomy and ileorectal anastomosis is the preferred procedure but the results are unpredictable. One-third of patients continues to have diarrhoea or constipation and two-thirds persisting abdominal pain. It is essential to exclude underlying psychiatric or psychological problems.

**Obstructed defecation**

Some patients complain of extreme difficulty in expelling stool. They may have repeated attempts at rectal evacuation and their transit is often normal. The common feature in these patients is weakness of the pelvic floor which descends on straining. Patients may resort to digital evacuation or pressure on the perineum or within the vagina to assist defecation. The cause is not known. It may arise from damage to pelvic nerves caused by prolonged straining at stool or childbirth.

Defecation proctography will show abnormal evacuation. There may be an intussusception with the upper rectum folding in to the lower rectum or an anterior rectocele where the rectum bulges forward into the posterior wall of the vagina (Fig. 57.7).

Biofeedback training may be helpful in some patients; dietary therapy and laxatives are usually unsuccessful. Surgery is a last resort, and either a defunctioning ileostomy or a colostomy with colostomy irrigation is used in intractable cases.
Vascular anomalies (angiodysplasia)

Capillary or cavernous haemangiomas are a cause of haemorrhage from the colon at any age presenting with colonic bleeding. In the middle-aged or elderly patient it needs to be distinguished from other causes of sudden massive haemorrhage, such as diverticulitis, ulcerative colitis or ischaemic colitis.

Angiodysplasia is a vascular malformation associated with ageing. It has been recognised since the introduction of intestinal angiography and colonoscopy. Angiodysplasias occur particularly in the ascending colon and caecum of elderly patients over the age of 60 years and are not associated with cutaneous lesions. The malformations consist of dilated tortuous submucosal veins and in severe cases the mucosa is replaced by massive dilated deformed vessels. On histological investigation, they are made up of dilated, distorted, thin-walled vessels with only a scanty amount of muscle in their walls.

Inspection of the mucosa is often unremarkable. The lesions are only a few millimetres in size and appear as reddish raised areas at endoscopy. Bleeding is usually chronic and intermittent and can be severe. Many patients previously thought to have bled from diverticular disease have probably been bleeding from angiodysplasia in the caecum. There is an association with aortic stenosis.

Barium enema is usually unhelpful and should be avoided. Provided the bleeding is not too brisk colonoscopy may show the characteristic lesion in the caecum or ascending colon. Selective superior and inferior mesenteric angiography shows the site and extent of the lesion by a blush. If this fails a radioactive test using technetium-99m (\(^{99}\text{Tc}\)) labelled red cells may confirm and localise the source of haemorrhage.

Some angiodysplastic lesions can be treated by colonoscopic diathermy, but if bleeding is brisk and the patient seriously ill emergency surgery will be necessary. Here a catheter is placed in the appendix stump and the colon irrigated progradely with saline or water. On-table colonoscopy is carried out and the site of the bleeding can then be confirmed. Angiodysplastic lesions are sometimes demonstrated by transillumination through the caecum (Fig. 57.8). If it is still not clear exactly which segment of colon is involved then a total abdominal colectomy with ileorectal anastomosis may be necessary.

Blind loop syndrome

It has been shown in dogs that, if a blind loop of the small intestine is made (Fig. 57.9), defects of absorption will appear. If this occurs in the upper intestine the defect is chiefly of fat absorption; if in the lower intestine there is vitamin B\(_12\) deficiency. This has been found to occur in humans and is referred to as the blind loop syndrome.

Essentially, the stasis produces an abnormal bacterial flora, which prevents proper breakdown of the food (especially fat) and mops up the vitamins that are present. Sometimes the only manifestation is anaemia, resulting from vitamin B\(_12\) deficiency, but if steatorrhoea appears, other serious malabsorption features follow. In general, high loops produce steatorrhoea, whereas low loops tend to produce anaemia.

Temporary improvement will follow the use of antibiotics to destroy the bacteria causing the trouble, but the main treatment is surgical extirpation of the cause of the stasis where applicable.
Diverticular disease

One meaning of diverticulum is a wayside house of ill-fame; certainly these ‘wayside houses’ live up to their evil reputation. Diverticula can occur from the stomach to the recto sigmoid. There are two varieties:

1. *Congenital*. All three coats of the bowel are present in the wall of the diverticulum, e.g. Meckel’s.

2. *Acquired*. The wall of the diverticulum lacks a proper muscular coat. Most alimentary diverticula are thought to be acquired.

Small intestine

Most of these diverticula arise from the mesenteric side of the bowel probably as the result of mucosal herniation through the point of entry of blood vessels.

**Duodenal diverticulum**

There are two types:

1. *Primary*. Mostly in older patients on the inner wall of the second and third parts, these diverticula are found incidentally on barium meal and usually do not cause symptoms. They can cause problems locating the ampulla during endoscopic retrograde cholangiopancreatography (ERCP) (Fig. 57.10).

2. *Secondary*. Diverticula of the duodenal cap resulting from long-standing duodenal ulceration (Fig. 57.11).

**Jejunal diverticula**

These are usually of variable size and multiple (Fig. 57.12). Clinically they may (1) be symptomless, (2) give rise to abdominal pain, flatulence and borborygmi, (3) produce a malabsorption syndrome, or (4) present as an acute abdomen with acute inflammation and occasionally rupture. They are more common in patients with connective tissue disorders. In patients with major malabsorption problems giving rise to anaemia, steatorrhoea, hypoproteinaemia or vitamin B₁₂ deficiency; resection of the affected segment with end-to-end anastomosis can be effective.

**Meckel’s diverticulum**

Meckel’s diverticulum is present in 2 per cent of the population; it is situated on the antimesenteric border of the small intestine, commonly 60 cm from the ileocaecal valve, and is usually 3—5cm long. Many variations occur (2 per cent — 2 feet — 2 inches is a useful aidenidmoirs) (Figs 57.13 and 57.14).

A Meckel’s diverticulum possesses all three coats of the intestinal wall and has its own blood supply. It is therefore vulnerable to infection and obstruction in the same way as the appendix. In 20 per cent of cases the mucosa contains heterotopic epithelium, namely, gastric, colonic or sometimes pancreatic tissue. When present, the abnormal mucosa lines the greater part of the proximal end of the pouch and extends sometimes for a short distance into the nearby ileum.

Although Meckel’s diverticulum occurs with equal frequency in both sexes, symptoms usually resulting from the epithelium contained in the diverticulum predominantly occur in males. In order of frequency,

these symptoms are as follows.

1. **Severe haemorrhage**, caused by peptic ulceration. The blood is passed per rectum, and is maroon in colour. Although the patient may vomit, the vomit does not contain blood. There is rarely any pain and sometimes the bleeding precedes perforation. An operation is required for serious progressive gastrointestinal bleeding. When no lesion in the stomach or duodenum can be found the terminal 150 cm of ileum should be carefully inspected.

2. **Intussusception**. In most cases, the apex of the intussusception is the swollen, inflamed, heterotopic epithelium at the mouth of the diverticulum.

3. **Meckel’s diverticulitis**, with or without perforation, may result from obstruction by food residue. The symptoms are those of acute appendicitis and, unless the appendix has already been removed, the diagnosis is impossible before operation. When a diverticulum perforates the symptoms may simulate those of a perforated duodenal ulcer. Whether or not the diverticulum is perforated urgent surgery is required. In nonperforated cases an inflamed diverticulum should be sought as soon as it has been demonstrated that the appendix and Fallopian tubes are not at fault.

4. **Chronic peptic ulceration**. As the diverticulum is part of the midgut, the pain, although related to meals, is felt around the umbilicus.

5. **Intestinal obstruction**. The presence of a hand between the apex of the diverticulum and the umbilicus may cause obstruction either by the band itself or by a volvulus around it.

**Radiology**

Meckel’s diverticulum can be very difficult to demonstrate by contrast radiology; small bowel enema would be the most accurate investigation. Technetium-99m scanning

In cases of repeated gastrointestinal haemorrhage of unknown cause where a Meckel’s diverticulum is suspected the abdomen is imaged with gamma camera after the injection of 30—100 mic Ci (111—370 x 10¹⁰ Bq) of ⁹⁹ᵐTc-labelled pertechnetate intravenously. This may localise heterotopic gastric mucosa revealing the site of a Meckel’s diverticulum in 90 per cent of cases.

‘Silent’ Meckel’s diverticulum

An aphorism attributed to Dr Charles Mayo is: ‘a Meckel’s diverticulum is frequently suspected, often sought for and seldom found’. A Meckel’s diverticulum usually remains symptomless throughout life and is found only at necropsy. When a silent Meckel’s diverticulum is encountered in the course of an abdominal operation, provided it is wide-mouthed and the wall of the diverticulum does not feel thickened, it can be left. Where
there is doubt and it can be removed without appreciable additional risk it should he resected.

Exceptionally a Meckel’s diverticulum is found in an inguinal or a femoral hernia sac — Littre’s hernia.

**Meckel’s diverticulectomy**

A Meckel’s diverticulum which is broad based should not he amputated at its base and invaginated in the same way as a vermiform appendix, because of the risk of stricture. Furthermore this does not remove heterotopic epithelium where it is present. The steps of diverticulectomy are shown in Fig. 57.15. Alternatively, a linear stapler device maybe used. Where there is induration of the base of the diverticulum extending into the adjacent ileum, it is advisable to resect a short segment of ileum containing the diverticulum, restoring continuity with an end-to-end anastomosis.

**Colon**

Diverticula of the colon are acquired herniations of colonic mucosa, protruding through the circular muscle at the points where the blood vessels penetrate the colonic wall. They tend to occur in rows between the strips of longitudinal muscle, sometimes partly covered by appendices epiploicae. The condition is most commonly found in the sigmoid colon but the caecum can also be involved and on occasion the entire large bowel can be affected. The rectum with its complete muscle layers is not affected. In 90 per cent of cases the sigmoid colon is involved and is almost always the site of inflammation, i.e. diverticulitis. Some 5 per cent of patients have associated gallstones and hiatus hernia (Saint’s triad).

Diverticular disease is rare in Africans and Asians who eat a diet that contains natural fibre. In Western countries, where the roughage has been removed from flour and refined sugar forms a large part of the diet, diverticula are found in 25 per cent of barium enemas of patients over the age of 40 and the incidence increases with age.

**Diverticulosis**

It is important to distinguish between diverticulosis and the presence of diverticula which may be asymptomatic, and clinical diverticulosis where the diverticula are causing symptoms. Diverticula probably arise as a result of muscular incoordination and spasm, resulting in increased segmentation and intraluminal pressures. Excessive segmentation in response to food, prostigmine and morphine is found in colonic motility studies, and this exaggerated response is more apparent in symptomatic than in asymptomatic individuals. On histological investigation the diverticulum consists of a protrusion of mucosal membranes covered with peritoneum. There is thickening of the circular muscle fibres of the taeniae and the intestine develops a concertina or saw-tooth appearance on barium enema (Fig. 57.16). The diver-ticula occur between the muscle clefs making the mucosal surface appear trabeculated. The elastin content of the taenia coli is increased compared with controls.

**Diverticulitis**

Diverticulitis is the result of inflammation of one or more diverticula, usually with some pericolicitis. Episodes of diverticulitis may be followed by years free of symptoms, but the condition is essentially progressive — the longer the duration the worse the symptoms and the greater the risk of complications. Diverticulitis is not a precancerous condition, but cancer may coexist.

The complications are the following:

1. recurrent periodic inflammation and pain — in some patients these episodes may be clinically silent;
2. perforation leading to general peritonitis or local (pericolic) abscess formation;
3. intestinal obstruction:
   (a) in the sigmoid as a result of progressive fibrosis causing stenosis,
   (b) in the small intestine caused by adherent loops of small intestine on the pericolic;
4. haemorrhage: diverticulitis may present with profuse colonic haemorrhage in 17 per cent of cases, often requiring blood transfusions;
5. fistula formation (vesicocolic, vaginocolic, enterocolic, colocutaneous) occurs in 5 per cent of cases, vesicolic being the most common.

**Clinical features**

**Diverticulosis** may be asymptomatic, but the disordered colonic function may cause symptoms of distension, flatulence and a sensation of heaviness in the lower abdomen, all of which may be indistinguishable from the symptoms of irritable bowel syndrome. Excessive colonic segmentation can cause severe pain in the left iliac fossa, but this must be distinguished from episodes of often subclinical inflammation in the sigmoid colon as a result of diverticulitis.

**Diverticulitis.** Persistent lower abdominal pain, usually in the left iliac fossa with or without peritonitis in patients of either sex over the age of 40, could be caused by diverticulitis. Fever, malaise and leucocytosis can differentiate diverticulitis from painful diverticulosis. The patient may pass loose stools or may be constipated; the lower abdomen is tender especially on the left but occasionally also in the right iliac fossa if the sigmoid loop lies across the midline. The sigmoid colon is often palpable, tender and thickened. Rectal examination may but does not usually reveal a tender mass. The condition has been likened to left-sided appendicitis. Any urinary symptoms may herald the formation of a vesicolic fistula which leads to pneumaturia (flatus in the urine) and even faeces in the urine.

**Diagnosis**

Radiology. Diverticulosis, as for the ‘irritable bowel’ syndrome, is a diagnosis of exclusion and symptoms should not be attributed to diverticulitis unless other diseases have been excluded by barium enema, sigmoidoscopy or colonoscopy. Although the diagnosis of acute diverticulitis is made on clinical grounds it can be confirmed during the acute phase by computerised tomography (CT). This will demonstrate...
not only the diverticula but also any associated pericolic abscess (Fig. 57.17). Barium enemas and sigmoidoscopy are usually reserved for patients who have recovered from an attack of acute diverticulitis for fear of causing perforation or peritonitis. Water-soluble contrast enemas may, however, be helpful in sorting out patients with large bowel obstruction. Barium radiology is carried out to exclude a carcinoma and to assess the extent of the disease. Where the sigmoid colon is thickened and narrowed, a 'saw-tooth' appearance may be seen. Some strictures can be very difficult to distinguish by radiology alone and in those circumstances colonoscopy will be necessary to rule out a carcinoma.

**Sigmoidoscopy.** The mucosa may be normal and in acute attacks the sigmoidoscopy will be painful and the mucosa inflamed. Colonoscopy or flexible sigmoidoscopy is more helpful (Fig. 57.18). The necks of diverticula can be seen and the narrowed area of diverticulitis can be entered, but on occasion not passed because of the severity of disease. The differential diagnosis from a carcinoma can be impossible if a tight stenosis prevents endoscopy.

**Management**

**Diverticulosis** should be treated with a high-residue diet containing roughage in the form of wholemeal bread, flour, fruit and vegetables. Bulk formers such as bran, Celevac, Isogel and Fybogel may be given until the stools are soft. Painful diverticular disease may require bed rest and antispasmodics.

**Acute diverticulitis** is treated by bed rest and intravenous antibiotics (usually cefuroxime and metronidazole). After the acute attack has subsided and if the diagnosis has not already been confirmed by CT, a barium enema should be carried out.

**Operative procedures for diverticular disease.** Some 10 per cent of patients require an operation either for recurrent attacks which make life a misery or for the complications of diverticulitis.

1. The ideal operation carried out as an interval procedure after careful preparation of the gut is a one-stage resection. This involves removal of the affected segment and restoration of continuity by end-to-end anastomosis. At this operation the sigmoid loop is often found adherent in the pouch of Douglas. Careful dissection will allow even-tual mobilisation of the recto sigmoid out of the pelvis exposing the normal rectum, and greater mobility will allow an easier anastomosis.

2. If there is obstruction, inflammatory oedema and adhesions or the bowel is loaded with faeces, a Hartmann's operation is the procedure of choice. The involved area is resected. The rectum is closed at the peritoneal reflection, and the left colon brought out as a left iliac fossa colostomy. The once popular staged procedures using a preliminary transverse colostomy are now rarely used except by inexperienced surgeons because of the high mortality associated with them. In selected obstructed cases the bowel can be cleaned by on-table lavage, placing a urinairy catheter through the appendix stump and washing the colon with physiological saline or water for irrigation. This makes subsequent restoration and bowel continuity with an anastomosis much safer (Fig. 57.19a, h).

3. In acute perforation, peritonitis soon becomes general and may be purulent, which has a mortality rate of about 15 per cent. Gross faecal peritonitis carries more than a 50 per cent mortality rate and pneumoperitoneum is usually present; the diagnosis may not be confirmed until emergency laparotomy. There is a choice of procedures:

   (a) primary resection and Hartmann’s procedure (see above);

   (b) primary resection and anastomosis after on-table lavage in selected cases;

   (c) exteriorisation of the affected bowel which is then opened as a colostomy, now rarely used;

   (d) suture of the perforation with drainage with or without proximal defunction. In selected cases with a small leak and minimal soiling.

4. Fistulae can only be cured by resection of the diseased bowel and closure of the fistula. In the case of a colovesical fistula it is usually possible to ‘pinch off’ the affected bowel from the bladder, close it and then resect the sigmoid. In very difficult cases a staged procedure with a preliminary defunctioning stoma may be necessary on occasion.

5. Haemorrhage from diverticulitis must be distinguished from angiodyplasia. It usually responds to conservative management and occasionally requires resection. On-table lavage and colonoscopy may be necessary to localise the bleeding site.

Diverticular disease and carcinoma coexist in 12 per cent of cases. Exploration may be necessary but, even then, differentiation may be difficult until histological investigations are available (Table 57.1). Weight loss, falling haemoglobin and persistently positive occult blood are sinister features.

**Solitary diverticulum of the caecum and ascending colon** is rare and is congenital, and may present with symptoms and signs identical to those of acute appendicitis.

**Extensive diverticular disease** can sometimes affect the right colon. This, however, is rare in the West but more common in Eastern countries. In Japan, China, Malaysia and Korea, right-sided disease is twice as common as left-sided disease.
Ulcerative colitis

Aetiology

The cause of ulcerative colitis is unknown; its prevalence among first-degree relatives of patients is 15 times that of the general population but there is no clear Mendelian pattern of inheritance. In spite of intensive bacteriological studies, no organisms or group of organisms can be incriminated. Relapse of colitis has, however, been reported in association with bacterial dysenteries. Some cases are allergic to milk protein. Smoking seems to have a protective effect and there have been anecdotal reports of remission of the disease with smoking or the use of nicotine chewing gum. Patients often comment that relapses are associated with periods of stress at home or at work, but personality and psychiatric profiles are the same as the normal population.

There remain three main hypotheses, none of which has been proved:

1. a mucosal immunological reaction;
2. a weakened mucous barrier;
3. defective mucosal metabolism of butyrate.

Epidemiology

There are 10—15 new cases per 100,000 population a year in the UK. The disease has been rare in Eastern populations but is now being reported more commonly, suggesting an environmental cause that has developed as a result of an increasing ‘westernisation’ of diet and/or social habits and better diagnostic facilities. The sex ratio is equal; it is uncommon before the age of 10 and most patients are between the ages of 20 and 40 at diagnosis.

Pathology

In 95 per cent of cases the disease starts in the rectum and spreads proximally. When the ileo-caecal valve is incompetent, retrograde (backwash) ileitis involving the last 30 cm of the ileum is likely to occur. It is a nonspecific inflammatory disease, primarily affecting the mucosa and superficial sub-mucosa, and only in severe disease are the deeper layers of the intestinal wall affected. There are multiple minute ulcers, and microscopic evidence proves that the ulceration is almost always more severe and extensive than the gross appearance indicates. When the disease is chronic, inflammatory polyps (psuedopolyps) occur in up to 20 per cent of cases and may be numerous. They result from previous episodes of ulceration having islands of spared mucosa which will remain prominent when the adjacent mucosa heals. In severe fulminating colitis a section of the colon, usually the transverse colon, may become acutely dilated and the intestinal wall then becomes extremely thin and may perforate (‘toxic megacolon’). On microscopic investigation there is an increase of inflammatory cells in the lamina propria, the walls of crypts are infiltrated by inflammatory cells and there are crypt abscesses. There is depletion of goblet cell mucin. The crypts are reduced in number and appear to be atrophic and irregularly spaced. With time these changes become severe and precancerous changes can develop (towards dysplasia or carcinoma in situ).

Symptoms

The first symptom is watery or bloody diarrhoea; there may be a rectal discharge of mucus which is either blood stained or purulent. Pain as an early symptom is unusual. In most cases the disease is chronic and characterised by relapses and remissions. In general, a bad prognosis is indicated by (1) a severe initial attack, (2) disease involving the whole colon and (3) increasing age, especially after 60 years. If the disease remains confined to the left colon the outlook is better.

Proctitis

Inflammation confined to the rectum accounts for about 25 per cent of all cases. As most of the colon is healthy the stool is formed or semi-formed and the patient is often severely troubled by tenesmus and urgency. The risk of cancer in these cases is low. In 5—10 per cent there is spread to involve the rest of the colon.

Left-sided and total colitis (Fig. 57.20)

Diarrhoea usually implies that there is active disease proximal to the rectum. Approximately 15 per cent of patients have left-sided colitis, and 25 per cent have total colitis extending beyond the mid-transverse colon. The clinical pattern is one of recurrent severe attacks of bloody diarrhoea up to 20 times a day, dehydration and fluid electrolyte losses. Anaemia and hypoproteinaemia are common.

Disease severity

Disease severity can be graded as:

1. mild — rectal bleeding or diarrhoea with four or fewer motions per day and the absence of systemic signs of disease;
2. moderate — more than four motions per day but no systemic signs of illness;
3. severe — more than four motions a day together with one or more signs of systemic illness: fever over 37.5°C, tachycardia more than 90/minute, hypoalbuminaemia less than 30 g/litre, weight loss more than 3 kg.

Complications of severe disease

Fulminating colitis and toxic dilatation (megacolon) (Fig. 57.21).

Patients with severe disease should he admitted to hospital. Dilatation should he suspected in patients with active colitis who develop severe abdominal pain. It is an indication that inflammation has gone through all the muscle layers of the colon. The diagnosis is confirmed by the presence on a plain abdominal radiograph of the colon with a diameter more than 6 cm. The condition must be differentiated from dysentery, typhoid and amoebic colitis. Plain abdominal radiographs should be obtained daily in patients with severe colitis and a progressive increase in diameter in spite of medical therapy is an indication for surgery (Fig. 57.22).

Perforation. Colonic perforation in ulcerative colitis is a grave complication with a mortality rate of 50 per cent or more. Steroids may mask the
physical signs. Perforation can sometimes occur without toxic dilatation. Generally patients with severe attacks should be managed so that they do not develop these complications.

**Severe haemorrhage.** Severe rectal bleeding is uncommon and may occasionally require transfusion and rarely surgery.

**Investigations**

A plain abdominal film can often show the severity of disease. Faeces are only present in parts of the colon that are normal or only mildly inflamed. Mucosal islands can sometimes be seen and have been mentioned. Small bowel loops in the right lower quadrant may be a sign of severe disease.

**Barium enema**

The principal signs are (Fig. 57.23):

- loss of haustration, especially in the distal colon;
- mucosal changes caused by granularity;
- pseudopolyps;
- in chronic cases, a narrow contracted colon.

In some centres an instant enema is used with a water-soluble medium for contrast instead of barium and no bowel preparation to avoid aggravating any underlying colitis (Fig. 57.24).

**Sigmoidoscopy**

Sigmoidoscopy is essential for diagnosis of early cases and mild disease not showing up on a barium enema. The initial findings are those of proctitis, the mucosa is hyperaemic, bleeds on touch and there may be a pus-like exudate. Later tiny ulcers may be seen and appear to coalesce. This is different from the picture of amoebic dysentery where there are large deep ulcers with intervening normal mucosa.

**Colonoscopy and biopsy**

This has an important place in management:

1. to establish the extent of inflammation;
2. to distinguish between ulcerative colitis and Crohn’s colitis;
3. to monitor response to treatment;
4. to assess long-standing cases for malignant change.

Although it may occasionally be helpful, colonoscopy is not usually used in acute cases for fear of aggravating the disease or perforation.

**The cancer risk in colitis**

Although this is an important complication the overall risk is only about 3.5 per cent. It is much less in early cases but increases with duration of disease. Thus, after 20 years of colitis the risk may be as much as 12 per cent. Carcinoma is more likely to occur where the whole colon is involved and where the disease started in early life (Fig. 57.25). Carcinomatous change, often atypical and high grade, may occur at many sites at once. The colon is involved rather than the rectum and the maximal incidence is during the fourth decade.

The golden rule is that, when the disease has been present for 10 years or more, regular colonoscopic checks must be carried out, even if the disease is clinically quiescent. If on biopsy there is severe epithelial dysplasia, surgery is indicated. Annual colonoscopy and biopsy is then part of cancer surveillance. In the rare cases with a fibrous stricture these should be examined especially carefully for the presence of an underlying carcinoma.

**Extraintestinal manifestations**

**Arthritis** occurs in around 15 per cent of patients and is of the large joint polyarthropathy type, affecting knees, ankles, elbows and wrists. Sacroilitis and ankylosing spondylitis are 20 times more common in patients with ulcerative colitis.

**Skin lesions:** erythema nodosum, pyoderma gangrenosum or aphthous ulceration.

**Eye problems:** iritis.

**Liver disease:** sclerosing cholangitis has been reported in up to 70 per cent of cases. Diagnosis is by ERCP which demonstrates the characteristic alternating stricturing and bleeding of the intrahepatic and extrahepatic ducts.

**Bile duct cancer** is a rare complication and colectomy does not appear to reduce the risk of subsequent bile duct cancer or sclerosing cholangitis.

**Treatment**

**Medical treatment of an acute attack**

Corticosteroids are the most useful drugs and can be given either locally for inflammation of the rectum or systemically when the disease is more extensive. Sulphasalazine and other 5-aminosalicylic acid (5-ASA) derivates, for example, mesalazine and olsalazine, can be given both topically and systemically.

Their main function is in maintaining remission rather than treating an acute attack. Nonspecific antidiarrhoeal agents have no place in the
routine management of ulcerative colitis.

Mild attacks

Patients with a mild attack and limited disease will usually respond to rectally administered steroids. In those with more extensive disease, oral prednisolone 20—40 mg/day is given over a 3—4-week period. Sulphasalazine 1 g three times a day or one of the newer 5-ASA compounds should be given concurrently.

Moderate attacks

These patients should be treated with oral prednisolone 40 mg/day, twice daily steroid enemas and 5-ASA. Failure to achieve remission as an out-patient is an indication for admission.

Severe attacks

These patients must be regarded as medical emergencies and require immediate admission to hospital. Their appearance is often misleading, and they must be examined at least twice a day with particular reference to the presence of signs of peritonism. Their abdominal girth is measured and liver dullness should be percussed regularly. A plain abdominal radiograph is taken daily and inspected for dilatation of the transverse colon of more than 5.5 cm. The presence of mucosal islands on plain radiographs (see Fig. 57.22), increasing colonic diameter or a sudden increase in pulse and temperature may indicate a colonic perforation. A stool chart helps in the assessment of response to therapy, and careful medical/surgical joint man-agement is essential. Fluid and electrolyte balance is main-tained, anaemia is corrected and adequate nutrition provided, sometimes in severe cases with intravenous nutrition. The patient is maintained nil by mouth and treated with intravenous hydrocortisone 100—200 mg four times daily. This can be supplemented with a rectal infusion of prednisolone. There is no evidence that antibiotics modify the course of a severe attack. Some patients are treated with azathioprine or cyclosporin A to induce remission. If there is failure to gain an improvement within 5—7 days then surgery must be seriously considered. Prolonged high-dose intravenous steroid therapy is fraught with danger. Patients who have had weeks of treatment, during which the colonic wall has become friable and disintegrates at laparotomy, are now fortunately rare.

Indications for surgery

The risk of colectomy is 20 per cent overall, ranging from 5 per cent in those patients with proctitis to 50 per cent in those patients with a very severe attack:

• severe or fulminating disease failing to respond to medical therapy;
• chronic disease with anaemia, frequent stools, urgency and tenesmus;
• steroid-dependent disease: here the disease is not severe but remission cannot be maintained without substantial doses of steroids;
• the risk of neoplastic change: patients who on review colonoscopy have severe dysplasia;
• extraintestinal manifestations;
• rarely, severe haemorrhage or stenosis causing obstruction.

Operations

1. In the emergency situation the ‘first-aid procedure’ is a total abdominal colectomy and ileostomy. The rectum can either he brought out at the lower end of the wound as a mucous fistula or closed just beneath the skin. This has the advantage that the patient recovers quickly, the histology of the resected colon can be checked, and restorative surgery can be contemplated at a later date when the patient is no longer on steroids and in optimal nutritional condition. The alternative, division of the rectum below the sacral promontory, can result in breakdown and pelvic abscesses, and makes subsequent identification of the stump more difficult.

2. Proctocolectomy and ileostomy: this is the procedure associated with the least complication rate. The patient is left with a permanent ileostomy There is, however, a 20 per cent long-term risk of adhesion obstruction, and 5—10 per cent of the perineal wounds are very slow to heal. The late result will be a chronic perineal sinus which may require repeated curettage or excision. The obvious disadvantage is an ileostomy and although many patients cope remarkably well there is a psychological and social ‘cost’.

Rectal and anal dissection. Refinements of the procedure have included a close rectal dissection to minimise damage to the nervi erigentis and hence erectile dysfunction which may occur in 0.5—2 per cent, and inter sphincteric excision of the anus which results in a smaller perineal wound and fewer healing problems.

3. Restorative proctocolectomy with an ileoanal pouch (Parks). In this operation a pouch or reservoir is made out of ileum (Fig. 57.26) as a substitute for the rectum and sewn or stapled to the anal canal. Various pouch designs have been described, hut the J is the most popular and the most easily made using staplers (Fig. 57.27). There is some controversy over the correct technique for ileoanal anastomosis. In the earliest operations, the mucosa from the dentate line up to midrectum was stripped off the underlying muscle, but it is now known that a long muscle cuff is not needed. A mucosectomy of the upper anal canal with an anastomosis at the dentate line is claimed to remove all of the at risk mucosa and any problem of subsequent cancer. It may also result in imperfect continence with nocturnal seepage. The alternative is a double stapled anastomosis to the top of the anal canal preserving the upper anal canal mucosa. Continence appears to be better, but the theoretical risk of leaving inflamed mucosa remains.

The procedure can he carried out in one, two or three stages. In selected cases a covering loop ileostomy is omitted hut is usually used. Complications include pelvic sepsis — usually resulting from a leak of the ileoanal anastomosis, small bowel obstruction and pouch vaginal fistula. Frequency of evacuation is determined by pouch volume, completeness of emptying, reservoir inflammation and intrinsic small bowel motility, but can be between three and six evacuations daily. Although associated with a higher complication rate, it is rapidly becoming the operation of choice in younger patients, avoiding a permanent ileostomy. About 20 per cent of patients have an episode of pouchitis, that is, inflammation of the reservoir, at some time. It usually responds to treatment with metronidazole.

4. Colectomy and ileorectal anastomosis: if there is minimal rectal inflammation this can occasionally he used; it has largely been superseded by restorative proctocolectomy.

5. ileostomy with a continent intra-abdominal pouch (Kock’s proce-dure). A reservoir is made of ileum and just beyond this a spout is made
by inverting the efferent ileum into itself to give a continent valve just below skin level. The pouch is emptied by the patient inserting a
catheter through the valve; now rarely used.

**Ileostomy**

End ileostomy (Brooke). In those patients with a permanent ileostomy there must be scrupulous attention to detail during the operation to
ensure that the patient has a good functional result. The position of the ileostomy should be carefully chosen by the patient with the help of a
stoma care nursing specialist. The ileum is normally brought through the lateral edge of the rectus abdominis muscle. The use of a spout *(Fig.
57.28)* was originally described by Bryan Brooke and it should project some 4 cm from the skin surface. A disposable appliance is placed over
the ileostomy so that it is a snug fit at skin level.

**Ileostomy care**

During the first few postoperative days, fluid and electrolyte balance must be adjusted with great care. There may be an ‘ileostomy flux’ while
the ileum adapts to the loss of the colon, and the fluid losses can amount to 4 or 5 litres/day. The stools thicken in a few weeks and are
semisolid in a few months. The help, skill and advice of the stoma care nursing specialist are essential. Modern appliances have transformed
stoma care and skin problems are unusual *(Fig. 57.29).*

Complications of an ileostomy include prolapse, retraction, stenosis, bleeding and paraileostomy hernia. Loop ileostomy. This is often used to
defunction a pouch ileoanal procedure or even a low anterior resection. A knuckle of ileum is pulled out through a skin trephine in the right iliac
fossa. An incision is made in the distal part of the knuckle and this is then pulled over the top of the more proximal part to create a spout on
the proximal side of the loop with a flush distal side still in continuity. This allows near-perfect defunction, but also the possibility of restoration
of continuity by taking down the spout and reanastomosing the partially divided ileum.
Crohn's disease (regional enteritis)

Crohn's disease became widely recognised following the report in 1932 by Crohn, Ginzburg and Oppenheimer describing young adults with a chronic inflammatory disease of the ileum. It can affect any part of the gastrointestinal tract from the lips to the anal margin, but ileocolonic disease is the most common presentation.

Epidemiology

It is most common in North America and northern Europe. Prevalence rates as high as 56 per 100 000 have been reported in the UK. Over the last four decades there seems to have been a rise in the incidence which cannot be accounted for by increased diagnosis. It is slightly more common in females than in males but is most commonly diagnosed in young patients between the ages of 25 and 40. There does, however, seem to be a second peak of incidence around the age of 17.

Aetiology

Although Crohn's disease has some features suggesting chronic infection, no causative organism has ever been found; similarities between Crohn's disease and tuberculosis have focused attention on mycobacteria. Focal ischaemia has also been postulated as a causative factor, possibly originating from a vasculitis arising through an immunological process. A wide variety of foods has now been implicated but none conclusively. Smoking increases the risk threefold.

About 10 per cent of patients have a first-degree relative with the disease and there is an association with ankylosing spondylitis. Cell-mediated immune function may be defective in patients with Crohn's disease but it is not known whether this is a consequence of the disease itself or the effects of malnutrition and medical therapy. As with ulcerative colitis it is now believed that Crohn's disease can predispose to cancer, although the incidence of malignant change is not nearly as high as in ulcerative colitis and is most manifest in the ileum.

Pathology

Ileal disease is the most common accounting for 60 per cent of cases; 30 per cent of cases are limited to the large intestine and the remainder consists of patients with ileal disease alone or more proximal small bowel involvement. Anal lesions are common. Crohn's disease of the mouth, oesophagus, and stomach and duodenum are uncommon. Resection specimens show a fibrotic thickening of the intestinal wall with a narrow lumen (Fig. 57.30). There is usually dilated gut just proximal to the stricture and, in the strictured area, there are deep mucosal ulcerations with linear or snake-like patterns. Oedema in the mucosa between the ulcers gives rise to a cobblestone appearance. The transmural inflammation leads to adhesions, inflammatory masses with mesenteric abscesses and fistulae into adjacent organs. The serosa is usually opaque, there is thickening in the mesentery and mesenteric lymph nodes are enlarged. The condition is discontinuous with inflamed areas separated from normal intestine; these are sometimes called skip lesions. Under the microscope there are focal areas of chronic inflammation involving all layers of the intestinal wall. There are noncaseating giant cell granulomas but these are only found in 60 per cent of patients. They are most common in anorectal disease. The earliest mucosal lesions are discrete aphthous ulcers. Recent studies have also shown multifocal arterial occlusions in the muscularis propria.

Clinical features

Presentation depends upon the area of involvement.

Acute Crohn's disease

Acute Crohn's disease occurs in only 5 per cent of cases. Symptoms and signs resemble those of acute appendicitis but there is usually diarrhoea preceding the attack. Rarely there could be a free perforation of the small intestine, resulting in a local or diffuse peritonitis. Acute colitis with or without toxic megacolon can occur in Crohn's disease but is less common than in ulcerative colitis.

Chronic Crohn's disease

There is often a history of mild diarrhoea extending over many months occurring in bouts accompanied by intestinal colic. Patients may complain of pain, particularly in the right iliac fossa, and there may be a tender mass palpable. Inter-mittent fevers, secondary anaemia and weight loss are common. A perianal abscess or fissure may be the first presenting feature of Crohn's disease; the cause is often an infected anal crypt associated with concomitant diarrhoea, but as the disease becomes chronic specific fistulae resulting from the Crohn's disease itself can develop.

After months of repeated attacks with acute inflammation the affected area of intestine begins to narrow with fibrosis causing abdominal pain on eating, giving rise to what has been described as 'food fear'. Children developing the illness before puberty may have retarded growth and sexual development.

With progression of the disease adhesions and transmural fissuring, intra-abdominal abscesses and fistulae can develop.

1. Entero-enteric fistulae can occur into adjacent small bowel loops or the pelvic colon and entero-vesical fistulae may cause repeated urinary tract infections and pneumaturia.

2. Enterocutaneous fistulae rarely occur spontaneously and usually follow surgery.

Anal disease (see Chapter 58)

In the presence of active disease, the perianal skin appears bluish. Three or more oedematous pinky-blue fleshy tags pro-trude from the anal margin; they may have superficial ulceration on the inner surface extending into the anal canal. Superficial ulcers with undermined edges are relatively painless and can heal with bridging of epithelium. Deep cavitating ulcers are usually found in the upper anal canal; they can be painful and cause perianal abscesses and fistulae, discharging around the anus and sometimes forwards into the genitalia.

The most distressing feature of anal disease is sepsis from secondary abscesses and perianal fistulae. Remarkably the rectal mucosa is often spared and may feel normal on rectal examination. If it is involved, however, it will feel thickened, nodular and irregular.

Investigation

Sigmoidoscopic examination
Sigmoidoscopic examination may be normal or show minimal involvement. Ulceration in the anal canal will, however, be readily seen.

**Colonoscopy**

As a result of the discontinuous nature of Crohn’s disease there will be areas of normal colon or rectum. In between these there are areas of inflamed mucosa which are irregular, ulcerated with a mucopurulent exudate. The earliest appearances are aphthoid-like ulcers surrounded by a rim of erythematous mucosa. These become larger and deeper with increasing severity of disease. In colonic Crohn’s disease there may be strictureing and it is important to exclude malignancy in these sites (Fig. 57.31). At the ileo-colic anastomosis of a patient having had previous ileocaecal resection, recurrent disease is usually seen on the ileal side of the anastomosis.

**Radiology**

Barium enema will show similar features to those of colono-scopy in the colon. The best investigation of the small intestine is small bowel enema (Fig. 57.32). This will show up areas of delay and dilatation characterising partial obstruction. The involved areas tend to be narrowed, irregular and sometimes, when a length of terminal ileum is involved, there may be the string sign of Kantor. Sinograms are useful in patients with entero-cutaneous fistulae. CT scans are used in patients with fistulae and those with intra-abdominal abscesses and complex involvement. Magnetic resonance imaging (MRI) has been shown to be useful in assessing perianal disease.

**Treatment**

**Medical therapy**

Steroids are the mainstay of treatment. Patients with a relapse of their Crohn’s disease are treated with up to 40 mg prednisolone orally, daily supplemented by 5-ASA compounds in those patients with colonic involvement, although there is some evidence that this may help small bowel disease as well. Those who have symptoms and signs of a mass or an abscess are also treated with antibiotics. Azathioprine is used for its additive and steroid-sparing effect. Nutritional support is essential. Severely malnourished people may require intravenous feeding or nasoenteric feeding regimens. Anaemia, hypoproteinaemia, electrolyte, vitamin and metabolic bone problems must all be addressed.

**Indications for surgery**

Surgical resection will not cure Crohn’s disease. Surgery is therefore focused on complications of the disease. As many of these indications for surgery may be relative, joint management by an aggressive physician and a conservative surgeon is thought to be ideal. These complications include:

- recurrent intestinal obstruction;
- bleeding;
- perforation;
- failure of medical therapy;
- intestinal fistula;
- fulminant colitis;
- malignant change;
- perianal disease.

**Surgery**

To preserve functional gut length, resection is kept to a minimum so as to deal with the local problem. The whole of the gastrointestinal tract has to be examined carefully at the time of laparotomy. If on occasion Crohn’s disease is diagnosed during the course of an operation for suspected appendicitis, the appendix should be removed. If the ileum is thick, rigid and pipe-like, senior help should be sought so that an ileocaecal resection can be carried out.

The course of the disease after surgery is unpredictable but recurrence is common. It does not seem to be related to the presence of disease at the resection line. Recurrence rates vary from site to site but the cumulative probability of recurrence requiring surgery for ileal disease is of the order of 20, 40, 60 and 80 per cent at 5, 10, 15 and 20 years, respectively, after previous resection. Restorative operations have a higher incidence of recurrence than, for example, proctocolectomy and ileostomy.

1. **Ileocaecal resection** is the usual procedure for ileocaecal disease with a primary anastomosis between the ileum and the transverse colon.

2. **Segmental resection**: short segments of small or large bowel involvement can be treated by segmental resection.

3. **Colectomy and ileorectal anastomosis**. In patients with widespread colonic disease with rectal sparing and a normal anus this can be a useful option.

4. **Temporary loop ileostomy**. This can be used either in patients with acute distal Crohn’s disease allowing remission and later restoration of continuity or in patients with severe perianal or rectal disease.

5. **Proctocolectomy**. Patients with colonic and anal disease failing to respond to medical treatment or defunction will eventually require a permanent ileostomy.

6. **Strictureplasty**. Multiple strictured areas of Crohn’s disease (Fig. 57.33) can be treated by a local widening procedure, strictureplasty, to avoid excessive small bowel resection (Fig. 57.34) (Lee).

7. **Anal disease** is usually treated conservatively by simple drainage of abscesses, placing setons around any fistulae, and occasionally in patients with inactive disease primary repair of a recto-vaginal or high fistula in ano could be attempted.
Infections

Intestinal amoebiasis. Amoebiasis is an infestation with *Entamoeba histolytica*. This parasite has a world-wide distribution.

**Life history of the parasite.** The active form of the parasite or trophozoite lives in the intestinal mucous membrane where it ingests red blood corpuscles and other cells and multiples by mitosis. Should the parasite become pathogenic, it makes its way into the follicles of Lieberkühn and, by dissolving into glandular tissue via the cytolyisin, submucous loculi are produced. Some of these burst through the mucous membrane to become amoebic ulcers. While the trophozoites continue their activities in the base of the ulcer, others cease to feed, migrate towards the surface and become transformed into cysts which pass into the outer world with the faeces. Amoebiasis is transmitted mainly in contaminated drinking water.

**Pathology.** The ulcers, which have been described as ‘bottlenec ked’ because of their considerably undermined edges, have a yellow necrotic floor, from which blood and pus exude. Although on rare occasions the ulcers are scattered throughout the large intestine, in 75 per cent they are confined to the lower sigmoid and upper rectum.

**Biopsy.** Endoscopic biopsies or fresh hot stools are examined carefully to look for the presence of amoebae. It is important to emphasise, however, that the presence of the parasite does not indicate that it is pathogenic (Fig. 57.35).

**Clinical features.** Dysentery is the principal manifestation of the disease but it may come in various guises.

**Appendicitis or amoebic caecal mass.** In tropical countries where amoebiasis is endemic, this is a constantly recurring problem. To operate on a patient with amoebic dysentery without the precautions subsequently described is to invite an exacerbation of amoebiasis which may prove fatal. The bowel is friable and satisfactory closure of the appendix stump becomes difficult or impossible, especially in cases where a palpable mass is present. When there is an amoebic mass there tends to be tenderness on deep palpation over the caecum and the sigmoid.

**Perforation.** The most common sites are the caecum and recto-sigmoid; usually perforation occurs into a confined space where adhesions have previously formed and a paracolic abscess results which eventually needs draining. When there is sudden faecal flooding in the general peritoneal cavity, drainage of the region of the perforation, gastrointestinal aspiration, intravenous fluid, antibiotics and a full course of emetine are sometimes successful.

**Severe rectal haemorrhage** as a result of separation of the slough is liable to occur.

**Granuloma.** Progressive amoebic invasion of the wall of the rectum or colon, with secondary inflammation, can produce a granulomatous mass indistinguishable from a carcinoma.

**Fibrous stricture** may follow the healing of extensive amoebic ulcers.

**Intestinal obstruction** is a common complication of amoebiasis, and the obstruction is the result of adhesions associated with pericolitis and large granuloma.

**Paracolic abscess,** ischiorectal abscess and fistula occur from perforation by amoebae of the intestinal wall followed by secondary infection.

**Ulcerative colitis.** A search for amoebae should always be made in the stools of patients believed to have ulcerative colitis.

**Treatment.** High-dose intravenous steroids in this situation can be catastrophic. Metronidazole (Flagyl) is the first-line drug, 800 mg three times daily for 7—10 days. Diloxanide furoate is best for chronic infections associated with the passage of cysts in stools. Intestinal antibiotics improve the results of the chronic stages, probably by coping with superadded infection.

Typhoid and paratyphoid. **Surgical complications.** Paralytic ileus is the most common complication of typhoid.

**Intestinal haemorrhage** may be the leading symptom.

**Perforation.** Perforation of a typhoid ulcer usually occurs during the third week and is occasionally the first sign of the disease. The ulcer is parallel to the long axis of the gut and is usually situated in the lower ileum.

**Paratyphoid B.** Perforation of the large intestine sometimes occurs. Vigorous intravenous antibiotic therapy is given; occasionally surgery is required to defunction the colon or in late cases remove the colon as for ulcerative colitis.

**Cholecystitis.** Acute typhoid cholecystitis is not uncommon and perforation can occur; gallstones occasionally contain typhoid bacilli and some patients may become typhoid carriers.

**Phlebitis.** Venous thrombosis, particularly of the left common iliac vein, is an occasional complication of typhoid fever.

**Genitourinary complications.** Typhoid cystitis, pyelitis and epididymo-orchitis may all occur.

**Joints.** All degrees of arthritis, from a mild effusion to suppuration, occur as a complication of this disease.

**Bone.** Typhoid osteomyelitis and typhoid of the spine occur.

Tuberculosis of the intestine. Tuberculosis can affect any part of the gastrointestinal tract from the mouth to the anus. The sites affected most often are the ileum, proximal colon and peritoneum. There are two principal types.

**Ulcerative tuberculosis** is secondary to pulmonary tuberculosis and arises as a result of swallowing tubercle bacilli. There are multiple ulcers in the terminal ileum, lying transversely, and the overlying serosa is thickened, reddened and covered in tubercles.

**Clinical features.** Diarrhoea and weight loss are the predominant symptoms and usually the patient will be receiving treatment for pulmonary tuberculosis.

**Radiology.** A barium meal and follow-through or small bowel enema will show the absence of filling of the lower ileum, caecum and most of the ascending colon as a result of narrowing and hypermotility of the ulcerated segment (Fig. 57.36).
**Treatment.** A course of chemotherapy is given. Healing often occurs provided the pulmonary tuberculosis is adequately treated. An operation is only required in the rare event of a perforation or intestinal obstruction.

**Hyperplastic tuberculosis.** This usually occurs in the ileocaecal region although solitary and multiple lesions in the lower ileum are sometimes seen. This is caused by the ingestion of *Mycobacterium tuberculosis* by patients with a high resistance to the organism. The infection establishes itself in lymphoid follicles, and the resulting chronic inflammation causes thickening of the intestinal wall and narrowing of the lumen. There is early involvement of the regional lymph nodes which may caseate. Unlike Crohn’s disease, with which it shares many similarities, abscess and fistula formation is rare.

Untreated, sooner or later subacute intestinal obstruction will supervene often together with the impaction of an enterolith in the narrowed lumen.

**Clinical features.** Attacks of abdominal pain with intermittent diarrhoea are the usual symptoms. The ileum above the partial obstruction is distended, and the stasis and consequent infection lead to steatorrhoea, anaemia and loss of weight. Sometimes the presenting picture is of a mass in the right iliac fossa in a patient with vague ill health. The differential diagnosis is that of an appendix mass, carcinoma of the caecum, Crohn’s disease, tuberculosis or actinomycosis of the caecum.

**Radiology.** A barium follow-through or small bowel enema will show a long narrow filling defect in the terminal ileum.

**Treatment.** When the diagnosis is certain and the patient has not yet developed obstructive symptoms, treatment with chemotherapy is advised and may cure the condition. Where obstruction is present, operative treatment is required and ileocaecal resection is best.

**Actinomycosis of the ileocaecal region.** Abdominal actinomycosis is rare. Unlike intestinal tuberculosis, narrowing of the lumen of the intestine does not occur and mesenteric nodes do not become involved. A local abscess, however, spreads to the retroperitoneal tissues and the adjacent abdominal wall, becoming the seat of multiple indurated discharging sinuses. The liver may become involved via the portal vein.

**Clinical features.** The usual history is that appendicectomy has been carried out for an appendicitis. Some 3 weeks after surgery a mass is palpable in the right iliac fossa and soon afterwards the wound begins to discharge. At first this is thin and watery, and then later it becomes thicker and malodorous. Other sinuses may form and a secondary faecal fistula develop. Pus should be sent for bacteriological examination where the characteristic sulphur granules can be seen.

**Treatment.** Penicillin or cotrimoxazole has to be prolonged and high dosage.

**Benign.** Adenoma, submucous lipoma and leiomyoma occur from time to time, and sometimes reveal themselves by causing an intussusception.

The second most common complication is intestinal bleeding from an adenoma in which event the diagnosis is frequently long delayed because the tumour is overlooked at barium radiology, endoscopy and even surgery.

**Peutz—Jeghers syndrome** consists of:

- familial intestinal hamartomatous polyposis affecting the jejunum, where it is a cause of haemorrhage, and often intussusception;
- melanosis of the oral mucous membrane and the lips.

The melanosis takes the form of melanin spots sometimes present on the digits and the perianal skin, but the pigmentation of the lips is the *sine qua non* (Fig. 57.37).

**Histology.** The polyps can be likened to trees. The trunk and branches are smooth muscle fibres and the foliage is virtually normal mucosa.

**Treatment.** As malignant change rarely occurs, resection is necessary only for serious bleeding or intussusception. Large single polyps can be removed by enterotomy or short lengths of heavily involved intestine can be resected. Those lesions within reach can be snared by colonoscopy.

**Malignant. Lymphoma.** There are three main types as follows.

1. **Western type lymphoma.** These are annular ulcerating lesions, which are sometimes multiple. They are now thought to be non-Hodgkin’s B-cell lymphoma in origin. They may present with obstruction and bleeding, perforation, anorexia and weight loss.

2. **Primary lymphoma associated with coeliac disease.** There is an increased incidence of lymphoma in patients with coeliac disease; this is now regarded as a T-cell lymphoma. Worsening of the patient’s diarrhoea, with pyrexia of unknown origin together with local obstructive symptoms, is the usual feature.

3. **Mediterranean lymphoma.** This is found mostly in North Africa and the Middle East and is associated with alpha-chain disease.

Unless there are particular surgical complications these conditions are usually treated with chemotherapy.

**Carcinoma.** As with other small bowel tumours these can present with obstruction, bleeding or diarrhoea. Complete resection offers the only hope of cure (Fig. 57.38).

**Carcinoid tumour.** These tumours occur throughout the gastro-intestinal tract, most commonly in the appendix, ileum and rectum in decreasing order of frequency. They arise from neuroendocrine cells at the base of intestinal crypts. The primary is usually small but when they metastasise, the liver is usually involved with numerous secondaries, which are larger and more yellow than the primary, and when this has occurred the carcinoid syndrome will become evident. The tumours can produce a number of vasoactive peptides, most commonly 5-hydroxytryptamine (serotonin), which may be present as 5-hydroxyindoleacetic acid in the urine during attacks.
The clinical syndrome itself consists of reddish-blue cyanosis, flushing attacks, diarrhoea, borborygmi, asthmatic attacks and, eventually, sometimes pulmonary and tricuspid stenosis. Classically the flushing attacks are induced by alcohol.

**Treatment.** Most patients with gastrointestinal carcinoids do not have carcinoid syndrome. Surgical resection is usually sufficient. In the cases found incidentally at appendicectomy nothing further is required. In patients with metastatic disease, multiple enucleations of hepatic metastases or even partial hepatectomy can be carried out. The treatment has been transformed by the use of octreotide (a somatostatin analogue) which reduces both flushing and diarrhoea, and octreotide cover is usually used in patients with a carcinoid syndrome who have surgery to prevent a carcinoid crisis. Carcinoid tumours generally grow more slowly than most metastatic malignancies; the patients may live with the syndrome of metastatic disease for many years.
Tumours of the large intestine

Benign

The term ‘polyp’ is a clinical description of any elevated tumour. It covers a variety of histologically different tumours shown in Table 57.2.

Polyps can occur either singly, synchronously in small numbers or as part of a polyposis syndrome. In familial adenomatous polyposis, more than 100 adenomas are present. It is important to be sure of the histological diagnosis because adenomas have significant malignant potential.

Adenomatous polyps

Adenomatous polyps vary from a tubular adenoma (Fig. 57.39), rather like a raspberry on a stalk, to the villous adenoma, a flat spreading lesion. Solitary adenomas are usually found during the investigation of colonic bleeding or sometimes fortuitously. Villous tumours more usually give symptoms of diarrhoea, mucus discharge and occasionally hypokalaemia. The risk of malignancy developing in an adenoma increases with increasing size of tumour, for example, in 1-cm diameter tubular adenomas there is a 10 per cent risk of cancer, whereas in villous adenomas over 2 cm in diameter there may be a 15 per cent chance of carcinoma. Adenomas larger than 5mm in diameter are usually treated because of their malignant potential. Colonoscopic snare polypectomy or diathermy obliteration with hot biopsy forceps can be used. Huge villous adenomas of the rectum can be difficult to remove even with techniques per anum and occasionally proctectomy is required; the anal sphincter can usually be preserved.

Hamartomatous polyps

Peutz—Jeghers polyps may occur in the colon as either solitary or multiple lesions. Juvenile polyps may occur as multiple lesions in the colon often associated with a congenital defect such as a malrotation or Meckel's diverticulum. They have minimal malignant potential and are only removed if they are causing troublesome pain, bleeding or hypoproteinaemia.

Haemangioma

A localised submucous telangiectasis is often the cause of bleeding which may be profuse. If bleeding is continuing, both angiography and colonoscopy can help to localise the source. If found by colonoscopy the lesion can be removed endoscopically, whereas arteriographic detection can be followed by the use of vasopressin or microspheres to stop the haemorrhage. Often the only method of detecting it is to operate while the bleeding is in progress. The distribution of blood within the intestine is noted; scrutiny of the blood-containing portion of the colon may reveal the lesion but on-table colonoscopy could be necessary. The tumour is resected once located.

Lipoma

Lipoma is less frequently encountered in the large than in the small intestine. In the large intestine it is almost always confined to the caecum. The tumour is submucous and in more than half the cases it is the cause of an intussusception. On occasion a lipoma at the ileocaecal valve can be confused with a caecal cancer.

Familial adenomatous polyposis

Familial adenomatous polyposis (FAP) is a general neoplastic disorder of the intestine. Although the large bowel is mainly affected polyps can occur in the stomach, duodenum and small intestine. The main risk is large bowel cancer, but duodenal and ampullary tumours have been reported. It is inherited as a Mendelian dominant and the gene responsible (APC gene) has now been identified on the short arm of chromosome 5 (Bodmer). Males and females are equally affected. It can also occur sporadically without any previous sign or history, presumably by new mutations. There is often, in these cases, a history of large bowel cancer occurring in young adulthood or middle age suggesting pre-existing adenomatosis.

FAP can be associated with benign mesodermal tumours such as desmoid tumours and osteomas. Epidermoid cysts can also occur (Gardner's syndrome); desmoid tumours in the abdomen invade locally to involve the intestinal mesentry and although nonmetastasising they can become unresectable.

Clinical features. Polyps are usually visible on sigmoidoscopy by the age of 15 years and will almost always be visible by the age of 30. Carcinoma of the large bowel occurs 10—20 years after the onset of the polyposis. One or more cancers will already be present in two-thirds of those patients presenting with symptoms.

Symptomatic patients. These are either new proposition or those from an affected family who have not been screened. They may have loose stools, lower abdominal pain, weight loss, diarrhoea and the passage of blood and mucus. Polyps are seen on sigmoidoscopy, and the number and distribution of polyps, and usually cancers if they are symptomatic, are shown on a double-contrast barium enema. If in doubt colonoscopy is performed with biopsies to establish the number and histological type of polyps. If over 100 adenomas (Fig. 57.40) are present the diagnosis can be made confidently but it is important not to confuse this with non-neoplastic forms of polyposis.

Asymptomatic patients. Usually members of affected families attend for screening. As yet there is no reliable means of knowing whether an individual is affected unless adenomas develop. If there are no adenomas by the age of 30, FAP is unlikely. Pigmented spots in the retina (CHIRPES) and deoxyribonucleic acid (DNA) tests for the FAP gene should make screening more reliable in the future.

If the diagnosis is made during adolescence, operation is deferred usually to the age of 17 or 18.

Screening policy.

1. All members of the family should be examined at the age of 10—12 years, repeated every 1—2 years.
2. Most of those who are going to get polyps will have them at 20 and these require operation.
3. If there are no polyps at 20, continue with 5-yearly examination until age 50; if there are still no polyps there is probably no inherited gene. Carcinomatous change may exceptionally occur before the age of 20. Examination of blood relatives, including cousins, nephews and nieces, is essential and a family tree should be constructed and a register of affected families maintained.

Treatment. Colectomy with ileorectal anastomosis has in the past been the usual operation because it avoids an ileostomy in a young patient. The rectum is subsequently cleared of polyps by snaring or fulguration. The patients are examined by flexible sigmoidoscopy at 6-monthly intervals thereafter. In spite of this, a proportion of patients develops carcinoma in the rectal stump. The risk of carcinoma in the St Mark’s
series was 10 per cent over a period of 30 years.

The alternative and now more common operation is a restorative proctocolectomy with an ileoanal anastomosis. This has a higher complication rate than ileorectal anastomosis. It is indicated in patients with serious rectal involvement with polyps, those who are likely to be poor at attending for follow-up and those with an established cancer of the rectum or sigmoid. However, it is now used more frequently for less severe cases.

Malignant

Adenocarcinoma of the colon

Pathology. Microscopically, the neoplasm is a columnar cell carcinoma originating in the colonic epithelium. Macroscopically the tumour may take one of four forms (Fig. 57.41). Type 4 is the least malignant form. It is likely that all carcinomas start as a benign adenoma, the so-called 'adenoma—carcinoma sequence'. The annular variety tends to give rise to obstructive symptoms whereas the others more commonly will present with bleeding. Site and distribution of cases of cancer are shown in Fig. 57.42. Tumours are more common in the left colon and rectum.

The spread of carcinoma of the colon. Generally this is a comparatively slow growing neoplasm.

Local spread

The tumour is limited to the bowel for a considerable time; it spreads round the intestinal wall and usually causes intestinal obstruction before it invades adjacent structures. The ulcerative type more commonly invades locally and an internal fistula may result, for example, into the bladder. There may also be a local perforation with an abscess or even an external faecal fistula. The progression of invasion occurs across the submucosa into the muscularis propria and thence out into the serosa and fat, lymphatics and veins in the mesentery alongside the bowel wall.

Lymphatic spread

Lymph nodes draining the colon are grouped as follows:

• N1 — nodes in the immediate vicinity of the bowel wall;
• N2 — nodes arranged along the ileo-colic, right colic, midcolic, left colic and sigmoid arteries;
• N3 — the apical nodes around the superior and inferior mesenteric vessels where they arise from the abdominal aorta. Involvement of the lymph nodes by the tumour progresses in a gradual manner from those closest to the growth along the course of the lymphatic vessels to those placed centrally.

Bloodstream spread

This accounts for a large proportion (30—40 per cent) of late deaths. Metastases are carried to the liver via the portal system sometimes at an early stage before clinical or operative evidence is detected (occult hepatic metastases).

Staging colon cancer. Dukes' classification was originally described for rectal tumours (see Chapter 60) but has been adopted for histopathological reporting of colon cancer as well. There have been numerous modifications of the original system leading to some confusion but in its most basic form Dukes' classification for colon cancer is as follows.

Dukes'

A — confined to bowel wall;
B — through the bowel wall but not involving the free peritoneal serosal surface;
C — lymph nodes involved.

Dukes himself never described a D stage, but this is often used to describe either advanced local disease or metastases to the liver.

TNM classification. The TNM classification is more detailed and accurate but more demanding.

T — tumour stage:
   — into submucosa;
   T2 — into muscularis propria;
   — into pericolic fat but-not breaching serosa;
   — breaches serosa or directly involving another organ.
N — nodal stage:
   N0 — no nodes involved;
   N1 — 1—2 nodes involved;
   N2 — 3 or more nodes.
M — metastases:
   — no metastases;
   — metastases.
Ly — lymphatic invasion:
   L0 — no lymphatic vessels involved;
   — lymphatics involved.
V — venous invasion:
   V0 — no vessel invasion;
   V1 — vessels invaded.
R — residual tumour:
   R0 — no residual tumour;
   — margins involved, residual tumour present.
Clinical features. Carcinoma of the colon usually occurs in patients over 50 years of age but it is not rare earlier in adult life. Twenty per cent of cases present as an emergency with intestinal obstruction or peritonitis. In any case of colonic bleeding in patients over the age of 40 a complete investigation of the colon is required. A careful family history should be taken. Those with first-degree relatives who have developed colorectal cancer at the age of 45 or below are at high risk and may be part of one of the colorectal cancer family syndromes.

Carcinoma of the left side of the colon

Most tumours occur in this location. They are usually of the stenosing variety. The main symptoms are those of increasing intestinal obstruction.

- **Pain** is referred to the suprapubic area. Patients will have episodes of colic; a constant ache may suggest an advanced tumour.

- **Alteration of bowel habit.** An adult previously having a predictably regular bowel habit suddenly develops irregularity. There may be increasing difficulty in getting the bowels to move, requiring laxatives. The episodes of constipation may be followed by attacks of diarrhoea.

- **Palpable lump.** The lump that is felt on abdominal, rectal or bimanual palpation is sometimes not the tumour itself, but impacted faeces above it. When the tumour is situated in a pendulous pelvic colon, a hard movable swelling may be felt in the rectovesical pouch on rectal examination.

- **Distension.** Lower abdominal distension is not uncommon and, as with the pain, is relieved by passing flatus.

Carcinoma of the sigmoid

This follows the general pattern of the above, with these differences.

- **Pain** is usually colicky from the outset.

- **Tenesmus.** Low tumours may give rise to a feeling of the need for evacuation which may result in tenesmus accompanied by the passage of mucus and blood, especially in the early morning.

- **Bladder symptoms** are not unusual and in some instances may herald a colovesical fistula.

Carcinoma of the transverse colon

This may be mistaken for a carcinoma of the stomach because of the position of the tumour together with anaemia and lassitude.

Carcinoma of the caecum and ascending colon

This may present with the following.

- Anaemia, severe and unyielding to treatment; there may be a palpable tumour present.

- The presence of a mass in the right iliac fossa. Colono-scropy may be needed to confirm the diagnosis.

- Caecal carcinoma is sometimes discovered unexpectedly at operation for acute appendicitis or for an appendix abscess failing to resolve. On rare occasions the appendix is inflamed, or even gangrenous, from the obstruction to its lumen by the tumour.

- A carcinoma of the caecum can be the apex of an intussusception presenting with the symptoms of intermittent obstruction.

Metastatic disease

Patients may present for the first time with liver metastases and an enlarged liver, ascitis from carcinomatosis peritonei and, more rarely, metastases to the lung, skin, bone and brain.

Methods of investigation

Sigmoidoscopy. This is part of the routine investigation of patients passing blood and mucus that is really limited to the rectum.

Flexible sigmoidoscopy. The 60-cm, fibre-optic, flexible sigmoidoscope is being used increasingly in the out-patient clinic or in special rectal bleeding clinics. The patient is pre-pared with a disposable enema and sedation is not usually necessary.

Colonoscopy. This has the advantage of not only picking up a primary cancer but also having the ability to detect synchronous polyps or even multiple carcinomas which occur in 5 per cent of cases. It tends to be used in patients with bleeding as their main presenting symptom, those with known polyps and those in whom there is doubtful radiology. Ideally every case should be proven histologically before surgery. Full bowel preparation and sedation are necessary.

Radiology. Double-contrast barium enema is used routinely now. It shows a cancer of the colon as a constant irregular filling defect (Fig. 57.43). It is the investigation of choice in patients with predominant change in bowel habit as their presenting symptom. Ultrasonography is often used as a screening investigation for liver metastases, and CT is used in patients with large palpable abdominal masses to determine local invasion and is particularly used in the pelvis in the assessment of rectal cancer.

Treatment

Preoperative preparation. Full mechanical bowel preparation before colonic surgery is essential. The most commonly used method is dietary restriction to fluids only for 48 hours before surgery; on the day before operation two sachets of Picolax (sodium picosulphate) are taken to purge the colon. In addition a rectal washout may be necessary. Alternatives include prograde lavage via a nasogastric tube using water or balanced electrolyte solutions. A stoma site is carefully discussed with the stoma care nursing specialist and antiembolus stockings are fitted; the patient is started on prophylactic sub-cutaneous heparin and intravenous prophylactic antibiotics are given at the start of surgery.

When intestinal obstruction is present, preparation in this way may precipitate abdominal pain and it may be safer to save preparation to the
time of the operation using an on table lavage technique.

**Operations**

*The test of operability.* The abdomen is opened and the tumour assessed for resectability.

1. The liver is palpated for secondary deposits, the presence of which is not necessarily a contraindication to resection because the best palliative treatment for carcinoma of the colon is removal of the tumour.

2. The peritoneum, particularly the pelvic peritoneum, is inspected for signs of small, white, seed-like, neoplastic implantations. Similar changes can occur in the omentum.

3. The various groups of lymph nodes that drain the involved segment are palpated. Their enlargement does not necessarily mean that they are invaded by metastases because the enlargement may be inflammatory.

4. The neoplasm is examined with a view to mobility and operability. Local fixation, however, does not always imply local invasion because some tumours excite a brisk inflammatory response.

The operations to be described are designed to remove the primary tumour and its draining locoregional lymph nodes which may be involved by metastases. Lesser resections are indicated, however, should hepatic metastases render the condition curable nonsurgically. There is some evidence that early division of major blood vessels supplying the involved colon (no-touch technique — Turnbull) can slightly improve the number of curative operations.

*Carcinoma of the caecum* or ascending colon (Fig. 57.44) is treated when resectable by right hemicolectomy (Fig. 57.45).

The abdomen is opened, the peritoneum lateral to the ascending colon is incised and the incision carried around the hepatic flexure. The right colon is elevated, with the leaf of peritoneum containing its vessels and lymph nodes, from the posterior abdominal wall, taking care not to injure the ureter, spermatic vessels in the male or the duodenum. The peritoneum is separated medially neat the origin of the ileo-colic artery, which is divided together with the right colic artery when this has a separate origin from the superior mesenteric. The mesentery of the last 30 cm of ileum, and the leaf of raised peritoneum attached to the caecum, ascending colon and hepatic flexure, after ligation of the mesenteric blood vessels, is divided as far as the proximal third of the transverse colon. When it is clear that there is an adequate blood supply at the resection margins, the right colon is resected and an end-to-end anastomosis fashioned between the ileum and transverse colon.

*Carcinoma of the hepatic flexure.* When the hepatic flexure is involved the resection must be extended correspondingly (Fig. 57.46).

*Carcinoma of the transverse colon.* When there is no obstruction, excision of the transverse colon and the two flexures together with the transverse mesocolon and the greater omentum, followed by end-to-end anastomosis, can be used. An alternative is an extended right hemicolectomy (Fig. 57.46), Carcinoma of the splenic flexure or descending colon. The extent of the resection is from right colon to descending colon. Sometimes removal of the colon up to the ileum, with an ileorectal anastomosis, is preferable.

*Carcinoma of the pelvic colon.* The left half of the colon is mobilised completely (Fig. 57.47). So that the operation is radical, the inferior mesenteric artery below its left colic branch, together with the related paracolic lymph nodes, must be included in the resection. This entails carrying the dissection as far as the upper third of the rectum. Many surgeons advocate flush ligation of the inferior mesenteric artery on the aorta (high litigation). Provided that there is no obstruction primary anastomosis is the rule. Occasionally a protecting upstream stoma may be necessary. The methods of dealing with large bowel obstruction as a result of colon cancer are described in Chapter 58.

*When a growth is found to be inoperable.* In the upper part of the left colon, a transverse colostomy is performed. In the pelvic colon, a left iliac fossa colostomy is preferable. With an inoperable growth in the ascending colon a bypass using an ileo-colic anastomosis is the best procedure. Over 95 per cent of colonic carcinomas can, however, be resected.

**Adjuvant therapy**

See Chapter 60.

**Hepatic metastases**

It is important to biopsy hepatic metastases for histological diagnosis. Unless they are on the very surface and edge of the liver, they are not usually resected at the time of colonic surgery. Patients with up to two or three liver metastases confined to one lobe of the liver may be offered hepatic resection. Multiple painful hepatic metastases can be palliated by cytotoxic drugs, cryosurgery or laser therapy (Fig. 57.48).
Other disorders

Traumatic rupture

The intestine can be ruptured with or without an external wound — so-called blunt trauma (Fig. 57.49). The most common cause of this is a blow on the abdomen which crushes the bowel against the vertebral column or sacrum; also a rupture is more likely to occur where part of the gut has been fixed, for example, in a hernia, or where a fixed part of the gut joins a mobile one such as the duodenojejunal flexure. Here the damage may be retroperitoneal and easily overlooked. In small perforations the mucosa may prolapse through the hole and partly seal it, making the early signs misleading. In addition there may be a laceration in the mesentery. The patient will then have a combination of intra-abdominal bleeding and release of intestinal contents into the abdominal cavity, giving rise to peritonitis.

Traumatic rupture of the large intestine is much less common. In blast injuries of the abdomen following the detonation of a bomb, the pelvic colon is particularly at risk of rupture. Compressed air rupture can follow the dangerous practical joke where an air-line carrying compressed air is turned on near the victim's anus.

Rupture of the upper rectum can occur during sigmoidoscopy and occasionally during the placement of rectal catheters for barium radiology. Traumatic rupture of the colon can occur during coloscopy. The most common site is the sigmoid colon where the formation of a sigmoid loop pushes against the antimesenteric border of the sigmoid colon, stretching it out and eventually perforating it.

Gun shot wounds and impalement injuries to the bowel have more serious consequences because of the introduction of debris from the patient's clothing or the missile itself mixing with the bacteria in the patient's gut. High-velocity missiles may cause extensive damage of the bowel over a much wider area than just the entry and exit wounds.

Treatment

Where rupture is suspected a plain radiograph in the erect or lateral decubitus position will demonstrate the presence of free air in the peritoneal cavity or indeed in the retroperitoneal tissues. In almost all cases an abdominal exploration must be performed and, in many instances, simple closure of the perforation is all that is required. In others, for example, where the mesentery is lacerated and the bowel is not viable, resection may be necessary. In the case of the large intestine small clean tears can be closed primarily, if there is a large tear with damage to the surrounding structures to the adja-cent mesentery resection, exteriorisation may be used. Much depends on the amount of intra-abdominal soiling.

In the case of retroperitoneal portions of the intestine, for example, the duodenum, perforations can involve the front and back walls and the duodenum in particular has to be carefully mobilised to check that a concealed tear is not over-looked. In all cases the abdomen is washed out with saline and broad-spectrum intravenous antibiotics are given.

Pneumatosis cystoides intestina lis

This is a rare condition in which gas-filled cysts are found in the sub-serosa or submucosa of the small intestine or colon. They ate usually translucent, thin-walled, range in size between 1 and 2 cm and contain gas, mainly nitrogen, but also an increased content of hydrogen, and have a lining of flattened cells. The cause is not known; there is an association with chronic obstructive pulmonary disease but an increased local production of intestinal gas is a more probable cause. It has been seen in patients with necrotising enteritis, enteroctitis and diverticulitis. The cysts ate usually symptomless but occasionally can give rise to intestinal obstruction and rectal bleeding, diarrhoea or mucus in the stool. The cysts may be recognised at sigmoidoscopy or seen on plain abdominal films, barium studies (Fig. 57.50) and even CT scans. Management of the uncomplicated primary disease is conservative. When symptoms demand treatment the first line is intermittent high-flow oxygen therapy providing a concentration of 70 per cent continuously for 5 days by nasal specula. The cysts may also resolve with antibiotic treatment, particularly metronidazole. In resistant cases maintenance treatment with sulphasalazine may be helpful.

Enterocutaneous or faecal fistula

An external fistula communicating with the caecum some-times follows an operation for gangrenous appendicitis or the draining of an appendix abscess. A faecal fistula can occur from necrosis of a gangrenous patch of intestine after the relief of a strangulated hernia, or from a leak from an intestinal anastomosis. The opening of an abscess connected with chronic diverticulitis or carcinoma of the colon frequently results in faecal fistula. Radiation damage is also another cause of fistula formation. The most common cause of enterocutaneous fistula is, however, previous surgery. This happens most often in patients with adhesions following previous operations. Damage to the small intestine occurs inad-vertently during dissection of the adhesions and, because of an associated subacute obstruction or abscess, the fistula 'blows' postoperatively.

Enterocutaneous fistulae can be divided into:

- those with a high output, more than 1 litre/day;
- those with a low output, less than 1 litre/day.

They can also be described anatomically as simple, with a direct communication between the gut and the skin, or complex, that is, those with one or more tracts that are tortuous and sometimes associated with an intervening abscess cavity half-way along the tract.

The discharge from a fistula connected with the duodenum or jejunal is bile stained and causes severe excoriation of the skin. When the ileum or caecum is involved the discharge is fluid faecal matter; when the distal colon is the affected site it is solid or semisolid faecal matter. The site of leakage and the length of the fistula can be determined by small bowel enema and barium enema, by fistulography and most importantly CT of the abdomen will show up any associated abscesses (Fig. 57.51).

Treatment

This can be very challenging in patients with a high-output fistula. Low-output fistulae can be expected to heal spontaneously, provided there is no obstruction beyond the fistula opening. Reasons for failure of spontaneous healing also include:

- epithelial continuity between the gut and the skin;
- the presence of active disease where, for example, there is Crohn's disease or carcinoma at the site of the anastomosis or in the tract;
- an associated complex abscess.

The abdominal wall must be protected from erosion by the use of appliances. The patient must remain nil by mouth, intravenous nutrition is
started and signs of a decrease in the fistula output are sought. The higher the fistula in the intestinal tract the more skin excoriation must be expected, and this is worst in the case of a duodenal fistula. High-output fistulae cause rapid dehydration and hypoproteinaemia. Vigorous fluid replacement and nutritional support are essential. The drainage of an intra-abdominal abscess can be life saving. This can be achieved by either CT-guided drainage or occasionally laparotomy. In patients with a complex fistula it may be necessary to bring out a defunctioning stoma upstream of the fistula site, even if this results in a high-output stoma.

Treatment with a somatostatin analogue (octreotide) may be useful in these cases to reduce fistula output and stoma output.

**Operative treatment**

Operative repair should only be attempted after a trial of conservative management. The surgery can on occasion be technically extremely demanding and anastomosis should not be fashioned in the presence of continuing intra abdominal sepsis or when the patient is hypoproteinaemic.
Stomas

Colostomy

A colostomy is an artificial opening made in the large bowel to divert faeces and flatus to the exterior, where it can be collected in an external appliance. Depending on the purpose for which the diversion has been necessary a colostomy may be temporary or permanent.

Temporary colostomy

This is most commonly established to defunction an anastomosis after an anterior resection, to prevent faecal peritonitis developing following traumatic injury to the rectum or colon, and to facilitate the operative treatment of a high fistula in ano. It is now less commonly used for patients with distal obstruction of the sigmoid colon as a result of carcinoma or diverticular disease.

A temporary colostomy is made bringing a loop of colon to the surface (loop colostomy) where it is held in place by a plastic bridge passed through the mesentery. Once the abdomen has been closed the colostomy is opened and the edges of the colonic incision are sutured to the adjacent skin margin (Fig. 57.52). When firm adhesion of the colostomy to the abdominal wall has taken place, after 7 days the bridge can be removed.

A loop of colon can most easily be brought to the surface using large bowel that has a mesentery. Most loop colostomies are made in the transverse colon but the sigmoid colon can also be suitable. Following the surgical cure or healing of the distal lesion for which the temporary stoma was constructed, the colostomy can be closed. It is usual to perform a contrast examination (distal loopogram) to check that there is no distal obstruction or continuing problem at the site of previous surgery. Colostomy closure is most easily and safely accomplished if the stoma is mature, that is, after the colostomy has been established for 2 months. Closure is usually performed by an intraperitoneal technique which is accompanied by fewer closure breakdowns with faecal fistulae.

Double-barrelled colostomy

This colostomy was designed so that it could be closed by crushing the intervening ‘spur’ using an enterotome or a stapling device. It is rarely used now but occasionally the colon is divided so that both ends can be brought separately to the surface ensuring that the distal segment is completely defunctioned.

Permanent colostomy

This is usually formed after excision of the rectum for a carcinoma by the abdominoperineal technique.

It is formed by bringing the distal end (end colostomy) of the divided colon to the surface in the left iliac fossa, where it is sutured in place joining the colonic margin to the surrounding skin.

The point at which the colon is brought to the surface must be carefully selected to allow a colostomy bag to be applied without impinging on the bony prominence of the antero-superior iliac spine. The best site is usually through the lateral edge of the rectus sheath, 6 cm above and medial to the bony prominence (Fig. 57.53).

An important point after the colostomy has been made is to close the lateral space between the intraperitoneal segment of the sigmoid colon and the peritoneum of the pelvic wall, to prevent internal herniation of strangulation of loops of small bowel through the deficiency. Alternatively a retroperitoneal tunnel for the colostomy avoids creating lateral space.

Colostomy bags and appliances (Fig. 57.54)

Faeces from a permanent colostomy are collected in disposable adhesive bags. A wide range of such bags is currently available. Many now incorporate a stomahesive backing, which can be left in place for several days. In most hospitals a stoma care service is available to offer advice to patients and to acquaint them with the latest appliances, and the appropriate psychological and practical help.

Complications of colostomies

The following complications can occur to any colostomy but are more common after poor technique:

- prolapse;
- retraction;
- necrosis of the distal end;
- stenosis of the orifice;
- colostomy hernia;
- bleeding (usually from granulomas around the margin of the colostomy);
- colostomy ‘diarrhoea’: this is usually an infective enteritis and will respond to oral metronidazole 200 mg three times daily.

Many of these complications require revision of the colostomy. Sometimes this can be achieved with an incision immediately around the stoma but on occasion reopening the abdomen and freeing up the colostomy may be necessary. Occasionally transfer to the opposite side of the abdomen may be necessary.

Loop ileostomy

An ileostomy is used by some surgeons as an alternative to colostomy, particularly for defunctioning a low rectal anastomosis. The creation of a loop ileostomy from a knuckle of terminal ileum has already been described. The advantages of a loop ileostomy over a loop colostomy are the ease with which the bowel can be brought to the surface and the absence of odour. Care is needed, when the ileostomy is closed, that suture line obstruction does not occur.
Caecostomy

This is rarely used now. In desperately ill patients with advanced obstruction, a caecostomy may be useful. In late cases of obstruction the caecum may become so distended and ischaemic that rupture of the caecal wall may be anticipated. This can occur spontaneously giving rise to faecal peritonitis or at operation when an incision in the abdominal wall reduces its supportive role and allows the caecum to expand. In such a situation it should be decompressed by suction as soon as the abdomen is opened. In thin patients it may then be possible to carry out direct suture of the incised or perforated caecal wall to the abdominal skin of the right iliac fossa, although a resection of this area is really the best treatment. Following on-table lavage, via the appendix stump the irrigating catheter can be left in place as a tube caecostomy. Caecostomy is only a short-term measure to allow a few days for the condition of the patient to improve. Reoperation should normally follow fairly soon thereafter and a proper surgical procedure carried out.

Introduction

Intestinal obstruction may be classified into two types.

• **Dynamic** — where peristalsis is working against a mechanical obstruction. The obstructing lesion may be:
  — intraluminal, for example impacted faeces, foreign bodies, bezoar, gallstones;
  — intramural, for example malignant or inflammatory strictures;
  — extramural, for example intraperitoneal bands and adhesions, hernias, volvulus or intussusception.

• **Adynamic** — this may occur in two forms. Peristalsis may be absent (e.g. paralytic ileus) or it may be present in a non-propulsive form (e.g. mesenteric vascular occlusion or pseudo-obstruction). In both types a mechanical element is absent.
Dynamic obstruction

The diagnosis of intestinal obstruction is based on the classic quartet of pain, distension, vomiting and absolute constipation.

Obstruction may be classified clinically into two types:

• small bowel obstruction — high or low;
• large bowel obstruction.

In high small bowel obstruction vomiting occurs early and is profuse with rapid dehydration. Distension is minimal with little evidence of fluid levels on abdominal radiography.

In low small bowel obstruction pain is predominant with central distension. Vomiting is delayed. Multiple central fluid levels are seen on radiography.

In large-bowel obstruction distension is early and pronounced. Pain is mild and vomiting and dehydration are late. The proximal colon and caecum are distended on an abdominal radiograph.

The nature of presentation will also be influenced by whether the presentation is:

• acute;
• chronic;
• acute on chronic;
• subacute.

Acute obstruction usually occurs in small bowel obstruction with sudden onsets of severe colicky central abdominal pain, distension, with early vomiting and constipation.

Chronic obstruction is usually seen in large bowel obstruction with lower abdominal colic and absolute constipation, followed by distension.

In acute on chronic obstruction there is a short history of distention and vomiting against a background of pain and constipation.

Subacute obstruction implies an incomplete obstruction. Presentation will be further influenced by whether the obstruction is:

• simple — where the blood supply is intact;
• strangulating/strangulated — where there is direct interference to blood flow, usually by hernial rings or intra-peritoneal adhesions/bands.

The common causes of intestinal obstruction in Western countries and their relative frequency are shown in Fig. 58.1. The underlying mechanisms are shown in Table 58.1.

Pathophysiology

Irrespective of aetiology or acuteness of onset, the proximal bowel dilates and develops an altered motility. Below the obstruction, the bowel exhibits normal peristalsis and absorption until it becomes empty, when it contracts and becomes immobile. Initially, proximal peristalsis is increased to overcome the obstruction, with the length of time it remains vigorous being proportional to the distance of the obstruction. If the obstruction is not relieved the bowel begins to dilate causing a reduction in peristaltic strength, ultimately resulting in flaccidity and paralysis. This is a protective phenomenon to prevent vascular damage secondary to increased intraluminal pressure.

The distension proximal to an obstruction is produced by two factors:

• Gas — regardless of the level of obstruction, there is a significant overgrowth of both aerobic and anaerobic organisms resulting in considerable gas production. Following the reabsorption of oxygen and carbon dioxide, the majority is made up of nitrogen (90 per cent) and hydrogen sulphide.

• Fluid — this is made up of the various digestive juices (Table 58.2). Following obstruction, fluid accumulates within the bowel wall and any excess is secreted into the lumen, whilst absorption from the gut is retarded. Dehydration and electrolyte loss are therefore due to:
  — reduced oral intake;
  — defective intestinal absorption;
  — losses due to vomiting;
  — sequestration in the bowel lumen.

Strangulation

When strangulation occurs the viability of the bowel is threatened secondary to a compromised blood supply. This may be due to:

• external compression (hernial orifices/adhesions/bands);
• interruption of mesenteric flow (volvulus, a twist of bowel loop on its mesenteric pedicle or intussusception where a segment of bowel invaginates into an adjacent segment);
• rising intraluminal pressure (closed-loop obstruction);
• primary obstruction of intestinal circulation (mesenteric infarction).

The venous return is compromised before the arterial supply unless primary obstruction is present. The resultant increase in capillary pressure leads to local mural distension with loss of intravascular fluid and red blood cells intramurally and intra-and extraluminally. Once the arterial supply is impaired, haemorrhagic infarction occurs. As the viability of the bowel wall is compromised there is marked translocation and
systemic exposure to aerobic and anaerobic organisms with their associated toxins. The associated danger is far greater for intraperitoneal strangulation than that of an external hernia where there is a smaller absorptive surface.

The morbidity and mortality associated with strangulation are dependent on age and extent. In strangulated external hernias the segment involved is short and the resultant blood and fluid loss is small. When bowel involvement is extensive the loss of blood and circulatory volume will cause peripheral circulatory failure.

**Closed-loop obstruction**

This occurs when the bowel is obstructed at both the proximal and distal point (Fig. 58.2). It is present in many cases of intestinal strangulation. Unlike cases of nonstrangulating obstruction, there is no early distension of the proximal intestine. When gangrene of the strangulated segment is imminent, retrograde thrombosis of the mesenteric veins results in distension on both sides of the strangulated segment.

A classic form of closed-loop obstruction is seen in the presence of a tight carcinomatous stricture of the colon with a competent ileocaecal valve (present in up to a third of individuals). The inability of the distended colon to decompress itself into the small bowel results in an increase in luminal pressure, greatest at the caecum, with subsequent impairment of blood supply. Unrelieved, this results in necrosis and perforation (Fig. 58.3).
Acute intestinal obstruction

Clinical features

There are four cardinal features:

- pain;
- vomiting;
- distension;
- constipation.

These features vary according to:

- the location of the obstruction;
- the age of the obstruction;
- the underlying pathology;
- the presence or absence of intestinal ischaemia.

Late manifestations which may be encountered include dehydration, oliguria, hypovolaemic shock, pyrexia, septicaemia, respiratory embarrassment and peritonism. In all cases of suspected intestinal obstruction, all hernial orifices must be examined.

Pain

Pain is the first symptom, it occurs suddenly and is usually severe. It is colicky in nature and is usually centred around the umbilicus (small bowel) or lower abdomen (large bowel). The pain coincides with increased peristaltic activity. With increasing distension, the colicky pain is replaced by a mild constant diffuse pain. The development of severe pain is indicative of the presence of strangulation. Pain may not be a significant feature in postoperative simple mechanical obstruction and does not occur in paralytic ileus.

Vomiting

The more distal the obstruction, the longer the interval between the onset of symptoms and the appearance of nausea and vomiting. As obstruction progresses the character of the vomitus alters from digested food to faeculent material due to the presence of enteric bacterial overgrowth.

Distension

In the small bowel the degree of distension is dependent on the site of the obstruction and is greater the more distal the lesion. Visible peristalsis may be present (Fig. 58.4). It is delayed in colonic obstruction and may be minimal or absent in the presence of mesenteric vascular occlusion.

Constipation

This may be classified as absolute (i.e. neither faeces nor flatus is passed) or relative (where flatus only is passed). Absolute constipation is a cardinal feature of complete intestinal obstruction. Some patients may pass flatus or faeces after the onset of obstruction owing to the evacuation of distal bowel contents.

The rule that constipation is present in intestinal obstruction does not apply in:

- Richter's hernia;
- gallstone obturation;
- mesenteric vascular occlusion;
- obstruction associated with a pelvic abscess;
- partial obstruction (faecal impaction/colonic neoplasm) where diarrhoea may often occur.

Other manifestations

Dehydration

This is seen most commonly in small bowel obstruction due to repeated vomiting and fluid sequestration. This results in dry skin and tongue, poor venous filling and sunken eyes with oliguria. The blood urea level and haematocrit rise giving a secondary polycythaemia.

Hypokalaemia

This is not a common feature in simple mechanical obstruction. An increase in serum potassium, amylase or lactate dehydrogenase may be associated with the presence of strangulation, as may leucocytosis or leucopenia.

Pyrexia in the presence of obstruction may indicate:

- the onset of ischaemia;
- intestinal perforation;
- inflammation associated with the obstructing disease.

Hypothermia indicates septicaemic shock.

Abdominal tenderness

Localized tenderness indicates pending or established ischaemia. The development of peritonism or peritonitis indicates overt infarction and/or
Clinical features of strangulation

It is vital to distinguish strangulating from nonstrangulating intestinal obstruction, as the former is a surgical emergency. The diagnosis is entirely clinical. In addition to the features outlined above, the following should be noted:

- the presence of shock indicates underlying ischaemia;
- in impending strangulation, pain is never completely absent;
- symptoms usually commence suddenly and recur regularly;
- the presence and character of any local tenderness are of great significance and, however mild, tenderness requires frequent reassessment.

In nonstrangulated obstruction there may be an area of localized tenderness at the site of the obstruction; in strangulation there is always localized tenderness associated with rigidity/rebound tenderness.

- Generalized tenderness and the presence of rigidity are indicative of the need for early laparotomy.
- In cases of intestinal obstruction where pain persists despite conservative management, even in the absence of the above signs, strangulation should be diagnosed.
- When strangulation occurs in an external hernia the lump is tense, tender, irreducible, there is no expansile cough impulse and it has recently increased in size.

Radiological diagnosis

Erect abdominal films are no longer routinely provided and the radiological diagnosis is based on a supine abdominal film (Fig. 58.5).

- When distended with gas the jejunum, ileum, caecum and remaining colon have a characteristic appearance that allows them to be distinguished radiologically. The diameter of the distended viscus is not diagnostic.
  - The obstructed small bowel is characterized by straight segments that are generally central and lie transversely. No gas is seen in the colon.
  - The jejunum is characterized by its valvulae conniventes that completely pass across the width of the bowel and are regularly spaced giving a ‘concertina’ or ladder effect.
  - Ileum — the distal ileum has been piquantly described by Wangensteen as featureless.
  - Caecum — a distended caecum is shown by a rounded gas shadow in the right iliac fossa.
  - Large bowel — except for the caecum shows haustral folds which, unlike valvulae conniventes, are spaced irregularly and the indentations are not placed opposite one another.

Volvulus of the sigmoid colon has a characteristic radiological appearance with a grossly dilated loop of colon, with or without visible hastrae which arises from the pelvis and extends obliquely across the spine to the upper abdomen.

- In intestinal obstruction fluid levels appear later than gas shadows as it takes time for gas and fluid to separate (Fig. 58.6). In infants less than 2 years of age, a few fluid levels in the small bowel may be physiological. In adults, two inconstant fluid levels may be regarded as normal — one at the duodenal cap and the other in the terminal ileum.

During the obstructive process, fluid levels become more conspicuous and more numerous when paralysis has occurred. When fluid levels are pronounced the obstruction is advanced. In the small bowel, the number of fluid levels is directly proportional to the degree of obstruction and to its site; the number increasing the more distal the lesion.

- In contrast, low colonic obstruction does not commonly give rise to small bowel fluid levels unless advanced, whilst high colonic obstruction may do in the presence of an incompetent ileocaecal valve. Colonic obstruction is usually associated with a large amount of gas in the caecum. A limited water-soluble enema may be undertaken to differentiate large bowel obstruction from pseudo-obstruction. A barium follow-through is contraindicated in the presence of acute obstruction and may be life threatening.

- Impacted foreign bodies may be seen on abdominal radiographs. In gallstone ileus, gas may be seen in the biliary tree with the stone visible, usually in the right iliac fossa, in 25 per cent of cases.

It is noteworthy that gas-filled loops and fluid levels in the small and large bowel can also be seen in established paralytic ileus and pseudo-obstruction. The former can, however, normally be distinguished on clinical grounds whilst the latter can be confirmed radiologically. Fluid levels may also be seen in non obstructing conditions such as inflammatory bowel disease, acute pancreatitis and intra-abdominal sepsis.
**Treatment of acute intestinal obstruction**

There are **three** main measures:

- gastrointestinal drainage;
- fluid and electrolytic replacement;
- relief of obstruction, usually surgical.

The first **two** steps are always necessary prior to the surgical relief of obstruction and are the mainstay of post-operative management. In a proportion of cases, particularly adhesive obstruction, they may be used exclusively.

Surgical treatment is necessary for most cases of intestinal obstruction, but should be delayed until resuscitation is complete, provided there is no:

- sign of strangulation;
- evidence of closed-loop obstruction.

There are three principles of surgical intervention (**Table 58.3**).

**Supportive management**

- Nasogastric decompression is achieved by the passage of a nonvented (Ryle) or vented (Salem) tube. The tubes are normally placed on free drainage, with 4-hourly aspiration, but may be placed on continuous or intermittent suction. As well as facilitating decompression proximal to the obstruction, they also reduce the risk of subsequent aspiration during induction of anaesthesia and postextubation.

- The basic biochemical abnormality is sodium and water loss, and therefore the appropriate replacement is Hartmann’s solution or normal saline. The volume required varies and should be determined by clinical haematological and biochemical criteria.

- Antibiotics — whilst not mandatory, many clinicians initiate broad-spectrum antibiotic early in therapy because of bacterial overgrowth. Antibiotic therapy is mandatory for all patients undergoing small or large bowel resection.

**Surgical treatment**

The timing of surgical intervention is dependent on the clinical picture with the indications of early operation being:

- obstructed or strangulated external herniae;
- internal intestinal strangulation;
- acute obstruction.

The classic clinical advice that ‘the sun should not both rise and set’ on a case of unrelieved intestinal obstruction is sound and should be followed unless there are positive reasons for delay. Such cases may include obstruction secondary to adhesions where there is no pain or tenderness, despite continued radiological evidence of obstruction. Under these circumstances, conservative management may be continued for up to 72 hours in the hope of spontaneous resolution.

If the site of obstruction is unknown, adequate exposure is best achieved by a midline incision. Operative assessment is directed to:

- the site of obstruction;
- the nature of the obstruction;
- the viability of the gut.

Identification and assessment of the caecum is the best initial manoeuvre. If it is collapsed, the lesion is in the small bowel and may be identified by careful retrograde assessment. A dilated caecum indicates large bowel obstruction. To display the cause of obstruction, distended loops of small bowel should be displaced with care and covered with warm moist abdominal packs.

**Operative decompression** may be required if dilatation of bowel loops prevents exposure, the viability of the bowel wall is compromised or subsequent closure will be compromised. Its benefits should be balanced against potential risk of septic complications from spillage. Decompression may be performed using Savage’s decompressor within a seromuscular purse-string suture (**Fig. 58.7**). Alternatively, with a large-bore nasogastric tube in place the small bowel contents may be gently milked in a retrograde manner to the stomach for aspiration. All volumes of fluid removed should be accurately measured and appropriately replaced.

The type of surgical procedure required will depend upon the nature of the cause — division of adhesions (enterolysis), excision, bypass or proximal decompression.

Following relief of obstruction, the viability of the involved bowel should be carefully assessed (see **Table 58.4**). Whilst frankly infarcted bowel is obvious, the viability status in many cases may be difficult to discern. If in doubt, the bowel should be wrapped in hot packs for 10 minutes with increased oxygenation and reassessed. The state of the mesenteric vessels and pulsation in adjacent arcades should be sought. Nevertheless, nonocclusive vascular insufficiency may occur despite adequate pulsation. In doubtful cases, following resection, both ends of the bowel should be raised as stomas. This is not only safe but also allows regular assessment of the bowel. Where no resection has been undertaken or there are multiple ischaemic areas (mesenteric vascular occlusion) a second look laparotomy at 24—48 hours may be required.

Special attention should always be paid to the sites of constriction at each end of an obstructed segment. If of doubtful viability they should be infolded by the use of a seromuscular suture and covered with omentum.

The surgical management of massive infarction in the form of superior mesenteric artery occlusion is dependent on the patient’s overall prognostic criteria. In the elderly, infarction of the small bowel from the duodenojejunal flexure and the right colon may be considered incurable, whilst in the young, with potential for long-term intravenous alimentation and small bowel transplantation, a less conservative policy may be justified. Whenever small bowel is resected, the exact site of resection, the length of the resected segment and that of the residual bowel should be recorded.
Large bowel obstruction

This is usually due to underlying carcinoma or occasionally diverticular disease, and presents in an acute or chronic form. The condition of pseudo-obstruction should always be considered and excluded by a limited contrast study or air computerised tomography (CT) scan to confirm organic obstruction.

After full resuscitation the abdomen should be opened through a midline incision. Distension of the caecum will confirm large bowel involvement. Identification of a collapsed distal segment of the large bowel and its sequential proximal assessment will readily lead to identification of the cause. When a removable lesion is found in the caecum, ascending colon, hepatic flexure or proximal transverse colon an emergency right hemicolectomy should be performed. If the lesion is irremovable, a proximal stoma (colo-stomy or ileostomy if the ileocaecal valve is incompetent) or ileotransverse bypass should be considered. Obstructing lesions at the splenic flexure should be treated by an extended right hemicolectomy with ileodescending colonic anastomosis.

For obstructing lesions of the left colon or rectosigmoid junction, immediate resection should be considered unless there are clear contraindications such as:
- inexperienced surgeon;
- moribund patient;
- advanced disease.

In rare instances, or where caecal perforation is imminent, time to improve the patient’s clinical condition can be bought by performing an emergency caecostomy (or ileostomy in the presence of an incompetent ileocaecal valve).

In the absence of senior clinical staff, it is safest to bring the proximal colon to the surface as a colostomy. Where possible the distal bowel should be brought out at the same time (Paul—Mikulicz procedure) to facilitate subsequent extraperitoneal closure. In the majority of cases the distal bowel will not reach and is closed and returned to the abdomen (Hartmann’s procedure). A second-stage colorectal anastomosis can be planned when the patient is fit.

If an anastomosis is to be considered using proximal colon, in the presence of obstruction, it must be decompressed and cleaned by an on-table colonic lavage. Nevertheless, the subsequent anastomosis should still be protected with a covering stoma.

Obstruction by adhesions and bands

In Western countries where abdominal operations are common, adhesions and bands are the commonest cause of intestinal obstruction. Furthermore, in the early postoperative period, the onset of such a mechanical obstruction may be difficult to differentiate from paralytic ileus.

The causes of intraperitoneal adhesions are shown in Table 58.5.

Any source of peritoneal irritation results in local fibrin production which produces adhesions between opposed surfaces. Early fibrinous adhesions may disappear when the cause is removed or they may become vascularised and replaced by mature fibrous tissue.

Prevention. The following factors may limit adhesion formation:
- good surgical technique;
- washing of the peritoneal cavity with saline to remove clots, etc.;
- minimize contact with gauze;
- cover anastomosis and raw peritoneal surfaces.

Numerous substances have been instilled in the peritoneal cavity to prevent adhesion formation, including hyaluronidase, hydrocortisone, silicone, dextran, polyvinylpyrrolidone (PVP), chondroitin and streptomycin, anticoagulants, antihistamines, nonsteroidal anti-inflammatory drugs and streptokinase. Currently no single agent has been shown to be safe and effective, and their use is not recommended.

Adhesions may be classified into various types by virtue of whether they are early (fibrinous) or late (fibrous) or by the underlying aetiology.

From a practical perspective, there are only two types — ‘easy’ flimsy ones and ‘difficult’ dense ones.

Postoperative adhesions giving rise to intestinal obstruction usually involve the lower small bowel. Operations for appendicitis and gynaecological procedures are the most common precursors and are an indication for early intervention.

Usually only one band is culpable. This may be:
- congenital, for example obliterated vitellointestinal duct;
- a string band following previous bacterial peritonitis;
- a portion of greater omentum usually adherent to the parietes.

Treatment. Initial management is based on intravenous rehydration and nasogastric decompression. Occasionally it is curative. Whilst an initial conservative regime is considered appropriate, regular assessment is mandatory to ensure that strangulation does not occur.

Conservative treatment should not be prolonged beyond 72 hours.

When, as is usual, laparotomy is required, although multiple adhesions may be found, only one may be causative. This should be divided and the remaining adhesions left in situ unless severe angulation is present. Division of these adhesions will only cause further adhesion formation.

When obstruction is caused by an area of multiple adhesions, they should be freed by sharp dissection. To prevent recurrence the bate area should be covered with omental grafts.

Following release of band obstruction, the constriction sites that have suffered direct compression should be carefully assessed and if they show residual colour changes, invaginated.

Treatment of recurrent intestinal obstruction due to adhesions

Several procedures may be considered in the presence of recurrent obstruction, including:
- repeat adhesiodyesis (enterolysis) alone;
- Noble’s plication operation;
- Charles—Phillips transmesenteric plication;
In Noble’s intestinal plication (Fig. 58.8) all involved intestine is freed. Adjacent coils (average length 15—20 cm) are sutured with serosal sutures to form gentle curves. If only a proportion of the small bowel is plicated, the mesentery must be united to prevent internal hernias. This procedure is time-consuming, and associated with a high morbidity and recurrent symptoms.

In the Charles—Phillips operation (Fig. 58.9), following adhesiolyis, the bowel is placed in an orderly fashion and three long synthetic sutures are passed through the mesentry of the plicated bowel, each doubled back upon itself and tied loosely. The stitch should pass a few centimetres from the bowel wall and not be adjacent to it. The resultant bowel should look like a packet of sausages. Results from this procedure are relatively good.

Intraluminal tube insertion (Baker), via a Witzel jejunostomy or gastrostomy, may facilitate the formation of gentle curves. Most tubes have an inflatable balloon near the tip to facilitate placement within the caecum. This procedure is associated with a long postoperative ileus, and reports of outcome are conflicting (Figs 58.10 and 58.11).

Postoperative intestinal obstruction

Differentiation between persistent paralytic ileus and early mechanical obstruction may be difficult in the early post-operative period. In practice, the latter is probably more common. Early evidence of obstruction (days 1—5) is usually due to nonstrangulating causes such as fibrinous adhesions and oedema. Obstruction is usually incomplete and the majority settles with continued conservative management. Late postoperative obstruction (greater than 7 days) is usually more significant in nature and timely surgical intervention is usually required.

Special types of mechanical intestinal obstruction

Internal hernia

Internal herniation occurs where a portion of the small intestine becomes entrapped in one of the retroperitoneal fossae or into a congenital mesenteric defect.

The following are potential sites of internal herniation:

• the foramen of Winslow;
• a hole in the mesentery;
• a hole in the transverse mesocolon;
• defects in the broad ligament;
• congenital or acquired diaphragmatic hernia;
• duodenal retroperitoneal fossa — left para duodenal and right duodenojejunal;
• caecal/appendiceal retroperitoneal fossa — superior, inferior and retrocaecal;
• intersigmoid fossa.

Internal herniation in the absence of adhesions is uncommon and a preoperative diagnosis is unusual. The standard treatment for a hernia is to release the constricting agent by division. This should not be undertaken in cases of herniation involving the foramen of Winslow, mesenteric defects and the para duodenal/duodenojejunal fossae as major blood vessels run in the edge of the constriction ring. The distended loop in such circumstances must first be decompressed with minimal contamination and then reduced.

Obstruction from enteric strictures

Small bowel strictures usually occur secondary to tuberculosis or Crohn’s disease. Malignant strictures associated with lymphoma are common, whilst carcinoma and sarcoma are rare. Presentation is usually subacute or chronic. Standard surgical management consists of resection and anastomosis. In Crohn’s disease stricureplasty may be considered in the presence of short multiple strictures without active sepsis.

Bolus obstruction

Bolus obstruction in the small bowel may be caused by food, gallstones, trichobezoar, phytobezoar, stercoliths and worms.

Gallstones. These tend to occur in the elderly secondary to erosion of a large gallstone through the gall bladder into the duodenum. Classically, there is impaction about 60 cm proximal to the ileocaecal valve. The patient may have recurrent attacks as the obstruction is frequently incomplete or relapsing due to a ball-valve effect. A radiograph will show evidence of small bowel obstruction with a diagnostic air—fluid level in the biliary tree. The stone may or may not be visible. At laparotomy it may be possible to crush the stone within the bowel lumen if it is soft, after milking it proximally. If not, the intestine is opened and the gallstone disimpacted, milked back and removed. If the gallstone is faceted a careful check for other enteric stones should be made. The region of the gall bladder should not be explored.

Food. Bolus obstruction may occur after partial or total gastrectomy when unchewed articles can pass directly into small bowel. Apple, coconut, brussels sprouts, dried fruit and orange pips are particularly liable to cause obstruction. The management is similar to a gallstone with intraluminal crushing usually being successful.

Trichobezoars and phytobezoar. These are firm masses of undigested hair balls and fruit/vegetable fibre, respectively. The former is due to persistent hair chewing and sucking, and may be associated with an underlying psychiatric abnormality. Phytobezoars are predisposed to by high fibre intake, inadequate chewing, previous gastric surgery, hypo-chlorhydria and loss of gastric pump mechanism. Where possible, the lesion may be kneaded into the caecum, otherwise open removal is required.

Stercoliths. Usually found in the small bowel in association with a jejunal diverticulum or ileal stricture. Presentation and management are identical to gallstones.

Worms. Ascaris lumbricoides may cause low small bowel obstruction particularly in children, the institutionalized and those near the tropics (Fig. 58.12). An attack frequently follows initiation of anthelmintic therapy. Debilily is frequently out of proportion to that produced by the obstruction. If worms are not seen in stool or vomitus, the diagnosis may be indicated by eosinophilia or the sight of worms within gas-filled small bowel loops on a plain radiograph (Naik). At laparotomy it may be possible to knead the tangled mass into the caecum; if not it should be removed. Occasionally worms may cause a perforation and peritonitis, especially if the enteric wall is already weakened by such conditions as
ameobiasis.

**Acute intussusception**

This occurs when one portion of the gut becomes invaginated within an immediately adjacent segment; invariably it is the proximal into distal bowel.

**Aetiology.** The condition is encountered most commonly in children, where it occurs in an idiopathic form with a peak incidence at 3—9 months. Seventy to 95 per cent of cases are classed as idiopathic, and an associated illness such as gastro-enteritis or urinary tract infection is found in 30 per cent. It is believed that hyperplasia of Peyer's patches in the terminal ileum may be the initiating event. This may occur secondary to weaning. In light of the seasonal variation with peak incidence in spring and summer, it may be related to upper respiratory tract infection pathogens such as adenovirus or rotavirus.

Children with intussusception associated with a lead point

— such as Meckel's diverticulum, polyp, duplication, Henoch—Schönlein purpura or appendix — are usually older than the idiopathic cases. Adult cases are invariably associated with a lead point which is usually a polyp (e.g. Peutz—Jegher syndrome), a submucosal lipoma or tumour, the exception being after periods of long fasting (Moro). The colocolic variety is common in adults.

Pathology. An intussusception is composed of three parts (Fig. 58.13):

- the entering or inner tube;
- the returning or middle tube;
- the sheath or outer tube (intussuscipiens).

The part which advances is the apex; the mass is the intussusception and the neck is the junction of the entering layer with the mass.

An intussusception is an example of strangulating obstruction as the blood supply of the inner layer is usually impaired. The degree of ischaemia depends on the tightness of the invagination, which is usually greatest as it passes through the ileocaecal valve.

Intussusception may be anatomically defined as ileo-ileal, ileo-caecal and ileo-colic depending on the site and extent of invagination (Table 58.6).

Clinical features. The presentation of intussusception in a child is classical. An otherwise fit and well male child of 6 months develops sudden onset of screaming associated with drawing up of the legs. The attacks last for a few minutes, recur every 15 minutes and become progressively severe. During attacks the child has facial pallor whilst between episodes he is listless and drawn.

Vomiting may or may not occur at the outset but becomes conspicuous with time. Initially the passage of stool may be normal, whilst later blood and mucus are evacuated — the 'redcurrent' jelly stool.

Examination should be undertaken, wherever possible, between episodes without disturbing the child. Classically, the abdomen is not distended, a lump may be felt which hardens on palpation but this is present in only 50—60 per cent of cases (Fig. 58.14). There may be an associated feeling of emptiness in the right iliac fossa (the sign of Dance). On rectal examination blood-stained mucus may be found on the finger. Occasionally, in extensive ileocolic or colocolic intussusception, the apex may be palpable or even protrude from the anus.

Unrelieved, the pain will become continuous with abdominal distension and profound vomiting. Ultimately death occurs from small bowel obstruction or peritonitis secondary to gangrene. Rarely, natural cure may occur due to sloughing of the intussusceptum.

Radiography. A plain abdominal film usually reveals evidence of small or large bowel obstruction with an absent caecal gas shadow in ileo-ileal or ileo-colic cases. A barium enema may be used to diagnose the presence of an ileo-colic or colocolic form (the claw sign) (Fig. 58.15) but would be negative for the ileo-ileal variant in the presence of a competent ileocaecal valve. Equivocal cases of ileo-ileal intussusception may be further evaluated by CT scan which should reveal the presence of a small bowel mass.

Barium enema may also be used therapeutically in selected cases to reduce an infant intussusception. Hydrostatic reduction is contraindicated in the presence of obstruction, peritonism or a prolonged history (greater than 48 hours) and is unlikely to succeed where a lead point is likely. It is successful in 50 per cent of cases with a recurrence rate in the order of 5 per cent. Complete reduction must be confirmed by the visualization of contrast entering the terminal ileum. In cases where complete reduction is not possible, the intussusception may be so reduced in size and near its origin that only a grid-iron incision is required for surgical management.

Unfortunately, in many cases the clinical scenario is not clear-cut enough for an early diagnosis to be made and the bowel is already ischaemic by the time treatment in hospital is instituted.

Differential diagnosis.

- Acute enterocolitis — whilst abdominal pain and vomiting are common with occasional blood and mucus in the stool, diarrhoea is a leading symptom and faecal matter or bile is always present in the stool.
- Henoch—Schönlein purpura (HSP) — HSP is associated with a characteristic rash and abdominal pain but intussusception may also occur. Laparotomy should be considered in equivocal cases.
- Rectal prolapse — this may be easily differentiated by the fact that the projecting mucosa can be felt in continuity with the perianal skin whereas in intussusception the finger may pass indefinitely into the depths of a sulcus.

Operative management. This is required where hydrostatic reduction has failed or is contraindicated.

A midline incision is used after complete preoperative resuscitation with nasogastric decompression and intravenous rehydration. Reduction is achieved by squeezing the most distal part of the mass in a cephalad direction (Fig. 58.16). Do not pull. The last part of the reduction is the most difficult and the majority of cases is achieved by squeezing the apex. After reduction, the terminal part of the small bowel and the appendix will be seen to he reddened and stiffened with oedema. The viability of all bowel should be checked carefully.
In difficult cases the little finger may be gently inserted into the neck of the intussusception to try and separate adhesions (Cope’s method). Subsequently, the thumb and forefinger are placed in such a way as to de-invaginate the apex. Gentle pressure is applied and gradually increased to reduce the oedema around the ileocaecal valve (Fig. 58.17). After reduction the underlying cause requires appropriate treatment.

In the presence of an irreducible or gangrenous intussusception the mass should be excised in situ and an anastomosis or temporary end stoma created.

Postoperative care. In the uncomplicated cases, gastric aspiration and intravenous rehydration should be continued for 24 hours. Oral fluids or breast feeding may be restarted on day 2 or when postoperative ileus shows signs of resolving.

Recurrent intussusception. This rare complication may occur in 5 percent of idiopathic cases. Anchorage of the last part of the terminal ileum to the ascending colon has been advocated where repeat surgery is required.
Volvulus

A volvulus is a twisting or axial rotation of a portion of bowel about its mesentery. When complete it forms a closed loop of obstruction with resultant ischaemia secondary to vascular occlusion.

Volvuli may be primary or secondary. The primary form occurs secondary to congenital malrotation of the gut, abnormal mesenteric attachments or congenital bands. Examples include volvulus neonatorum, caecal and sigmoid volvulus. A secondary volvulus, which is the more common variety, is due to actual rotation of a piece of bowel around an acquired adhesion or stoma.

Volvulus neonatorum is predisposed to by arrested gut rotation with a resultant narrow mesentery of the small bowel and caecum. The symptoms are similar to arrested rotation (vide in IRA) with repeated vomiting, hutt the onset is more catastrophic with abdominal distention and rapid dehydration. Abdominal radiography reveals evidence of duodenal obstruction. Laparotomy reveals a distended stomach and coils of small bowel (Fig. 58.19). The whole midgut should be delivered to the wound and wrapped in warm, moist towels, in order to demonstrate the volvulus which usually occurs in a clockwise direction. The operation consists of reduction by untwisting and division of any secondary obstructive lesions — such as the transduodenal band of Ladd.

Volvulus of the small intestine

This may be primary or secondary and usually occurs in the lower ileum. It may occur spontaneously in Africans, particularly following consumption of a large volume of vegetable matter, whilst in the West it is usually secondary to adhesions passing to the parietes or female pelvic organs. Treatment consists of reduction of the twist and is then directed to any underlying cause.

Caecal volvulus

This may occur as part of volvulus neonatorum or de novo and is usually a clockwise twist. It is more common in females and usually presents acutely with the classic features of obstruction. At first the obstruction may be partial with the passage of flatus and faeces. In 25 per cent of cases, examination may reveal a palpable tympanic swelling in the midline or left side of the abdomen. Plain radiograph may reveal a gas-filled ileum and occasionally a distended caecum. A barium enema may be used to confirm the diagnosis with an absence of barium in the caecum and a bird beak deformity.

At operation the volvulus should be reduced. Sometimes this can only be achieved after decompression of the caecum by a needle. Further management consists of either fixation of the caecum to the right iliac fossa (caecopexy) and/or a caecostomy. If the caecum is ischaemic or gangrenous a right hemicolectomy should be performed.

Sigmoid volvulus

This is rare in Europe and the USA but more common in Eastern Europe and Africa; indeed it is the commonest cause of large bowel obstruction in indigenous black Africans (Loefler). The predisposing cause is summarised in Fig. 58.18. Rotation nearly always occurs in an anticlockwise direction. Predisposing factors include high residue diet and chronic constipation. Thesymptoms are of large bowel obstruction which may initially be intermittent, followed by the passage of large quantities of flatus and faeces. Presentation varies in severity and acuteness, with younger patients appearing to develop the more acute form. Abdominal distension is an early and progressive sign which may be associated with hiccough and wretching; vomiting occurs late. Constipation is absolute. In the elderly a more chronic form may be seen. A plain radiograph shows massive colonic distension. The classic appearance is of a dilated loop of bowel running diagonally across the abdomen from right to left with two fluid levels seen, one within each loop of bowel.

Treatment

Flexible sigmoidoscopy or rigid sigmoidoscopy and insertion of a flatus tube should be carried out to allow deflation of the gut. Success, as long as ischaemic bowel is excluded, will provide temporary respite allowing resuscitation and an elective procedure. Failure results in an early laparotomy, with untwisting of the loop and per-rectal decompression (Fig. 58.19). When the bowel is viable, fixation of the sigmoid colon to the posterior abdominal wall may be a safer manoeuvre in inexperienced hands. Resection is preferable if it can be achieved safely. A Paul—Mikulicz procedure is a useful procedure particularly if there is suspicion of impending gangrene (Fig. 58.20). An alternative is a sigmoid colectomy and, where anastomosis is considered unwise, a Hartmann’s procedure with subsequent reanastomosis.

Compound volvulus

This is a rare condition also known as ileo-sigmoid knotting. The long pelvic mesocolon allows the ileum to twist around the sigmoid colon resulting in gangrene of either or both segments of bowel. The patient presents with acute intestinal obstruction, but distension is comparatively mild. Plain radiography reveals distended ileal loops in a distended sigmoid colon. At operation decompression, resection and anastomosis are required.
Acute intestinal obstruction of the newborn

Neonatal intestinal obstruction has an approximate incidence of 1:2000 live births. Congenital atresia and stenosis are the commonest causes. Volvulus neonatorum, meconium ileus and Hirschsprung's disease may also be responsible.

Congenital atresia

The incidence of atresia varies with anatomical site:

- duodenum — 35 per cent;
- jejunum — 15 per cent;
- ileum — 25 per cent;
- ascending colon — 10 per cent;
- multiple sites — 15 per cent.

The high incidence of multiple sites makes peroperative assessment of the whole small and large bowel mandatory. Except in the case of duodenal atresia there are frequently associated abnormalities of the heart and great vessels.

Atresia/stenosis of the duodenum

Atresia and stenosis occur with equal frequency. In most cases, except for the oesophagus, duodenum and rectum, the atresia is a result of an intrauterine vascular accident occurring late in pregnancy such as volvulus, intussusception or strangulation at the umbilical ring. As the foetus is germ-free the ischaemic portion is absorbed and disappears. In the presence of complete obstruction, persistent vomiting occurs from birth. The presence or absence of bile is dependent on the relationship of the septum to the duodenal papilla. Bile-stained vomiting is nearly always organic in origin. Distension is often absent but visible peristalsis may be seen in the left upper quadrant. Atresia of the duodenum occurs at the level of the ampulla of Vater. Thirty per cent of babies have associated Down’s syndrome. Radiography reveals a classic so-called double stomach due to gross distention of the stomach and upper part of the duodenum with two air—fluid levels (Fig. 58.21). In cases of partial obstruction the location of the lesion may be confirmed by installation, via a nasogastric tube, of a small volume of gastrograffin. Once the lesion is confirmed the medium must be aspirated. Suprapapillary duodenal atresia may be distinguished from oesophageal atresia by the absence of dribbling saliva, and from infantile pyloric stenosis by the absence of a lump.

Duodenal obstruction in infancy may also be due to midgut volvulus, a band obstruction or an annular pancreas.

Treatment

Surgery is required as soon as resuscitation is complete. Duodeno-jejunostomy is the operation of choice. A silastic catheter is introduced through a stab incision in the antrum and guided through the anastomosis. A Witzel gastrostomy is constructed around the proximal tube which is brought out through a stab incision. Early enteral feeding through this tube is recommended.

Atresia/stenosis of the jejunum/ileum

There are four main types:

- type 1 — diaphragm with continuity of the bowel wall;
- type 2 — gap between the two ends (may be connected by fibrous cord) plus a mesenteric defect;
- type 3 — multiple atresias;
- type 4 — apple peel atresia with loss of dorsal mesentery.

The vital importance of a diagnosis lies in the fact that proximal distention of the bowel may be so great that the vascular integrity of the bowel wall is compromised leading to gangrene and perforation (Fig. 58.22).

In ileal atresia the child is born with abdominal distension or it presents within 24 hours of birth. In jejunal atresia early distention is lacking but vomiting occurs early. In both conditions the vomit contains bile and some meconium is likely to be evacuated.

Radiography

Plain radiographs are only diagnostic when air—fluid levels are seen. When they are present the obstruction is usually well advanced.

Surgery

If the stenosis is ileal and the discrepancy in bowel diameter above and below the obstruction is marked the two limbs may he brought out in a manner similar to the Paul—Mikulicz procedure. The proximal limb will need to be proud of the abdominal wall (usually by eversion) in order to prevent skin excoriation. Secondary closure by circumstomal mobilization and anastomosis, rather than use of crushing clamps, is recommended. When the stenosis is jejunal, the impact of the high jejunostomy output can make subsequent management difficult and wherever possible an end-to-end anastomosis is recommended.

Arrested rotation

Up to 10 weeks of gestation the gut lies outside the abdominal cavity. The orderly return may he arrested at any stage resulting in four major types of arrest.

The whole bowel may remain free as a narrow-based mesentery. The caecum may he displaced with transduodenal bands. The intestine may return in a clockwise direction producing a reversed intestinal rotation or a failure of rotation altogether, with the small bowel on the right and the large bowel on the left.
The most common anomaly is where the caecum remains in the left hypochondrium and a peritoneal band is found running from the caecum to the right side of the abdomen and then across the second part of the duodenum — the transduodenal hand of Ladd. The symptoms of repeated vomiting, due to pressure on the duodenum, and the radiographic appearances are identical to those of duodenal stenosis. Treatment consists of early laparotomy after appropriate resuscitation. The band is divided near its attachment to the parietal peritoneum. Often there is a second band which must also be divided, extending from the midline to the commencement of the caecum. The caecum and the colon are centred on the left of the abdominal cavity with the small bowel on the right (Nixon).

**Meconium ileus**

This is the neonatal manifestation of cystic fibrosis. Meconium is normally kept fluid by the action of pancreatic enzymes. The terminal ileum becomes filled with meconium and viscid mucus resulting in progressive inspissation in utero and neonatal obstruction. Inspissated meconium may be palpated as a rubbery swelling. Abdominal radiography may reveal a distended small intestine, with mottling. Fluid levels are generally not seen. Unlike ileal atresia there is no abrupt termination of the gas-filled intestine. As the condition is due to an autosomal recessive genetic defect a family history may be present. Further assessment includes absence of trypsin from stool or bile and a concentration of sodium chloride in sweat greater than 80 mmol/litre, or a negative immunoreactive blood trypsin estimation.

Forty per cent of cases are associated with complications such as volvulus neonatorum, atresia or meconium peritonitis (Dickson). Any evidence to suggest an acute intra-abdominal process due to twisting of the grossly distended proximal bowel indicates the need for urgent laparotomy. When this is not so, a gastrogafin or myopaque enema may be given to confirm the diagnosis. The radio- opaque fluid will pass easily to the ileum where it may disperse the obstructing meconium and relieve the condition owing to its high osmolarity and detergent action. As the instilled solution is markedly hypertonic, the rapid loss of fluid into the bowel lumen must be corrected by replacement. If conservative management fails, laparotomy is indicated. The only condition with which meconium ileus may be confused is Hirschsprung’s disease affecting the whole colon. The standard treatment is resection of the most dilated segment with an end-to-side anastomosis of the colon to the ileum. The distal ileal opening is formed into an ileostomy, through which the meconium may be irrigated postoperatively (the Bishop—Koop operation). The ileostomy becomes a mucus fistula which usually requires subsequent closure (Fig. 58.23).

**Necrotising enterocolitis**

This is a common phenomenon amongst sick premature neonates. The risk is inversely proportional to birth weight and may be associated with hypoxia, hypothermia, hypotension and umbilical artery cannulation. The ileum, caecum, distal colon and total colon are affected with a complete spectrum from mucosal to transmural necrosis.

The usual presentation is bilious vomiting, abdominal distension, colour change and lethargy in a high-risk neonate. The abdomen is usually soft. Abdominal radiographs may show pneumatosis intestinalis or free intraperitoneal air. Management consists of aggressive resuscitation with intravenous feeding. The optimal time for surgery is not in the acute phase as the baby can withstand the pressure of necrosis better than an adult but not the stress of laparotomy. At laparotomy excision of all necrotic bowel with primary anastomosis is usual. The overall mortality is 25 per cent with 10—30 per cent of neonates developing a colonic stricture.
Chronic intestinal obstruction

The symptoms of chronic intestinal obstruction may arise from two sources — the cause and the subsequent obstruction.

The causes of obstruction may be organic:

• intramural — faecal impaction;
• mural — colorectal cancer, diverticulitis, strictures (Crohn’s disease, ischaemia), anastomotic stenosis;
• extramural — adhesion (small bowel only), metastatic deposits, endometriosis; or
• functional — Hirschsprung’s disease, idiopathic megacolon, pseudo-obstruction.

The symptoms of chronic obstruction differ in their predominance, timing and degree from acute obstruction. Constipation appears first. It is initially relative and then absolute, associated with distension. In the presence of large bowel disease, the point of greatest distension is in the caecum and this is heralded by the onset of pain. Vomiting is a late feature and therefore dehydration is exceptional. Examination is unremarkable, save for confirmation of distension and the onset of peritonism in late cases. Rectal examination may confirm the presence of faecal impaction or a tumour.

Investigation

Plain abdominal radiography may confirm the presence of large bowel obstruction. All such cases should be confirmed by a subsequent single contrast water-soluble enema study to rule out functional disease. Organic disease requires a laparotomy, whilst functional disease requires colonoscopic decompression and conservative management.

In the presence of organic obstruction, after resuscitation surgical management depends on the underlying cause and the relevant chapters in this book should be consulted.

Hirschsprung’s disease

This is due to failure of complete migration of the ganglion cells of the large bowel to the anus. This results in an aganglionic segment producing physiological obstruction. Eighty per cent present in the neonatal period with acute large bowel obstruction, whilst 20 per cent present with failure to thrive or severe constipation.

Barium enema reveals a characteristic narrow segment, whilst a full-thickness rectal strip biopsy will show absence of ganglion cells. The rectoanal inhibitory reflex is absent on physiological testing.

Treatment consists of an initial loop colostomy followed by a definitive pull-through procedure.

Introduction

The vermiform appendix is considered by most to be a vestigial organ, its importance in surgery due only to its propensity for inflammation which results in the clinical syndrome known as acute appendicitis. Acute appendicitis is the most common cause of an ‘acute abdomen’ in young adults, and as such the associated symptoms and signs have become a paradigm for clinical teaching. Appendicitis is sufficiently common that appendicectomy (termed appendectomy in North America) is the most frequently performed urgent abdominal operation, and is often the first major procedure performed by a surgeon in training. Yet, despite extraordinary advances in modern radiographic imaging and diagnostic laboratory investigations, the diagnosis of appendicitis remains essentially clinical requiring a mixture of observation, clinical acumen and surgical science. In an age accustomed to early and accurate preoperative diagnosis, acute appendicitis remains an enigmatic challenge and a reminder of the art of surgical diagnosis.
The vermiform appendix is present only in humans, certain anthropoid apes and the wombat (a nocturnal, burrowing Australian marsupial). It is a blind muscular tube with mucosal, submucosal, muscular and serosal layers. Morphologically, it is the undeveloped distal end of the large caecum found in many lower animals. At birth, the appendix is short and broad at its junction with the caecum, but differential growth of the caecum produces the typical tubular structure by about the age of 2 years (Condon). During childhood, continued growth of the caecum commonly rotates the appendix into a retrocaecal but intraperitoneal position (Fig. 59.1). In approximately a quarter of cases, rotation of the appendix does not occur resulting in a pelvic, suhaecal or paracaecal position. Occasionally, the tip of the appendix becomes extraperitoneal lying behind the caecum or ascending colon. Rarely, the caecum does not migrate during development to its normal position in the right lower quadrant of the abdomen. In these circumstances the appendix can be found near the gall bladder or, in the case of *situs inversus viscerum*, in the left iliac fossa causing diagnostic difficulty if appendicitis develops (Fig. 59.2).

The position of the base of the appendix is constant, being found at the confluence of the three taeniae coli of the caecum which fuse to form the outer longitudinal muscle coat of the appendix. At operation, use can be made of this to find an elusive appendix, as gentle traction on the taeniae coli, particularly the anterior taenia, will lead the operator to the base of the appendix.

The mesentery of the appendix or *mesoappendix* arises from the lower surface of the mesentery of the terminal ileum, and itself is subject to great variation. Sometimes as much as the distal third of the appendix is bereft of mesoappendix. Especially in childhood, the mesoappendix is so transparent that the contained blood vessels can be seen (Fig. 59.3). In many adults it becomes laden with fat, which obscures these vessels. The *appendicular artery*, a branch of the lower division of the ileocolic artery, passes behind the terminal ileum to enter the mesoappendix a short distance from the base of the appendix. It then comes to lie in the free border of the mesoappendix. An *accessory appendicular artery* may be present but, in most people, the appendicular artery is an ‘end-artery’, thrombosis of which results in necrosis of the appendix (syn. gangrenous appendicitis). Four, six or more lymphatic channels traverse the mesoappendix to empty into the ileocaecal lymph nodes.

**Microscopic anatomy**

The appendix varies considerably in length and circumference. The average length is between 7.5 and 10 cm. The lumen is irregular, being encroached upon by multiple longitudinal folds of mucous membrane lined by columnar cell intestinal mucosa of colonic type (Fig. 59.4). Crypts are present but are not numerous. In the base of the crypts lie argentaffin cells (Kultschitzky cells) which may give rise to carcinoid tumours (*vide infra*). The appendix is the most frequent site for carcinoid tumours which may present with appendicitis due to occlusion of the appendiceal lumen.

The submucosa contains numerous lymphatic aggregations or follicles. This profusion of lymph tissue has promoted the concept that the appendix is the human equivalent of the avian bursa of Fabricius as a site of maturation of thymus-independent lymphocytes. While no discernible change in immune function results from appendicectomy, the prominence of lymphatic tissue in the appendix of young adults seems important in the aetiology of appendicitis (*vide infra*).
Acute appendicitis

While there are isolated reports of periappendicitis (fetal inflammation of the caecal region) from the late 1500s, recognition of acute appendicitis as a clinical entity is attributed to Reginald Fitz who presented a paper to the first meeting of the Association of American Physicians in 1886 entitled ‘Perforating inflammation of the vermiform appendix’. Soon afterwards Charles McBurney described the clinical manifestations of acute appendicitis including the point of maximum tenderness in the right iliac fossa that since bears his name. The incidence of appendicitis seems to have risen greatly in the first half of the twentieth century, particularly in Europe, America and Australasia, with up to 16 per cent of the population undergoing appendicectomy. In the past 30 years the incidence has fallen dramatically in these countries, with the number of operations in England and Wales declining from 113 000 in 1966 to 48 000 in 1990. In developing countries, which are adopting a more refined Western-type diet, the incidence continues to rise. No reason has been established for these changes in the incidence of acute appendicitis.

Acute appendicitis is relatively rare in infants, and becomes increasingly common in childhood and early adult life, reaching a peak incidence in the teens and early 20s. After middle age the risk of developing appendicitis in the future is quite small. The incidence of appendicitis is equal amongst males and females before puberty. In teenagers and young adults the male:female ratio increases to 3:2 at the age of 25 years, thereafter the greater incidence in males declines.

Aetiology

There is no unifying hypothesis regarding the aetiology of acute appendicitis. While appendicitis is clearly associated with bacterial proliferation within the appendix, no single organism is responsible, indeed a mixed growth of aerobic and anaerobic organisms is usual. The initiating event causing bacterial proliferation is controversial. Obstruction of the appendix lumen has been widely held to be important, and indeed some form of luminal obstruction by either a faecolith or stricture is found in the majority of cases.

A faecolith is composed of inspissated faecal material, calcium phosphates, bacteria and epithelial debris. Rarely a foreign body is incorporated into the mass. The incidental finding of a faecolith is a relative indication for prophylactic appendicectomy (Fig. 59.5). A fibrotic stricture of the appendix usually indicates previous appendicitis which resolved without surgical intervention (Fig. 59.6). Obstruction of the appendiceal orifice by tumour, particularly carcinoma of the caecum, is an occasional cause of acute appendicitis in middle age and the elderly. Intestinal parasites, particularly *Oxyuris vermicularis* (syn. pinworm), can proliferate in the appendix and occlude the lumen.

Pathology

Obstruction of the appendiceal lumen seems to be essential for development of appendiceal gangrene and perforation. Yet, in many cases of early appendicitis the appendix lumen is patent despite the presence of mucosal inflammation and lymphoid hyperplasia. Occasional clustering of cases amongst children and young adults suggests an infective agent, possibly viral, which initiates an inflammatory response, which within the narrow lumen of the appendix leads to luminal obstruction. Once obstruction occurs, continued mucus secretion and inflammatory exudation increase intraluminal pressure, obstructing lymphatic drainage. Oedema and mucosal ulceration develop with bacterial translocation to the submucosa. Resolution may occur at this point either spontaneously or in response to antibiotic therapy. Where the condition progresses, further distension of the appendix may cause venous obstruction and ischaemia of the appendix wall. With ischaemia, bacterial invasion occurs through the muscularis propria and submucosa producing acute appendicitis (Fig. 59.7). Finally, ischaemic necrosis of the appendix wall produces gangrenous appendicitis, with free bacterial contamination of the peritoneal cavity. Alternatively, the greater omentum and loops of small bowel become adherent to the inflamed appendix, walling off the spread of peritoneal contamination resulting in a phlegmonous mass or paracaeal abscess (Fig. 59.8). Rarely, appendiceal inflammation resolves leaving a distended mucus-filled organ termed a mucocele of the appendix (Fig. 59.9).

It is the potential for peritonitis that is the great threat of acute appendicitis. Peritonitis occurs as a result of free migration of bacteria through an ischaemic appendicular wall, through frank perforation of a gangrenous appendix or delayed perforation of an appendix abscess. Factors which promote this process include extremes of age, immunosuppression, diabetes mellitus, faecolith obstruction of the appendix lumen, a free-lying pelvic appendix and previous abdominal surgery which limits the ability of the greater omentum to wall off the spread of peritoneal contamination (Table 59.1). In these situations a rapidly deteriorating clinical course is accompanied by signs of diffuse peritonitis and systemic sepsis syndrome.

Clinical diagnosis — history

The classical features of acute appendicitis begin with poorly localised colicky abdominal pain (Table 59.2). This is due to midgut visceral discomfort in response to appendiceal inflammation and obstruction. The pain is frequently first noticed in the periumbilical region and is similar to, but less intense than, the colic of small bowel obstruction. Central abdominal pain is associated with anorexia, nausea and usually one or two episodes of vomiting which follow the onset of pain (Murphy). Anorexia is a useful and constant clinical feature, particularly in children. The patient often gives a history of similar discomfort which settled spontaneously.

Typically, two clinical syndromes of acute appendicitis can be discerned, acute catarhal (nonobstructive) appendicitis and acute obstructive appendicitis. The latter is characterised by a much more acute course. The onset of symptoms is abrupt and there may be generalised abdominal pain from the start. The temperature may be normal and vomiting is common, so that the clinical picture may mimic acute intestinal obstruction. Once recognised, urgent surgical intervention is required because of the more rapid progression to perforation.
Clinical diagnosis — signs (Tables 59.3 and 59.4)

The diagnosis of appendicitis rests more on thorough clinical examination of the abdomen than on any aspect of the history or laboratory investigation. The cardinal features are those of an unwell patient with low grade pyrexia, localised abdominal tenderness, muscle guarding and rebound tenderness. Inspection of the abdomen may show limitation of respiratory movement in the lower abdomen. The patient is then asked to point to where the pain began and to where it moved (the pointing sign). Gentle superficial palpation of the abdomen, beginning in the left iliac fossa moving anticlockwise to the right iliac fossa, will detect muscle guarding over the point of maximum tenderness, classically McBurney point. Asking the patient to cough or gentle percussion over the site of maximum tenderness will elicit rebound tenderness.

Deep palpation of the left iliac fossa may cause pain in the right iliac fossa (Rovsing’s sign), which is helpful in supporting a clinical diagnosis of appendicitis. Occasionally an inflamed appendix lies on the psoas muscle and the patient, often a young adult, will lie with the right hip flexed for pain relief (the psoas sign). Spasm of the obturator internus is sometimes demonstrable when the hip is flexed and internally rotated. If an inflamed appendix is in contact with the obturator internus, this manoeuvre will cause pain in the hypogastrum (the obturator test) (Zachery Cope). Cutaneous hyperaesthesia may be demonstrable in the right iliac fossa, but is rarely of diagnostic value.

Special features, according to position of the appendix

Retrocaecal

Rigidity is often present and even on deep pressure tenderness may he lacking (silent appendix), the reason being that the caecum, distended with gas, prevents the pressure exerted by the hand from reaching the inflamed structure. However, deep tenderness is often present in the loin, and rigidity of the quadratus lumborum may be in evidence. Psoas spasm, due to the inflamed appendix being in contact with that muscle, may he sufficient to cause flexion of the hip joint. Hyperextension of the hip joint may induce abdominal pain when the degree of psoas spasm is insufficient to cause flexion of the hip.

Pelvic

Occasionally early diarrhoea results from an inflamed appendix being in contact with the rectum. When the appendix lies entirely within the pelvis there is usually complete absence of abdominal rigidity, and often tenderness over McBurney’s point is lacking as well. In some instances deep tenderness can be made out just above and to the right of the symphysis pubis. In either event, a rectal examination reveals tenderness in the rectovesical pouch or the pouch of Douglas, especially on the right side. Spasm of the psoas and obturator internus muscles may he present when the appendix is in this position. An inflamed appendix in contact with the bladder may cause frequency of micturition.

Post ileal

Although this is rare, it accounts for some of the cases of missed appendix. Here the inflamed appendix lies behind the terminal ileum. It presents the greatest difficulty in diagnosis because the pain may not shift, diarrhoea is a feature and marked retching may occur. Tenderness, if any, is ill-defined, although it may he present immediately to the right of the umbilicus.

Special features, according to age

Infants

Appendicitis is relatively rare in infants under 36 months of age and for obvious reasons the patient is unable to give a history. Because of this, diagnosis is often delayed and thus the incidence of perforation and postoperative morbidity is considerably higher than in older children. Diffuse peritonitis can develop rapidly due to the underdeveloped greater omentum, which is unable to give much assistance in localising the infection.

Children

It is rare to find a child with appendicitis who has not vomited. Children with appendicitis usually have complete aversion to food. In addition, they do not sleep during the attack and very often bowel sounds are completely absent in the early stages.

The elderly

Gangrene and perforation occur much more frequently in elderly patients. Elderly patients with lax abdominal walls or obesity may harbour a gangrenous appendix with little evidence of it, and the clinical picture may simulate subacute intestinal obstruction. These features coupled with coincident medical conditions produce a much higher mortality for acute appendicitis in the elderly.

The obese

Obesity can obscure and diminish all the local signs of acute appendicitis. Delay in diagnosis coupled with the technical difficulty of operating in the obese make it wiser to consider operating through a midline abdominal incision.

Pregnancy

Appendicitis is the most common extra uterine acute abdominal condition in pregnancy with a frequency of from one in 1500 to one in 2000 pregnancies. Diagnosis is complicated by delay in presentation; early nonspecific symptoms are often attributed to the pregnancy, and the changing location of the appendix during pregnancy. As pregnancy develops during the second and third trimesters, the caecum and appendix are progressively pushed to the right upper quadrant of the abdomen. This displacement can result in flank or back pain, and may be confused with pyelonephritis, while lower abdominal pain may be confused with torsion of an ovarian cyst. Foetal loss occurs in 3—5 per cent of cases, increasing to 20 per cent if perforation is found at operation.
Differential diagnosis

Although acute appendicitis is the most common abdominal surgical emergency, the diagnosis at times can be extremely difficult. It is important to remember that many conditions which mimic appendicitis also require surgical intervention, or if they do not are rarely made worse by appendicectomy. However, there is a number of common conditions that it is wise to consider carefully and, where possible, exclude. The differential diagnosis differs in patients of different ages and in adult life, females have the added differential of diseases of the female genital tract (Table 59.5).

Children

The diseases most commonly mistaken for acute appendicitis are acute gastroenteritis and mesenteric lymphadenitis. In acute gastroenteritis there is intestinal colic together with diarrhoea and vomiting, but localised tenderness does not usually occur. There is often a history of other family members being affected. Post ileal appendicitis may mimic this condition, thus hospital admission and careful observation are warranted. Where serious doubt persists laparoscopy or surgical exploration may be indicated. In mesenteric lymphadenitis, the pain is colicky in nature and the patient may be completely free from pain between attacks, which last for a few minutes. Cervical lymph nodes may be enlarged. If present, shifting tenderness when the child turns on to his or her left side is convincing evidence. The condition presents a common diagnostic difficulty in children and if doubt exists exploration is advisable.

It may be impossible clinically to distinguish Meckel’s diverticulitis from acute appendicitis. The pain is similar, however signs may be central or left-sided. Occasionally, there is a history of antecedent abdominal pain or anaemia.

It is important to distinguish between acute appendicitis and intussusception. Appendicitis is uncommon before the age of 2 years, whereas the median age for intussusception is 18 months. A mass may be palpable in the right lower quadrant and the preferred treatment of intussusception is reduction by careful barium enema.

Henoch—Schönlein purpura

This is often preceded by a sore throat or respiratory infection. Abdominal pain can be severe and be confused with intussusception or appendicitis. There is nearly always an ecchymotic rash, typically affecting the extensor surfaces of the limbs and on the buttocks. The face is usually spared. The platelet count and bleeding time are within normal limits.

Lobar pneumonia and pleurisy

Lobar pneumonia and pleurisy, especially at the right base, may give rise to right-sided abdominal pain and mimic appendicitis. Abdominal tenderness is minimal, pyrexia is marked and chest examination may reveal a pleural friction rub or altered breath sounds on auscultation. A chest radiograph is diagnostic.

Adults

Terminal ileitis

In its acute form terminal ileitis may be indistinguishable from acute appendicitis unless a doughy mass of inflamed ileum can be felt. An antecedent history of abdominal cramping, weight loss and diarrhoea suggests regional ileitis rather than appendicitis. The ileitis may be nonspecific, due to Crohn’s disease or Yersinia infection. Yersinia enterocolitica causes inflammation of the terminal ileum, appendix and caecum with mesenteric adenopathy. If suspected, serum antibody titres are diagnostic and treatment with intravenous tetracycline antibiotic is appropriate. If Yersinia infection is suspected at operation, a mesenteric lymph node should be excised, divided, and half submitted for microbiological culture (including tuberculosis) and half for histological examination.

Ureteric colic

Ureteric colic does not commonly cause diagnostic difficulty as the character and radiation of pain differ from those of appendicitis. Urinalysis should always be performed and the presence of red cells should prompt a supine abdominal X-ray. Renal ultrasound or an intravenous urogram is diagnostic.

Right-sided acute pyelonephritis

This is accompanied and often preceded by increased frequency of micturition. It may cause difficulty in diagnosis, especially in women. The leading features are tenderness confined to the loin, fever (temperature 39°C), and possibly rigors and pyuria.

Perforated peptic ulcer

(Duodenal contents pass along the paracolic gutter to the right iliac fossa.) There is usually a history of dyspepsia and a very sudden onset of pain, which starts in the epigastrium and passes down the right paracolic gutter. In appendicitis the pain starts classically in the umbilical region. Rigidity and tenderness in the right iliac fossa are present in both conditions, but in perforated duodenal ulcer the rigidity is usually greater in the right hypochondrium. Radiography may show gas under the diaphragm. continues unabated until operation. Usually there is a history of a missed menstrual period and urinary pregnancy test may be positive. Severe pain is felt when the cervix is moved on vaginal examination. Signs of intraperitoneal bleeding usually become apparent and the patient should be questioned specifically regarding referred pain in the shoulder. Pelvic ultrasonography should be carried out in all cases where an ectopic pregnancy is a possible diagnosis.

Testicular torsion

Testicular torsion in a teenager or young adult male is easily missed. Pain can be referred to the right iliac fossa, and shyness on the part of patient may lead the unwary to suspect appendicitis unless the scrotum is examined in all cases.

Acute pancreatitis

Acute pancreatitis should be considered in the differential diagnosis of all adults suspected of acute appendicitis and when appropriate excluded by serum or urinary amylase measurement.

Rectus sheath haematoma
This is a relatively rare but easily missed differential diagnosis. It usually presents with acute pain and localised tenderness in the right iliac fossa, often after an episode of strenuous physical exercise. Localised pain without gastrointestinal upset is the rule. Occasionally, in an elderly patient, particularly those on anticoagulant therapy, a rectus sheath haematoma may present with a mass and tenderness in the right iliac fossa following minor trauma (Fig. 59.10).

**Adult females**

It is in women of child-bearing age that pelvic disease most often mimics acute appendicitis. A careful gynaecological history should be taken in all women with suspected appendicitis concentrating on menstrual cycle, vaginal discharge and possible pregnancy. The most common diagnostic mimics are salpingitis, mittelschmerz, torsion or haemorrhage of an ovarian cyst and ectopic pregnancy.

**Salpingitis**

This is the condition which poses greatest diagnostic difficulty in young women. Typically, the pain is lower than in appendicitis and is bilateral. A history of vaginal discharge, dysmenorrhoea and burning pain on micturition are all helpful differential diagnostic points. There may be a history of contact with sexually transmitted disease. When suspected, the opinion of a gynaecologist should be obtained, and high vaginal swab taken for *Chlamydia* culture. When serious diagnostic uncertainty persists, diagnostic laparoscopy should be undertaken.

**Mittelschmerz**

Midcycle rupture of a follicular cyst with bleeding produces lower abdominal and pelvic pain, typically midcycle. Systemic upset is rare, pregnancy test is negative and symptoms usually subside within hours. Occasionally, diagnostic laparoscopy is required.

**Torsion/haemorrhage of an ovarian cyst**

This can prove a difficult differential diagnosis. When suspected, pelvic ultrasound and a gynaecological opinion should be sought. If encountered at operation, ovarian cystectomy should be performed, if necessary, in women of child-bearing years. Documented visualisation of the contralateral ovary is an essential medicolegal precaution.

**Ectopic pregnancy**

It is unlikely that a ruptured ectopic pregnancy, with its well-defined signs of haemoperitoneum, will be mistaken for acute appendicitis, but the same cannot be said for a right-sided tubal abortion, or still more for a right-sided unruptured tubal pregnancy. In the latter, the signs are very similar to those of acute appendicitis, except that the pain commences on the right side and stays there. The pain is severe and

**Elderly**

**Sigmoid diverticulitis**

In some patients with a long sigmoid loop, the colon lies to the right of the midline and it may be impossible to differentiate between diverticulitis and appendicitis. A trial of conservative management with intravenous fluids and antibiotics is often appropriate, with a low threshold for exploratory laparotomy in the face of deterioration or lack of clinical response.

**Intestinal obstruction**

The diagnosis of intestinal obstruction is usually clear, the subtlety lies in recognising acute appendicitis as the occasional cause in the elderly. As with diverticulitis, intravenous fluids, antibiotics and nasogastric decompression should be instigated with early resort to laparotomy.

**Carcinoma of the caecum**

When obstructed or locally perforated, carcinoma of the caecum may mimic or cause obstructive appendicitis in adults. A history of antecedent discomfort, altered bowel habit or unexplained anaemia should raise suspicion. A mass may be palpable (*vide infra*) and barium enema or colonoscopy is diagnostic.

**Rare differential diagnoses**

**Preherpetic pain of the right 10th and 11th dorsal nerves** is localised over the same area as that of appendicitis. It does not shift and is associated with marked hyperaesthesia. There is no intestinal upset or rigidity. The herpetic eruption may be delayed for 3—8 hours. *Tabetic* crises are now rare. Severe abdominal pain and vomiting usher in the crisis. Other signs of tabes confirm the diagnosis. Spinal conditions are sometimes associated with acute abdominal pain, especially in children and the elderly. These may include tuberculosis of the spine, metastatic carcinoma, osteoporotic vertebral collapse and multiple myeloma. The pain is due to compression of nerve roots and may be aggravated by movement. There is rigidity of the lumbar spine and intestinal symptoms are absent. The abdominal crises of *porphyria* and *diabetes mellitus* need to be remembered. A urinalysis should be tested in every abdominal emergency. In *cyclical vomiting* of infants or young children there is a history of previous similar attacks, and abdominal rigidity is absent. Acetone is found in the urine but is not diagnostic as it may accompany starvation. *Typhilitis* or *leukaemic ileocaecal syndrome* is a rare but potentially fatal enterocolitis occurring in immunosuppressed patients. Gram-negative or *clostridia* (especially *C. septicum*) septicaemia can be rapidly progressive. Treatment is with appropriate antibiotics and haematopoetic factors. Surgical intervention is rarely indicated.
Investigation

The diagnosis of acute appendicitis is essentially clinical. A full blood count and urinalysis should be performed in all cases. In women of reproductive years, it is wise to obtain a urinary pregnancy test before proceeding to exploration. Pelvic ultrasound is of value in excluding tubal or ovarian disease if suspected. Abdominal ultrasound examination is a useful diagnostic tool, particularly in children, with a diagnostic accuracy of appendicitis in excess of 90 per cent (Fig. 59.11).

In dehydrated or elderly patients or where comorbid conditions dictate, serum urea and electrolytes should be checked. If a diagnosis of intestinal obstruction, intussusception or ureteric colic is being entertained, a supine abdominal X-ray should be performed (Table 59.6).
Treatment

The treatment of acute appendicitis is appendicectomy. There is a perception that urgent operation is essential to prevent the increased morbidity and mortality of peritonitis. While there should be no unnecessary delay, all patients, particularly those most at risk of serious morbidity, benefit from a short period of intensive preoperative preparation. Intravenous fluids sufficient to establish adequate urine output (catheterisation is needed only in the very ill) and appropriate antibiotics should be given. There is ample evidence that a single perioperative dose of antibiotics reduces the incidence of postoperative wound infection. When peritonitis is suspected, therapeutic intravenous antibiotics to cover Gram-negative bacilli, as well as anaerobic cocci, should be given. Hyperpyrexia in children should be treated with salicylates in addition to antibiotics and intravenous fluids. With appropriate use of intravenous fluids and parenteral antibiotics, a policy of deferring appendicectomy after midnight to first case on the following morning does not increase morbidity. However, when acute obstructive appendicitis is recognised, operation should not be deferred longer than it takes to optimise the patient’s condition.
Appendicectomy

Appendicectomy may be performed by conventional open operation or by using laparoscopic techniques. The first surgeon to perform deliberate appendicectomy for acute appendicitis was Lawson Tam, in May 1880. The patient recovered. It is recorded in 1736 that Claudius Amyand successfully removed an acutely inflamed appendix from the hemi-sac of a boy.

Appendicectomy should be performed under general anaesthetic with the patient supine on the operating table. When a laparoscopic technique is to be used, a nasogastric tube should be inserted and the bladder must be empty (ensure the patient has voided before leaving the ward). Prior to preparing the entire abdomen with an appropriate antisepic solution, the right iliac fossa should be palpated for a mass. If a mass is felt, it may, on occasion, be preferable to adopt a conservative approach (vide infra). Draping of the abdomen is in accordance with the planned operative technique, taking account of any requirement to extend the incision or convert a laparoscopic technique to open operation.

Conventional appendicectomy

When the preoperative diagnosis is considered reasonably certain, the incision that is widely used for appendicectomy is the so-called grid-iron incision (a grid-iron was a frame of cross-beams to support a ship during repairs). The grid-iron incision (described first by McArthur) is made at right angles to a line joining the anterior superior iliac spine to the umbilicus, its centre being along the line at McBurney’s point (Fig. 59.12). In the subcutaneous tissues an arterial twig from the superficial circumflex iliac artery usually requires ligation. The external oblique is incised in the line of its fibres along the length of the incision. The fibres of the internal oblique and transversus abdominis are split, and with suitable retraction the peritoneum is opened. If better access is required, it is possible to convert the grid-iron to a Rutherford Morrison incision (vide infra) by cutting the internal oblique and transversus muscles in the line of the incision.

In recent years, a transverse skin crease (Lanz) incision has become more popular, as the exposure is better and extension, when needed, is easier. The incision, in length to the size and obesity of the patient, is made approxi-mately 2 cm below the umbilicus centred on the mid-cla-vicular—midinguinal line (Fig. 59.13). The external oblique aponeurosis, internal oblique and transversus muscles are split in the direction of the fibres and the peritoneum is opened. When necessary the incision may be extended medially, with retraction or suitable division of the rectus abdominis muscle.

When the diagnosis is in doubt, particularly in the presence of intestinal obstruction, a lower midline abdominal incision is to be preferred over a right lower paramedian incision. The latter, although widely practised in the past, is difficult to extend, more difficult to close and provides less good access to the pelvis and peritoneal cavity.

Rutherford Morrison’s incision is useful if the appendix is paracaecal or retrocaecal and fixed. It is essentially an oblique muscle-cutting incision with its lower end over McBurney’s point and extending obliquely upwards and laterally as necessary. All layers are divided in the line of the incision.

Removal of the appendix

It will be assumed that the abdomen has been opened by a skin crease incision. A retractor is placed under the medial side of the wound and the peritoneum, and the abdominal wall is elevated. Serous exudate is removed with a sucker. Pus, if present, is likewise removed having first retained a specimen for microbiological culture. The caecum is identified by the presence of teniae coli, and using a finger or a swab the caecum is withdrawn. A turgid appendix may be felt at the base of the caecum. Inflammatory adhesions must be gently broken with a finger which is then hooked around the appendix to deliver it into the wound. The appendix is conveniently controlled using a Babcock or Lane’s forceps applied in such a way as to encircle the appendix and yet not damage it. The base of the mesoappendix is clamped in a haemostat, divided and ligated (Fig. 59.14a). When the mesoappendix is broad the procedure must be repeated with a second, or rarely, a third haemostat. The appendix, now completely freed, is crushed near its junction with the caecum in a haemostat, which is removed and reapplied just distal to the crushed portion. An absorbable 2/0 ligature is tied around the crushed portion close to the caecum. The appendix is amputated between the haemostat and the ligature (Fig. 59.14b). An absorbable 2/0 or 3/0 purse-string or ‘Z’ suture may then be inserted into the caecum about 1 cm from the base (Fig. 59.14c). The stitch should pass through the muscle coat, picking up the taeniae coli. The stump of the appendix is invaginated (Fig. 59.14d) while the purse-string or ‘Z’ suture is tied, thus burying the appendix stump. Many surgeons believe that invagination of the appendicular stump is unnecessary.

Methods to be adopted in special circumstances

When the caecal wall is oedematous, the purse-string suture is in danger of cutting out. If the oedema is of limited extent this can be overcome by inserting the purse-string suture into more healthy caecal wall at a greater distance from the base of the appendix. Occasions may arise when, because of the extensive oedema of the caecal wall, it is better not to attempt invagination.

When the base of the appendix is inflamed, it should not be crushed but ligated close to the caecal wall just tightly enough to occlude the lumen, after which the appendix is amputated and the stump invaginated. Should the base of the appendix be gangrenous, neither crushing nor ligation must be attempted. Two stitches are placed through the caecal wall close to the base of the gangrenous appendix, which is amputated flush with the caecal wall, after which these stitches are tied. Further closure is effected by means of a second layer of interrupted seromuscular sutures.

Retrograde appendicectomy

When the appendix is retrocaecal and adherent, it is an advantage to divide the base between haemostats. The appendiceal vessels are then ligated, the stump is ligated and invaginated, and gentle traction on the caecum will enable the surgeon to deliver the body of the appendix which is then removed from base to tip. Occasionally, this manoeuvre requires division of the lateral peritoneal attachments of the caecum.

Drainage of the peritoneal cavity

This is usually unnecessary provided adequate peritoneal toilet has been done. If, however, there is considerable purulent fluid in the retrocaecal space or the pelvis, a soft silastic drain may be inserted through a separate stab incision. The wound should be closed using absorbable sutures to oppose muscles and aponeurosis. In the presence of soiling or if a gangrenous appendix has been delivered through the wound, it is often wise to leave open or to delay primary closure by inserting a gauze wick between interrupted skin sutures (Brady) (Fig. 59.15).

Laparoscopic appendicectomy

The most valuable aspect of laparoscopy in the management of suspected appendicitis is as a diagnostic tool, particularly in women of...
child-bearing age. In general, an open technique should be used to establish a pneumoperitoneum, and for insertion of the laparoscopic ports as it is safer than the closed techniques using a Verres needle. The placement of the operating port may vary according to operator preference and previous abdominal scars. The operator stands to the patient’s left and faces a video monitor placed at the patient’s right foot (Fig. 59.16). A moderate Trendelenberg tilt of the operating table assists delivery of loops of small bowel from the pelvis. The appendix is found in the conventional manner by identification of the caecal taeniae and is controlled using laparoscopic tissue-holding forceps. By elevating the appendix the mesoappendix is displayed (Fig. 59.17a). A dissecting forceps is used to create a window in the mesoappendix to allow the appendicular vessels to be coagulated or ligated using a clip applicator. The appendix, free of its mesentery, can be ligated at its base with an absorbable loop ligature (Fig. 59.17b), divided (Fig. 59.17c) and removed through one of the operating ports. It is not usual to invert the stump of the appendix (Fig. 59.17d). A single absorbable suture is used to close the linea alba at the umbilicus and the small skin incisions may be closed with a subcuticular suture (Fig. 59.18).

Patients who undergo laparoscopic appendicectomy are likely to be discharged from hospital and return to work slightly sooner than those who have undergone open appendicectomy, but it remains to be seen whether this justifies the slightly longer operating time and higher costs involved.

Problems encountered during appendicectomy

- **A normal appendix is found** — this demands careful exclusion of other possible diagnoses, particularly terminal ileitis, Meckel’s diverticulitis and tubal or ovarian causes in women. It is usual to remove the appendix to avoid future diagnostic difficulties, even though the appendix is macroscopically normal, particularly if a skin crease or grid-iron incision has been made. A case can be made for preserving the macroscopically normal appendix seen at diagnostic laparoscopy, although approximately a quarter of seemingly normal appendices show microscopic evidence of inflammation.

- **The appendix cannot be found** — the caecum should be mobilised and the taenia coli should be traced to their confluence on the caecum before the diagnosis of ‘absent appendix’ is made.

- **An appendicular tumour is found** — small tumours (under 2.0 cm in diameter) can be removed by appendicectomy; larger tumours should be treated by a right hemicolectomy.

- **An appendix abscess is found** and the appendix cannot be removed easily — this should be treated by local peritoneal toilet, drainage of any abscess and intravenous antibiotics. Very rarely a caecectomy or partial right hemicolectomy is required. (The first recorded operation for an appendix abscess was by Henry Hancock of Charing Cross Hospital, London, in 1848.)

Appendicitis complicating Crohn’s disease

Occasionally, a patient is operated on for acute appendicitis who is found to have concomitant Crohn’s disease of the ileo-caecal region. Providing the caecal wall is healthy at the base of the appendix, appendicectomy can be performed without increasing the risk of an enterocutaneous fistula. Rarely, the appendix is involved with the Crohn’s disease. In this situation a conservative approach may be warranted, and a trial of intravenous corticosteroids and systemic antibiotics used to resolve the acute inflammatory process.

Appendix abscess

Failure of resolution of an appendix mass or continued spiking pyrexia usually indicates that there is pus within the phlegmonous appendix mass. Ultrasound or abdominal CT scan may identify an area suitable for insertion of a percutaneous drain. Should this prove unsuccessful, laparotomy through a midline incision is indicated.

Pelvic abscess

Pelvic abscess formation is an occasional complication of appendicitis and can occur irrespective of the position of the appendix within the peritoneal cavity. The most common presentation is a spiking pyrexia several days following appendicitis; indeed the patient may have already been discharged from hospital. Pelvic pressure or discomfort associated with loose stool or tenesmus is common. Rectal examination reveals a buggy mass in the pelvis, anterior to the rectum, at the level of the peritoneal reflection (Fig. 59.19). Pelvic ultrasound or CT scan will confirm. Treatment is transrectal drainage under general anaesthetic.
Management of an appendix mass

If an appendix mass is present and the condition of the patient is satisfactory, the standard treatment is the conservative Ochsner—Sherren regimen. This strategy is based on the premise that the inflammatory process is already localised and that inadvertent surgery is difficult and may be dangerous. It may be impossible to find the appendix and, occasionally, a faecal fistula may form. For these reasons it is wise to observe a nonoperative programme, but to be prepared to operate should clinical deterioration occur (Table 59.7).

Careful record of the patient’s condition and the extent of the mass should be made, and the abdomen regularly re-examined. It is helpful to mark the limits of mass on the abdominal wall using a skin pencil. A nasogastric tube should be passed and intravenous fluid and antibiotic therapy instigated. Temperature and pulse rate should be recorded 4-hourly and a fluid balance record maintained. Clinical deterioration or evidence of peritonitis is indication for early laparotomy. Clinical improvement is usually evident within 24—48 hours at which time the nasogastric tube can be removed and oral fluids introduced. Failure of the mass to resolve should raise suspicion of a carcinoma or Crohn’s disease. Using this regime approximately 90 per cent of cases resolve without incident. It is advisable to remove the appendix usually after an interval of 6—8 weeks.

Postoperative complications

Postoperative complications following appendicectomy are relatively uncommon and reflect the degree of peritonitis that was present at the time of operation and intercurrent diseases that may predispose to complications (Table 59.8).

Wound infection

This is the most common postoperative complication which occurs in 5—10 per cent of all cases. This usually presents with pain and erythema of the wound on the fourth or fifth postoperative day, often soon after hospital discharge. Treatment is by wound drainage and antibiotics when required. The organisms responsible are usually a mixture of Gram-negative bacilli and anaerobic bacteria, predominantly Bacteroides species and anaerobic streptococci.

Intra-abdominal abscess

Intra-abdominal abscess has become a relatively rare complication after appendicectomy with the use of perioperative antibiotics. Postoperative spiking fever, malaise and anorexia, developing 5—7 days after operation, suggest an intraperitoneal collection. Interloop, paracolic, pelvic and subphrenic sites should be considered. Abdominal ultrasonography and CT scanning greatly facilitate diagnosis and allow percutaneous drainage. Laparotomy should be considered in patients suspected to have intrabdominal sepsis in whom imaging fails to show a collection, particularly those with continuing ileus.

Ileus

A period of adynamic ileus is to be expected after appendicectomy, and may last for a number of days following removal of a gangrenous appendix. Ileus persisting for more than 4—5 days, particularly in the presence of a fever, is indicative of continuing intra-abdominal sepsis and should prompt further investigation (see above).

Respiratory

In the absence of concurrent pulmonary disease, respiratory complications are rare following appendicectomy. Adequate postoperative analgesia and physiotherapy, when appropriate, reduce the incidence.

Venous thrombosis and embolism

These are rare after appendicectomy except in the elderly and women taking the oral contraceptive pill. Appropriate prophylactic measures should be taken in such cases.

Portal pyaemia (Pylephlebitis)

Pylephlebitis is a rare but very serious complication of gangrenous appendicitis associated with high fever, rigors and jaundice. It is due to septicaemia in the portal venous system and may lead to the development of intrahepatic abscesses (often multiple). Treatment is with systemic antibiotics and percutaneous drainage of hepatic abscesses as appropriate.

Faecal fistula

Leakage from the appendicular stump rarely occurs, but may follow if the encircling stitch has been put in too deeply or if the caecal wall was involved by oedema or inflammation. Occasionally, a fistula may result following appendicectomy in Crohn’s disease.

Adhesive intestinal obstruction

Adhesive intestinal obstruction is the most common late complication of appendicectomy. At operation often a single band adhesion is responsible. Occasionally, chronic pain in the right iliac fossa is attributed to adhesion formation after appendicectomy. In such cases laparoscopy is of value in confirming the presence of adhesions and allowing division.

Right inguinal hernia

This is said to be more common following a grid-iron incision for appendicitis due to injury to the iliohypogastric nerve.
Recurrent acute appendicitis

Appendicitis is notoriously recurrent. It is not uncommon for patients to attribute such attacks to ‘biliousness’ or dyspepsia. The attacks vary in intensity, may occur every few months and the majority of cases ultimately culminate in severe acute appendicitis. If a careful history is taken from patients with acute appendicitis many remember having had milder but similar attacks of pain. The appendix in these cases shows fibrosis indicative of previous inflammation (Fig. 59.20). Chronic appendicitis, per se, does not exist. Patients labelled thus are usually examples of the recurrent form of the disease.
Less common pathological conditions

Mucocele of the appendix

Mucocele of the appendix may occur when the proximal end of the lumen slowly becomes completely occluded, usually by a fibrous stricture, and the pent up secretion remains sterile. The appendix is greatly enlarged and sometimes it contains several millilitres of mucus (Fig. 59.9). The symptoms produced are those of mild subacute appendicitis unless infection supervenes, when the mucocele is converted into an empyema. Rupture of a mucocele of the appendix is a cause of pseudomyxoma peritonei. Occasionally, the mucocele is caused by a mucus secreting adenocarcinoma, in which case a right hemicolectomy is the correct treatment.

Diverticulae of the appendix

Diverticulosis of the appendix is relatively rare and the diverticulae may be true congenital (all coats) or acquired (no muscularis layer). The condition may occur in conjunction with mucocele, in which case the intramural pressure rises sufficiently to cause herniation of the mucous membrane through the muscle coat at several points. More often, there is no demonstrable obstruction to the lumen. The patient usually gives a history of previous recurrent attacks of appendicitis. If encountered during the course of an operation for another condition, a diverticulae-bearing appendix should be removed because of a propensity to perforate if inflamed.

Intussusception of the appendix

This is rare and occurs mostly in childhood. It can be diagnosed only at operation. The symptoms usually are not acute. Untreated, the condition may pass on to an appendiculocolic intussusception. The appendix may slough, and this accounts for most of the very rare cases in which the appendix is absent. The treatment is appendicectomy.

Neoplasms of the appendix

Carcinoid tumour (syn. argentaffinoma)

Carcinoid tumours arise in argentaffin tissue (Kulchitzky cells of the crypts of Lieberkuhn) and are most commonly found in the vermiform appendix. Carcinoid tumour is found once in every 300—400 appendices subjected to histological examination and is 10 times more common than any other neoplasm of the appendix. In many instances the appendix had been removed because of symptoms of subacute or recurrent appendicitis. The tumour can occur in any part of the appendix, but it frequently does so in the distal third. The neoplasm feels moderately hard, and on sectioning the appendix it can be seen as a yellow tumour between the intact mucosa and the peritoneum. Microscopically, the tumour cells are small, arranged in small nests within the muscle and have a characteristic pattern using immunohistochemical stain for Chromogranin B (Fig. 59.21). Unlike carcinoid tumours arising in other parts of the intestinal tract, carcinoid tumour of the appendix rarely gives rise to metastases. Appendicectomy has been shown to be sufficient treatment, unless the caecal wall is involved, the tumour is 2 cm or more in size, or involved lymph nodes are found, otherwise right hemicolecctionomy is indicated.

Primary adenocarcinoma

Primary adenocarcinoma of the appendix is extremely rare. It is usually of the colonic type and should be treated by right hemicolecctionomy (as a second-stage procedure if the condition is not recognised at the first operation).

Anatomy

Surgical anatomy

The rectum has an ill-defined anatomical beginning, but surgically the rectosigmoid junction lies opposite the sacral promontory. From here the rectum follows the curve of the sacrum to end at the anorectal junction. At this point, the puborectalis muscle encircles the posterior and lateral aspects of the junction, creating the anorectal angle (normally 120°). The rectum has three lateral curvatures: the upper and lower are convex to the right, and the middle convex to the left: on the mucosal (lumen) aspect these three curves are marked by semicircular folds (Houston’s valves) (Fig. 60.1). That part of the rectum that lies below the middle valve has a much wider diameter than the upper third, and is known as the ampulla of the rectum. The adult rectum is approximately 18—20 cm in length and is conveniently divided into three equal parts: the upper third, which is mobile and has a peritoneal coat except near to the middle third where the peritoneum only covers the anterior and part of the lateral surfaces; the middle third, which is the widest part of the rectum and is confined within the diameter of the bony pelvis; and the lowest third, which lies within the muscular floor of the pelvis and has important relations to fascial layers.

The lowest part of the rectum is separated by a fascial condensation — Denonvilliers’ fascia — from the prostate in front, and behind by another fascial layer — Waldeyer’s fascia — from the coccyx and last two sacral vertebrae (Table 60.1). These fascial layers are surgically important as they are a barrier to malignant penetration, and are valuable guides at operation.

Blood supply

The superior rectal artery is the direct continuation of the inferior mesenteric artery and is the main arterial supply of the rectum. Opposite the third sacral vertebra, the artery divides again behind the lower third of the rectum into two an anterior and a posterior branch. The arteries and their accompanying lymphatics are kept applied to the back of the rectum by dense connective tissue (the mesorectum or ‘rectal fascia’).

The middle rectal artery arises on each side from the internal iliac artery (Fig. 60.2) and passes to the rectum in the lateral ligaments. It is usually small and breaks up into several terminal branches.

The inferior rectal artery arises on each side from the internal pudendal artery as it enters Alcock’s canal. It hugs the inferior surface of the levator ani muscle as it crosses the roof of the ischiorectal fossa to enter the anal muscles (Fig. 60.2).

Venous drainage

The superior haemorrhoidal veins draining the upper half of the anal canal above the dentate line pass upwards to become the rectal veins: these unite to form the superior rectal vein which later becomes the inferior mesenteric vein. This forms part of the portal venous system, and ultimately drains into the splenic vein. Middle rectal veins exist, but are small, unimportant channels unless the normal paths are blocked.

Lymphatic drainage

The lymphatics of the mucosal lining of the rectum interchange freely with those of the muscular layers. The usual drainage flow is upwards, and only to a limited extent lateral-ly and downwards. For this reason, surgical ablation of malignant disease concentrates mainly on achieving wide clearance of proximal lymph nodes. However, if the usual upwards routes are blocked (e.g. by carcinoma) flow can reverse, and it is then possible to find metastatic lymph nodes on the side walls of the pelvis (along the middle rectal vessels) or even in the inguinal region (along the inferior rectal artery).

Superior rectal nodes

These are an important group of nodes on the back of the rectal ampulla above the levator ani muscle (Fig. 60.3), also known as the pararectal lymph glands of Gerota.

Middle rectal nodes

These lie close to the middle rectal arteries and pass to lymph nodes around the internal arteries. The Japanese have stressed the importance of removing these lymph glands when operating on rectal cancer.
Clinical features of rectal disease

Symptoms

Rectal diseases are common and serious, and can occur at any age. The symptoms of many of them overlap. In general, the inflammations affect younger age groups, while the tumours occur in the middle-aged and elderly. But no age is exempt from any of the diseases, however young; ulcerative colitis has been reported in the newborn, and rectal cancer is not rare in young people. The common symptoms of rectal disease are the following.

**Bleeding**

This demands at least digital examination at any age.

**Altered bowel habit**

Early morning stool frequency (‘spurious diarrhoea’) is a symptom of rectal carcinoma, while blood stained frequent loose stools characterise the inflammatory diseases.

**Discharge**

Mucus and pus are associated with rectal pathology.

**Tenesmus**

Often described by the patient as ‘I feel I want to go but nothing happens’; this is normally an ominous symptom of rectal cancer.

**Prolapse**

This usually indicates either mucosal (partial) or full thickness (complete) rectal wall descent.

**Pruritis**

This may be secondary to a rectal discharge.

**Loss of weight**

This usually indicates serious or advanced disease, e.g. hepatic metastases.

Main symptoms of rectal disease

- Bleeding per rectum
- Altered bowel habit
- Mucus discharge
- Tenesmus
- Prolapse

Signs

Because the rectum is accessible via the anal orifice these can be elicited by systematic examination. The patient is either positioned in the left lateral (Sims) position or examined in the knee-elbow position (Fig. 60.4).

**Inspection**

Visual examination of the anus precedes rectal examination to exclude the presence of anal disease, e.g. fissure, haemorrhoids or fistula.

**Digital examination**

The index finger used with gentleness and precision remains the most valuable test for rectal disease (Fig. 60.5). Tumours in the lower and middle thirds of the rectum can be felt and assessed; by asking the patient to strain, even some tumours in the upper third can be tipped with the finger. After it is removed the finger should be examined for tell-tale traces of mucus, pus or blood. It is always useful to note the normal as well as the abnormal findings on digital examination, e.g. the prostate in the male. Digital findings can be recorded as intraluminal (e.g. blood, pus), intramural (e.g. tumours, granular areas, strictures) or extramural (e.g. enlarged prostate, uterine fibroids).

**Proctoscopy**

This can be used to inspect the anus, anorectal junction and the lower rectum (up to 10 cm) (Fig. 60.6). Biopsy can be performed of any suspicious areas.

**Sigmoidoscopy**

The sigmoidoscope was in the past a rigid stainless steel instrument of variable diameter and was normally 25 cm in length (Fig. 60.6). This has in the main been replaced by a disposable Perspex instrument which has major advantages when considering transmittable disease. The rectum must be empty for proper inspection with a sigmoidoscope. Gentle-ness and skill are required for its use, and perforations can occur if care is not exercised.

**Flexible sigmoidoscope**

The ‘flexiscope’ can be used to supplement or replace rigid sigmoidoscopy (Fig. 60.7). It requires special skill and experience, and the lower bowel should be cleaned out with preliminary enemas. In addition to the rectum, the whole sigmoid colon is within visual reach of this instrument. The instrument is expensive and requires careful maintenance.
Injuries

The rectum or anal canal may be injured in a number of ways, all uncommon.

• By falling in a sitting posture on to a spiked or blunt pointed object.
  
  The upturned leg of a chair, handle of a broom, floor mop, pitchfork
  or a broken shooting stick have all resulted in rectal impalement.

• By the fetal head during childbirth, especially forceps assisted.

Diagnosis. When there is a history of rectal impalement, the first interrogation should be, ‘Has the patient passed urine since the accident?’

The anus having been inspected, the abdomen should be palpated. If rigidity or tenderness is present, early laparotomy is imperative. Prior to the operation, a urethral catheter is passed. If the urine is bloodstained and/or the quantity recovered is unexpectedly small, it is wise to suspect ruptured bladder or urethra (see Chapters 65 and 67).

Treatment. After the patient has been anaesthetised, the rectum is examined with a finger and a speculum, especial attention being directed to the anterior wall. A lower laparotomy is then performed. If an intra peritoneal rupture of the rectum is found, the perforation is closed with sutures. Should blood be present beneath the pelvic peritoneum, it is necessary to mobilise the rectosigmoid, which allows the rectum to be drawn upwards, thus permitting the perforation below the pelvic diaphragm to be closed securely. A perforation in the bladder can also be sutured via this avenue. After closing the laparotomy wound, a defunctioning colostomy is constructed in the left iliac fossa. In cases where the bladder has been injured, a self-retaining urethral catheter is placed in position. If the rectal injury is below the pelvic floor, wide drainage from below is indicated. A ‘protective’ colostomy is advisable. If the defect in the rectum is very large, resection may have to be contemplated. In such circumstances, a Hartmann’s procedure is indicated. Care must be taken to preserve sphincter function during the debridement of the perineal wounds. Antibiotic cover should be provided against both aerobic and anaerobic organisms.

Foreign bodies in the rectum

The variety of foreign bodies which have found their way into the rectum is hardly less remarkable than the ingenuity displayed in their removal (Fig. 60.8). A turnip has been delivered per anum by the use of obstetric forceps. A stick firmly impacted has been withdrawn by inserting a gimlet into its lower end. A tumbler, mouth looking downwards, has been extracted by filling the interior with a wet plaster of Paris bandage, leaving the end of the bandage protruding, and allowing the plaster to set.

If insurmountable difficulty is experienced in grasping any foreign body in the rectum, a laparotomy is necessary, which allows that object to be pushed from above into the assistant’s finger in the rectum. If there is considerable laceration of the mucosa, a temporary colostomy is advisable.
Prolapse

Partial prolapse

The mucous membrane and submucosa of the rectum protrude outside the anus for approximately 1–4 cm. When the prolapsed mucosa is palpated between the finger and thumb, it is evident that it is composed of no more than a double layer of mucous membrane (cf. complete prolapse). There is some confusion as to its exact nature. Some believe that partial rectal prolapse represents the head of a rectal intussusception, and is the early manifestation of a complete rectal prolapse. Others consider that it is a separate entity. The probable truth is that both types exist. The condition occurs most often at the extremes of life — in children between 1 and 3 years of age, and in elderly people.

In infants

The direct downward course of the rectum, due to the as yet undeveloped sacral curve (Fig. 60.9), predisposes to this condition, as does the reduced resting anal tone which offers diminished support to the mucosal lining of the anal canal (Mann).

In children

Partial prolapse often commences after an attack of diarrhoea, as a result of severe whooping cough, or from loss of weight and consequent diminution in the amount of fat in the ischiorectal fossae.

In adults

The condition in adults is usually associated with third-degree haemorrhoids. In the female, a torn perineum predisposes to prolapse, and in the male straining from urethral obstruction. In old age, both partial and complete prolapse are associated with atony of the sphincter mechanism but whether this is the cause of the problem or secondary to it is unknown.

Partial prolapse may follow an operation for fistula-in-ano where a large portion of muscle has been divided. Here the prolapse is usually localised to the damaged quadrant and is seldom progressive.

Prolapsed mucous membrane is pink; prolapsed internal haemorrhoids are plum coloured and more pedunculated.

Treatment

In infants and young children

Digital reposition. The parent must be taught to replace the protrusion. The distal two-thirds of the index finger is wrapped in tissue paper. The finger is inserted into the protrusion and the mass is eased into place. Gently, the finger is withdrawn, leaving the tissue paper to disintegrate. In cases of malnutrition, dietetic adjustments are necessary.

Submucous injections. If digital reposition fails after 6 weeks’ trial, injections of 5 per cent phenol in almond oil are carried out under general anaesthesia. As a result of the aseptic inflammation following these injections, the mucous membrane becomes tethered to the muscle coat.

Technique. The submucosa at the apex of the prolapse is injected circularly, so as to form a raised ring, up to 10 ml of the solution being injected. A similar injection is made at the base of the prolapse. Alternatively, if the prolapse cannot be brought down, the injections are given through a proctoscope.

Thiersch’s operation. When the prolapse persists in spite of these measures, Thiersch’s operation (below) may succeed. In infants, insertion of the little finger into the anus before the stitch is tied is recommended. In infants and young children, strong chromic catgut should be used for the stitch instead of silver wire: if wire were employed (or any other retained unabsorbable material) as growth proceeded, the stitch would have to be removed or anal stenosis would result. As the procedure is designed only as a temporary measure in the young, chromic catgut is adequate for the purpose.

In adults

Submucous injections. Submucous injections of phenol in almond oil occasionally are successful in cases of early partial prolapse.

Excision of the prolapsed mucosa. When the prolapse is unilateral the redundant mucosa can be excised after inserting and tying Goodsall’s ligature (Fig. 60.10) which, after the needles have been cut off, permits the base of the prolapsed mucous membrane to be ligated in three portions lying in juxtaposition. When necessary, the operation is combined with haemorrhoidectomy, and if the pedicle of one or more of the haemorrhoids is broad, Goodsall’s ligature is applied. Alternatively, an endoluminal stapling technique can now be used.

Complete prolapse

Complete prolapse (syn. procidentia) is less common than the partial variety. The protrusion consists of all layers of the rectal wall and is a descending hernia-en-glissade of the rectum downwards through the levator ani. As the rectum descends, it intussuscepts upon itself. The mucous membrane and submucosa of the rectum protrude outside the anus for approximately 1–4 cm. When the prolapsed mucosa is palpated between the finger and thumb, it is evident that it is composed of no more than a double layer of mucous membrane (cf. complete prolapse). There is some confusion as to its exact nature. Some believe that partial rectal prolapse represents the head of a rectal intussusception, and is the early manifestation of a complete rectal prolapse. Others consider that it is a separate entity. The probable truth is that both types exist. The condition occurs most often at the extremes of life — in children between 1 and 3 years of age, and in elderly people.

In infants

The direct downward course of the rectum, due to the as yet undeveloped sacral curve (Fig. 60.9), predisposes to this condition, as does the reduced resting anal tone which offers diminished support to the mucosal lining of the anal canal (Mann).

Submucous injections. Submucous injections of phenol in almond oil occasionally are successful in cases of early partial prolapse.

Excision of the prolapsed mucosa. When the prolapse is unilateral the redundant mucosa can be excised after inserting and tying Goodsall’s ligature (Fig. 60.10) which, after the needles have been cut off, permits the base of the prolapsed mucous membrane to be ligated in three portions lying in juxtaposition. When necessary, the operation is combined with haemorrhoidectomy, and if the pedicle of one or more of the haemorrhoids is broad, Goodsall’s ligature is applied. Alternatively, an endoluminal stapling technique can now be used.

Complete prolapse

Complete prolapse (syn. procidentia) is less common than the partial variety. The protrusion consists of all layers of the rectal wall and is a descending hernia-en-glissade of the rectum downwards through the levator ani. As the rectum descends, it intussuscepts upon itself. The mucous membrane and submucosa of the rectum protrude outside the anus for approximately 1–4 cm. When the prolapsed mucosa is palpated between the finger and thumb, it is evident that it is composed of no more than a double layer of mucous membrane (cf. complete prolapse). There is some confusion as to its exact nature. Some believe that partial rectal prolapse represents the head of a rectal intussusception, and is the early manifestation of a complete rectal prolapse. Others consider that it is a separate entity. The probable truth is that both types exist. The condition occurs most often at the extremes of life — in children between 1 and 3 years of age, and in elderly people.
rectopexy is recommended, but when the patient is elderly and very frail, or is suffering from injury or disease of the spinal cord, or in very early life, a perineal operation is indicated.

**Perineal approach.** Two procedures have been used most commonly.

**Delorme’s operation (Fig. 60.15).** In this procedure, the rectal mucosa is removed circumferentially from the prolapsed rectum over its length, apart from 0.5-cm strips at its proximal end and at its tip. The underlying muscle is then imbricated with a series of chromic catgut sutures, such that, when these are tied, the rectal muscle is concertinaed towards the anal canal. The anal canal mucosa is then sutured circumferentially to the rectal mucosa remaining at the tip of the prolapse. This manoeuvre has the effect of reducing the prolapse and creating a ring of muscle within the anal canal, which narrows the orifice and prevents recurrence.

**Thiersch’s operation.** This procedure, which aims to place a steel wire or, more commonly now, a silastic or nylon suture, around the anal canal has in the past been the most frequently performed perineal procedure. However, it has become obsolete for the treatment of rectal prolapse in adults, although it still does have a place in the treatment of partial prolapse in children. The reasons for its lack of popularity are that the suture would often break or cause chronic perineal sepsis, or both, or the anal stenosis so created would produce severe functional problems. Delorme’s operation is now the preferred perineal operation.

If an abdominal repair must be avoided (e.g. in a young man in whom sexual potency must be preserved by avoiding damage to the pelvic nerves) more extensive perineal procedures are available. These include strengthening the puborectalis and external anal sphincters by an approach through the intersphincteric plane (see above), the so-called postanal repair (Parks) and perineal rectosigmoidectomy (Altemeier) in which the prolapsed rectum is excised from below.

**Abdominal approach.** The principle of all abdominal operations for rectal prolapse is to replace and hold the rectum in its proper position. Of the many operations described, the following are relatively simple. They are recommended in patients with complete prolapse, who are otherwise in good health.

**Wells’ operation.** In this operation the rectum is fixed firmly to the sacrum by inserting a sheet of polyvinyl alcohol sponge or, more commonly now, polypropylene mesh between them (Fig. 60.16). The rectum is separated from the sacrum in the usual way. The mesh is fixed by a series of sutures to the peristome over the midline of the sacrum and is then wrapped loosely about the rectum covering all except the anterior wall. The free margins of the mesh are sutured to the lateral margins of the anterior wall of the rectum. The peritoneal floor is resutured so that the mesh is excluded from the peritoneal cavity. The mesh does not give rise to a foreign body reaction, but it does produce very marked fibrous tissue formation. Many proctologists regard this as the method of choice. Recently, the technique has been performed laparoscopically, thus reducing the operative trauma and limiting the time in hospital (Fig. 60.17).

**Ripstein’s operation.** In this operation, the rectosigmoid junction is hitched up by a Teflon sling to the front of the sacrum just below the sacral promontory. The operation is very safe and simple, and the results are good. Some surgeons recommend combining this procedure with resection of the sigmoid colon (Goldberg).

**Lahaut’s operation.** This operation depends entirely upon mobilising the rectum and lower sigmoid colon, and holding it up by taking it through the rectus sheath. The results are moderate and few surgeons use this method. It should be noted that approximately 50 per cent of adult patients with a complete rectal prolapse are incontinent, and rectopexy cures only about one-third. Consequently, it may be necessary to perform a subsequent procedure to correct the incontinence.
Proctitis

Inflammation is sometimes limited to the rectal mucosa; in others it is associated with a similar condition in the colon (proctocolitis). The inflammation can be acute or chronic. The symptoms are tenesmus, the passage of blood and mucus and, in severe cases, of pus also. Although the patient has a frequent intense desire to defecate, the amount of faeces passed at a time is small. Acute proctitis is usually accompanied by malaise and pyrexia. On rectal examination the mucosa feels swollen and is often exceedingly tender. Proctoscopy is seldom sufficient and sigmoidoscopy is the more valuable method of examination. If the diagnosis is confirmed, colonoscopy with multiple biopsies is mandatory, so as to determine the extent of the inflammatory process. Skilled pathological assistance is required to establish or exclude the diagnosis of specific infection by bacteriological examination and culture of the stools, examination or scrapings or swabs from ulcers, and serological tests. When early carcinoma cannot be excluded, biopsy is necessary.

**Nonspecific proctitis** is an inflammatory condition affecting the mucosa and, to a lesser extent, the submucosa, confined to the terminal rectum and anal canal. It is the most common variety. In 10 per cent of cases the condition extends to involve the whole colon (total ulcerative colitis).

**Aetiology.** This is unknown. The concept that the condition is a mild and limited form of ulcerative colitis (although actual ulceration is often not present) is the most acceptable hypothesis.

**Clinical features.** The patient is usually middle-aged, and complains of slight loss of blood in the motions. Often the complaint is one of diarrhoea, but on closer questioning it transpires that usually one relatively normal action of the bowels occurs each day, although it is accompanied by some blood. During the day the patient attempts to defecate, with the passage of flatus and a little blood-stained faecal matter, which is mistakenly interpreted as diarrhoea. On rectal examination, the mucosa feels warm and smooth. Often there is some blood on the examining fin-ger. Proctoscopic and Sigmoidoscopic examination shows inflamed mucous membrane of the rectum, but usually no ulceration. The inflammation usually extends for only 12.5—15 cm from the anus, the mucosa above this level being quite normal.

**Treatment.** Although, fortunately, the condition is usually self-limiting, much relief may be obtained from the use of sulphasalazine (Salazopyrin) and its more active component 5-ASA (Asacol), acetylsalicylate suppositories or prednisolone retention enemas. Milk should be rigidly excluded from the diet. In very severe resistant cases, oral steroids may have to be used to obtain remission. Rarely, surgical treatment is used as a last resort when the patient is desperate for relief of symptoms.

**Ulcereative proctocolitis.** Proctitis is present in a high percentage of cases of ulcerative colitis, and the degree of severity of the rectal involvement may influence the type of operative procedure (see Chapter 57).

Proctitis due to Crohn’s disease. Crohn’s disease can occasionally affect the rectum, although classically it is spared. Sigmoidoscopic char-acteristics differ from those in nonspecific proctitis. The inflammatory process tends to he patchy rather than confluent and there may be fissuring, ulceration and even a cobblestone appearance. Rectal Crohn’s disease is often associated with severe perineal disease characterised by fistulation. Skid lesions are also often present in the rest of the colon or small bowel, or both.

**Proctitis due to specific infections**

*Clostridium difficile*. An acute form of proctocolitis by infection with *C. difficile* can follow broad-spectrum antibiotic administration (espe-cially lincomycin). A ‘membrane’ can sometimes he seen on proctoscopy (‘pseudomembranous’ enterocolitis).

Bacillary dysentery. The appearance is that of an acute purulent proctitis with multiple small, shallow ulcers. The examination of a swab taken from the ulcerated mucous membrane is more certainly diagnostic than is a macroscopical examination of the stools. Proctological examination is painful; agglutination tests may render it unnecessary.

Amoebic dysentery. The infection is more liable to be chronic, and exacerbations after a long period of freedom from symptoms often occur. Proctoscopy and sigmoidoscopy are not painful. The appearance of an amoebic ulcer is described in Chapter 57. Scrapings from the ulcer should be immersed in warm isotonic saline solution and sent to the laboratory for immediate microscopical examination.

Amoebic granuloma. This presents as a soft mass, usually in the recto-sigmoid region. This lesion is frequently mistaken for a carcinoma. Sigmoidoscopy shows an ulcerated surface, but the mass is less friable than a carcinoma. A scraping should he taken, preferably with a small, sharp spoon on a long handle, and the material sent for immediate microscopical examination, as detailed above. If doubt exists, a provocative dose of emetine may cause cysts of the amoebae to appear in the stools. A biopsy can also help. Treatment is as described in Chapter 57.

Amoebic granuloma of the rectum is from time to time encountered in a patient who has never visited a country in which the disease is endemic. Persons living in old people’s institutions are liable to harbour this deceptive lesion.

Tuberculous proctitis. This is nearly always associated with active pulmonary tuberculosis ulceration of the anus. Submucous rectal abscesses burst and leave ulcers with an undermined edge. A hypertrophic type of tuberculous proctitis occurs in association with tuberculous peritonitis, or tuberculous proctitis occurs in association with tuberculous peritonitis or tuberculous salpingitis. This type of tuberculous proctitis requires biopsy for confirmation of the diagnosis.

Gonococcal proctitis. Gonococcal proctitis occurs in both sexes as the result of rectal coitus, and in the female from direct spread from the vulva. In the acute stage, the mucous membrane is hyperaemic and thick pus can be expressed as the proctoscope is withdrawn. In the early stages, the diagnosis can be readily established by bacteriological examination, but later, when the infection is mixed, it is more difficult to recognise. Specific treatment is so effective that local treatment is unnecessary.

**Lymphogranuloma inguinale.** The modes of infection are similar to those of gonococcal proctitis, but in the female infection spreading from the cervix uteri via lymphatics to the pararectal lymph nodes is common. The proctological findings are similar to those of gonococcal proctitis. The diagnosis of lymphogranuloma in inguinale should be suspected when the inguinal lymph nodes are greatly enlarged, although the enlargement may be subsiding by the time proctitis commences (Chapter 67).

Primary syphilis. A primary chancre may occur inside the anus (Chapter 64) — a paradox — ‘a painless anal fissure’.

**Acquired immunodeficiency syndrome (AIDS).**

AIDS may present with a particularly florid type of proctitis. In such patients unusual organisms such as cytomegalovirus (CMV) are often found on culture.

‘Strawberry’ lesion of the rectosigmoid. This is due to an infection by Spirochaeta vincenti and Bacillus fusiform is. The leading symptom is diarrhoea, often scantily blood stained. Occasionally the diagnosis can be made by the demonstration of the specific organisms in the stools.
More often sigmoidoscopy is required. The characteristic lesion is thickened, somewhat raised mucosa with superficial ulceration in the region of the rectosigmoid. The inflamed mucous membrane oozes blood at numerous pin-points, giving the appearance of an over-ripe strawberry. A swab should be taken from the lesion and examined for Vincent’s and fusiform organisms. Swabs from the gums and the throat are also advisable.

**Treatment.** Acetarsol suppositories together with vitamin C are almost specific.

Rectal bilharziasis. Rectal bilharziasis is caused by *Schistosoma mansoni*, which is endemic in many tropical and subtropical countries, and particularly in the delta of the Nile.

Stage 1. A cutaneous lesion develops at the site of entrance of the cercariae (parasites of freshwater snails).

Stage 2 is characterised by pyrexia, urticaria and a high eosinophilia. Both of these stages are frequently overlooked.

Stage 3 is due to deposition of the ova in the rectum (much more rarely in the bladder, Chapter 65) and is manifested by bilharzial dysentery. On examination in the later stages, papillomas are frequently present. The papillomas, which are sessile or pedunculated, contain the ova of the trematode, the life-cycle of which resembles that of *Schistosoma haematobium*.

Untreated, the rectum becomes festooned, and prolapse of the diseased mucous membrane is usual. Multiple fistulae-in-ano are prone to develop.

**General treatment of bilharziasis mansoni.** Compounds not containing antimony include niridazole (Ambilhar) in cases of infestation with *S. haematobium* or *S. mansoni* (not *S. japonicum* or in those with heart, mental or liver disease). Dose is 25 mg/kg body weight daily in two divided doses for 5—7 days. Hycanthone, lucanthone and oxamniquine are other compounds with weight-related single doses given by deep intramuscular (i.m.) injection, and all have toxic side effects. Metrifonate is an organophosphorous compound, effective against *S. haematobium* only and must be handled with care. Praziquantel (Biltricide) has proved a major advance in drug therapy, and is highly effective against all schistosome species. It is generally given as a single oral dose of 40 mg/kg for *S. haematobium* and *S. mansoni*, and for *S. japonicum* a higher dose of 60 mg/kg is given as two or three divided doses throughout 1 day.

Compounds containing antimony, either as the salts, tartar emetic (antimony potassium tartrate) and sodium salt given intravenously (i.v.), or antimony lithium thiomalate, sodium antimonygluconate, stibogluconate and stibocaptate (Astiban) may still be required.

**Local treatment.** When the papillomas persist in spite of general treatment, they must be treated in the same manner as other papillomas by local destruction.

Proctitis due to herbal enemas. This is a well-known clinical entity to those practising in tropical Africa. Following an enema consisting of a concoction of ginger, pepper and bark, administered by a witch doctor, a most virulent proctitis sets in. Pelvic peritonitis frequently supervenes.

Not infrequently, a complete gelatinous cast of the mucous membrane of the rectum is extruded. Very large doses of morphine, together with streptomycin, often prevent a fatal issue if commenced early (Bowesman). Temporary colostomy is often advisable.

**Treatment**

General treatments should include bed rest in extreme cases. The stools should be kept soft with Isogel. Suppositories of 5-ASA are often beneficial. The specific treatments for the dysenteries, tuberculosis, gonorrhea, lymphogranuloma inguinale and syphilis are described in the appropriate sections of this book.
Solitary rectal ulcer

This is becoming a more commonly diagnosed problem. Classically, it takes the form of an ulcer on the anterior wall of the rectum. In this form it must be differentiated from a rectal carcinoma or inflammatory bowel disease, particularly Crohn’s disease. In recent years, it has been appreciated that the ulceration may heal, leaving a polypoid appearance. A variety of explanations as to its cause has been suggested, including persistent trauma by sexual malpractices. However, recent proctographic studies indicate that the cause may be due to a combination of internal intussusception or anterior rectal wall prolapse, and an increase in intrarectal pressure. This combination of factors is usually due to chronic straining as a result of constipation. The histological appearances confirm the diagnosis (Morson) and they are similar to the appearances of biopsies from a full-thickness overt rectal prolapse. The condition, although benign, is difficult to treat. Symptomatic relief from bleeding and discharge may some-times be achieved by preventing the internal prolapse by an abdominal rectopexy. In rare cases rectal excision may be required.
Benign tumours

The rectum, along with the sigmoid colon, is the most frequent site of polyps (and cancers) in the gastrointestinal tract. All neoplastic polyps of the colon and rectum (with rare exceptions) have a tendency to become malignant. This tendency is greatly enhanced if the polyp is more than 1 cm in diameter, shows obvious signs of increasing size and has a sessile rather than a penduculated shape. For these reasons, removal of all polyps is recommended, and total removal is mandatory. Only total removal will give complete histological examination and exclude (or confirm) localised carcinoma in situ, and also prevent local recurrence. For these reasons, destruction of anorectal tumours by fulguration is not the best treatment, and should be used for only the tiniest polyps. If one or more rectal polyps are discovered on sigmoidoscopic examination, a colonoscopy must be performed as further polyps are frequently found in the colon and treatment may be influenced. No rectal tumour should be removed until the possibility of a proximal carcinoma has been ruled out, otherwise local implantation of cancer cells may occur in the distally situated rectal wound.

The rectum shares substantially the same spectrum of polyps as the colon. Polyps are described chiefly in terms of their tissue organisation. For further clinical details the reader is referred to Chapter 67. Certain polyps which have features relevant to the rectum are now described.

Polyps relevant to the rectum

Juvenile polyp

This is a bright red glistening pedunculated sphere (‘cherry tumour’) which is found in infants and children. Occasionally it persists into adult life. It can cause bleeding, or pain if it prolapses during defecation. It often separates itself, but can be removed easily with forceps or a snare. It has virtually no tendency to malignant change but should be treated if it is causing symptoms. It has a unique histological structure of large mucus-filled spaces covered by a smooth surface of thin rectal cuboidal epithelium (Fig. 60.18).

Meta plastic polyps

These are small, pinkish, sessile polyps 2—4 mm in diameter and frequently multiple. They are harmless.

Pseudo polyps

These are oedematous bosses of mucous membrane. They are usually associated with colitis in the UK, but most inflammatory diseases (including tropical diseases) can cause them. They are more likely to cause radiological difficulty as the sigmoidoscopic appearances are usually associated with obvious signs of the inflammatory cause.

Villous adenomas

These have a characteristic frond-like appearance. They are often of very large size, and occasionally fill the entire rectum. The large tumours have an enhanced tendency to become malignant — a change that can be detected most easily by palpation with the finger; any hard area should be assumed to be malignant and should be biopsied.

Rarely, the profuse mucous discharge from these tumours, which is high in potassium content, causes dangerous electrolyte and fluid losses (Fig. 60.19).

Provided cancerous change has been excluded, these tumours can be removed either by submucous dissection per anum, or by sleeve resection from above. Only very unusually is rectal excision required, and then only when malignant change has occurred. A recent technique known as transanal endoscopic microsurgery (TEM) has been developed (Buess) which has improved the endoanal approach for the local removal of villous adenomas. The method requires the insertion of a very large operating sigmoidoscope. The rectum is distended by carbon dioxide insufflation, the operative field is magnified by a camera inserted via the sigmoidoscope, and the image is displayed on a monitor (Fig. 60.20). The lesion is excised using specially designed instruments with the surgeon observing the monitor screen. The technique is highly specialised and takes a considerable amount of time to master.

All neoplastic polyps can be solitary or multiple. Small colonic polyps (under 5 cm in size) can now be snared through the colonoscope. This instrument has revolutionised the treatment of multiple polyps.

Familial adenomatous polyposis

(formerly known as familial polyposis coli)

This disease usually manifests itself by the development of multiple rectal and colonic polyps around puberty. A colonoscopy and biopsy will confirm the presence of multiple colonic adenomatous polyps. Recently the adenomatous polyposis cell (APC) gene responsible for the disease has been isolated on chromosome 5 (Bodmer). This discovery should make screening of affected families far more cost effective than at present. As this condition is premalignant, a total colectomy must be performed, but often the rectum can be preserved by regular fulguration of polyps before they develop carcinoma. The operation of restorative proctocolectomy with pouchanal anastomosis is now being used in most centres of coloproctology: the rectum is replaced by a ‘pouch’ of folded ileum (Chapter 57). A pan-proctocolectomy with permanent ileostomy is necessary in some instances, especially when patient follow-up may be impractical.

Differential diagnosis

Bilharzia

In patients who have lived in Egypt, or any country where bilharzial infestation is rife, bilharzial papilloma must be excluded.

Treatment. Diathermy coagulation is satisfactory in the case of a small papilloma, but the patient must be examined at regular intervals as recurrence is common, as in the case of the bladder. For large papillomas, especially the sessile variety, excision of the rectum may be the only curative treatment. Some cases (not, as a rule, those invading the anal canal) are suitable for conservative resection of the rectum. In a few cases intestinal continuity can be restored by a low coloanal ‘sleeve’ anastomosis or one achieved by the circular stapling gun.

Benign lymphoma. This occurs as a circumscribed movable nodule, firm but not hard, greyish-white to pink in colour, and is essentially submucosal. This neoplasm, which occurs at all ages and in both sexes, has no definite capsule. Notwithstanding, complete local excision is curative.

Endometrioma. Endometrioma is rare, and as a rule is diagnosed as a carcinoma. This neoplasm produces either a constricting lesion of the
rectosigmoid or a tumour invading the rectum from the rectovaginal septum. The latter variety gives rise to a very tender submucous elevation of the rectal wall. Endometriosis occurs usually between 20 and 40 years of age; less often at the menopause. Dysmenorrhoea with rectal bleeding are the main symptoms. On sigmoidoscopy endometriosis involving the rectosigmoid junction usually presents as a stricture with the mucous membrane intact. Bilateral Oophorectomy may be followed by regression of the tumour, rendering resection unnecessary. The contraceptive pill is also effective as it inhibits ovulation.

**Haemangioma.** Haemangioma of the rectum, which is an uncommon tumour, is a cause of serious and, if the neoplasm is large, sometimes fatal haemorrhage. When localised in the lower part of the rectum or anal canal, a haemangioma can be excised after applying, Goodsell’s ligature. When the neoplasm is diffuse, or lying in the upper part of the rectum, the symptoms simulate ulcerative colitis, and often the diagnosis is missed for a long period. At other times, the neoplasm is mistaken for a vascular carcinoma, an error which, fortunately, is not often a cause for serious regret because the correct treatment of an extensive haemangioma is excision of that portion of the anorectum hearing the neoplasm. Lesser procedures are followed nearly always by recurrence amid renewed loss of blood.

**Leiomyoma.** Benign smooth muscle tumours of the rectum are rare. They consist of spindle cells. It is often difficult to predict how they will behave. If the mitotic rate is high, and if there is variation in number, size and shape, hyperchromasia and frequent bizarre cells, these tumours are likely to metastasise. In these circumstances, they should be classified as leiomyosarcomas. This uncertainty in their behaviour means that treatment should, whenever possible, be by radical excision.
Carcinomas

Colorectal carcinoma is the fourth most common variety of malignant tumour found in women, and its frequency in men is surpassed only by carcinoma of the bronchus and stomach. Overall, it is the second most common carcinoma in the Western countries, with approximately 18,000 patients in the UK dying per annum. The rectum is the most frequent site involved.

Origin

In many cases, operation specimens show that in some part of the bowel that has been removed, in addition to the carcinoma, there are one or more synchronous adenomas or papillomas, proof indeed that adenoma and papilloma of the rectum are precarcinomatous conditions. In approximately 5 per cent of cases, there is more than one carcinoma present. It is now believed that most rectal cancers start as an adenoma and this is due to a series of genetic changes which progressively change the adenoma from one that is not dysplastic to one that shows severe dysplasia and finally becomes a carcinoma (the adenoma—carcinoma sequence) (Vogelstein) (Chapter 67).

Pathological histology

Three types are recognised:

• well-differentiated adenocarcinoma;
• averagely differentiated adenocarcinoma;
• anaplastic, highly undifferentiated adenocarcinoma.

The more malignant varieties frequently contain large numbers of mucin-producing cells. The prognosis after treatment is greatly influenced by the histological grading of the tumour (see below).

Types of carcinoma spread

Local spread

Local spread occurs circumferentially rather than in a longitudinal direction. Usually a period of 6 months is required for involvement of a quarter of the circumference, and 7 1/2 months to 2 years for complete encirclement, the annular variety being common at the rectosigmoid junction. After the muscular coat has been penetrated, the growth spreads into surrounding mesorectum, but is still limited by the fascia propria (perirectal fascia). Eventually, the fascia propria is penetrated but this occurrence is rare before 18 months from the commencement of the disease. If penetration occurs anteriorly, the prostate, seminal vesicles or the bladder become involved in the male; in the female the vagina or the uterus is invaded. In either sex, if the penetration is lateral, a ureter may become implicated, while posterior penetration involves the sacrum and the sacral plexus. Downward spread for more than a few centimetres is rare except in anaplastic tumours.

Lymphatic spread

Enlargement of lymph nodes from bacterial infection is more frequent than enlargement from metastasis, and microscopical examination is required to detect carcinomatous involvement of the nodes.

Lymphatic spread from a carcinoma of the rectum above the peritoneal reflection occurs almost exclusively in an upward direction; below that level to within 1—2 cm of the anal orifice the lymphatic spread is still upwards, but the first halting place is in the pararectal lymph nodes of Gerota. The exception to this rule is when the neoplasm lies within the field — the middle rectal artery, i.e. between 4 and 8 cm from the anus, in which case primary lateral spread along the lymphatics that accompany the middle rectal vein is not infrequent.

Metastasis at a higher level than the main trunk of the superior rectal artery occurs only late in the disease. A radical operation should ensure that the high-lying lymph nodes are removed by ligating the inferior mesenteric artery and vein at the highest possible level.

Atypical and widespread lymphatic permeation can occur in highly undifferentiated neoplasms.

Venous spread

As a rule, spread via the venous system occurs late, except in that portion of the anal canal where the anoderm is firmly adherent to deeper structures. Anaplastic and rapidly growing tumours in younger patients are much more liable to spread in this way than tumours of relatively low malignancy. The principal sites for blood-borne metastases are: liver (34 per cent), lungs (22 per cent) and adrenals (11 per cent).

The remaining 33 per cent is divided among the many other locations where secondary carcinomatous deposits are wont to lodge, including the brain.

Peritoneal dissemination

This may follow penetration of the peritoneal coat by a high-lying rectal carcinoma.

Stages of progression

As a rule, carcinoma of the rectum does not metastasise early.

Dukes classified carcinoma of the rectum into three stages (Fig. 60.21).

A The growth is limited to the rectal wall (15 per cent). Prognosis excellent.

B The growth is extended to the extrarectal tissues, but no metastasis to the regional lymph nodes (35 per cent). Prognosis reasonable.
C. There are secondary deposits in the regional lymph nodes (50 per cent). These are subdivided into C1 where the local pararectal lymph nodes alone are involved, and C2 where the nodes accompanying the supplying blood vessels are implicated up to the point of division. This does not take into account cases that have metastasised beyond the regional lymph nodes or by way of the venous system. Prognosis bad. A stage D is often included which was not described by Dukes. This stage signifies the presence of widespread metastases, usually hepatic. Other staging systems have been developed (e.g. Astler—Coller TNM) to improve prognostic accuracy. The TNM classification has become popular inter-nationally. T represents the extent of local spread and there are four grades, T1, T2, T3, and T4, depending on whether the tumour (T) is confined to the mucosa or has penetrated the rectal wall. N describes nodal involvement and M indicates the pressure of distant metastases. Histological grading. In the great majority of cases, carcinoma of the rectum is a columnar-celled adenocarcinoma. The more nearly the tumour cells approach normal shape and arrangement, the less malignant is the tumour. Conversely, the greater the percentage of cells of an embryonic or undifferentiated type, the more malignant is the tumour:

**Colloid carcinoma.** This type of carcinoma is present in 12 per cent of cases. There are two forms: primary and secondary; much the more frequent is secondary mucoid degeneration of an adenocarcinoma. Histologically the glandular arrangement is preserved and mucus fills the acini. This type is of average malignancy. In a small number of cases the tumour is a primary mucoid carcinoma. The mucus lies within the cells, displacing the nucleus to the periphery, like the seal of a signet ring. Primary mucoid carcinoma gives rise to a rapidly growing bulky growth which metastasises very early and the prognosis of which is very bad.

**Clinical features**

Carcinoma of the rectum is not uncommon early in life, and when the disease commences in youth, in spite of radical treatment, death usually results within a year. However, the adult age of presentation is above 55 years. Often the early symptoms are so slight that the patient does not seek advice for 6 months or more.

**Bleeding**

Bleeding is the earliest and most common symptom. There is nothing characteristic about the time at which it occurs, neither is the colour or the amount of blood distinctive; often the bleeding is slight in amount, and occurs at the end of defecation, or is noticed because it has stained underwear. Indeed, more often than not, the bleeding in every respect simulates that of internal haemorrhoids (haemorrhoids and carcinoma sometimes coexist) and it is lamentable that, in spite of oft-repeated exhortations, the patient’s doctor sometimes fails to examine the rectum but prescribes a saline while the growth advances to inoperability (see footnote, Chapter 59).

**Sense of incomplete defecation**

The patient’s bowels open but there is the sensation that there are more faeces to be passed (tenesmus, a painful straining to empty the bowels without resultant evacuation). This is a very important early symptom and is almost invariably present in tumours of the lower half of the rectum. The patient may endeavour to empty the rectum several times a day (spurious diarrhoea), often with the passage of flatus and a little blood-stained mucus (‘bloody slime’).

**Alteration in bowel habit**

This is the next most frequent symptom. The patient may find it necessary to start taking an aperient, or to supplement the usual dose, and as a result a tendency towards diarrhoea ensues. A patient who has to get up before the accustomed hour in order to defecate, and one who passes blood and mucus in addition to faeces (‘early morning bloody diarrhoea’), is usually found to be suffering from carcinoma of the rectum. Usually, it is the patient with an annular carcinoma at the pelvicrectal junction who suffers with increasing constipation, and the one with a growth in the ampulla of the rectum with early morning diarrhoea (Bruce).

**Pain**

Pain is a late symptom, but pain of a colicky character accompanies advanced growths of the rectosigmoid, and is due to some degree of intestinal obstruction. When a deep carcinomatous ulcer of the rectum erodes the prostate or bladder, there is severe pain. Pain in the back, or sciatica, occurs when the growth invades the sacral plexus. Weight loss is suggestive of hepatic metastases.

**Early symptoms of rectal cancer**

- Bleeding per rectum
- Tenesmus
- Early morning diarrhoea

**Abdominal examination**

Abdominal examination is negative in early cases. Occasionally, when an advanced annular growth is situated at the rectosigmoid junction, signs of obstruction to the large intestine are likely to be present. By the time the patient seeks advice, metastases in the liver may be palpable. When the peritoneum has become studded with secondary deposits, ascites results.

**Rectal examination**

In approximately 90 per cent of cases, the neoplasm can be felt digitally: in early cases as a plateau or as a nodule with an indurated base. When the centre ulcerates, a shallow depression will be found, the edges of which are raised and everted; this, combined with induration of the base of the ulcer, is a frequent and unmistakable finding. On bimanual examination, it may be possible to feel the lower extremity of a carci-noma situated in the rectosigmoid. After the finger has been withdrawn, if it has been in direct contact with a carcinoma, it is smeared with blood or mucopurulent material tinged with blood. When a carcinomatous ulcer is situated in the lower third of the rectum, involved lymph nodes can sometimes be felt as one or more hard, oval swellings in the extrarectal tissues posteriorly or posterolaterally above the tumour. In females, a vaginal examination should be performed, and when the neoplasm is situated on the anterior wall of the rectum, with one finger in the vagina and another in the rectum, very accurate palpation can be carried out.
**Procto-sigmoidoscopy**

Procto-sigmoidoscopy will always show a carcinoma, if present — provided that the rectum is emptied of faeces beforehand.

**Biopsy**

Employing biopsy forceps ([Fig. 60.22](#)) by way of a sigmoidoscope, a portion of the edge of the tumour is removed. If possible, another specimen from the more central part of the growth is also obtained. Expert histological examination will not only enable the diagnosis of carcinoma to be confirmed, but the tumour can be graded as to its relative malignancy, although not always with complete accuracy.

**Barium enema.** Barium enema or, preferably, a colonoscopy is required if possible in all patients to exclude a synchronous tumour, be it an adenoma or a carcinoma. If an adenoma is found, it can be conveniently snared and removed via the colonoscope. If a synchronous carcinoma is present, the operative strategy will need changing.

When a stenosing carcinoma is present, it may not be possible using these investigations, especially colonoscopy, to visualise the proximal colon. However, in view of the high incidence of synchronous tumours, it is imperative that a colonoscopy is always performed either before or after surgical resection.

**Differential diagnosis.** When a seemingly benign adenomatous shows evidence of induration or unusual friability, it is almost certain that malignancy has occurred, even in spite of biopsy findings to the contrary. On the other hand, biopsy is invaluable in distinguishing carcinoma from an inflammatory stricture or an amoebic granuloma, which simulates a carcinoma very closely. The possibility of a neoplasm being an endometrioma should always be entertained in patients with dysmenorrhoea. The possibility of a carcinoid tumour in atypical cases must be remembered. In the last four instances biopsy should establish the correct diagnosis. The solitary ulcer syndrome has already been alluded to above.
Treatment

Some form of excision of the rectum is essential, if at all possible, because of the extreme suffering entailed if the neoplasm remains. However, before surgery is embarked upon, it is necessary to assess:

- the fitness of the patient for operation;
- the extent of spread of the tumour.

The findings will affect the surgical approach.

Assessment of spread should include ultrasonography or computed tomography (CT) of the liver, and a chest radio-graph to exclude distant metastases (Fig. 60.23).

Endoluminal ultrasound whereby a probe is placed in the rectal lumen can be used to assess the local spread of the tumour (Fig. 60.24), as can CT and, more recently, magnetic resonance imaging (MRI).

Principles of surgical treatment

Radical excision of the rectum, together with the mesorectum and associated lymph nodes, should be the aim. Even in the presence of widespread metastases a rectal excision should be considered, as this is often the best means of palliation. The presence of a solitary liver metastasis does not necessarily rule out the feasibility of a radical excision. Many instances have been reported where a presumed solitary liver metastasis has been resected either at the time of excision of the rectum or subsequently with long term survival being achieved.

When a tumour appears to be locally advanced, the administration of a course of preoperative radiotherapy may reduce its size and make it more amenable to radical excision. Indeed, recent evidence suggests that the administration of preoperative adjacent radiotherapy in all rectal cancer cases reduces the incidence of local recurrence significantly (Pahlman).

For patients who are unfit for radical surgery or who have widespread metastases, a local procedure such as transanal excision, laser destruction or interstitial radiation should be considered.

When a rectal excision is possible, whenever feasible, the aim should be to restore gastrointestinal continuity and continence by preserving the anal sphincter. A sphincter-saving operation (anterior resection) is usually possible for tumours of the upper two-thirds of the rectum. Although removal of the rectum with a permanent colostomy (abdominoperineal excision) is often required for tumours of the lower third of the rectum, the introduction of the stapling gun has enabled many more of these patients to be treated by a sphincter-saving procedure. Provided a minimum distal margin of clearance of 2 cm can be secured, it is safe to restore gastro-intestinal continuity (Williams). Because of the much wider degree of local spread by anaplastic tumours and the high risk of local recurrence, it has been customary not to perform restorative operations where these carcinomas are in the lower third of the rectum. However, with the realisation that a preoperative biopsy is often inaccurate with respect to the degree of histological differentiation, coupled with the more widespread use of preoperative and postoperative radiotherapy, many more anaplastic lesions are being treated by sphincter saving procedures. Anterior resection is now applied to at least two-thirds of cases presenting with carcinoma of the rectum. The principles of the operation involve radical excision of the neoplasm, with at least a 2 cm margin of normal bowel below the lower edge of the tumour, removal of all the mesorectum, i.e. total mesorectal excision (TME) (Heald) and high proximal ligation of the inferior mesenteric lymphovascular pedicle. Once the rectum has been mobilised adequately, and the bowel washed out proximally and distally, it is removed. Restoration of continuity by direct end-to-end anastomosis (manually or by stapling) must be carried out by a meticulous technique to reduce risks of suture line breakdown. If a perfect union is achieved, a protecting colostomy is not necessary (see later).

Preoperative preparation of the alimentary tract

This is usually achieved by a combination of mechanical cleansing (purgatives, enemas or 'whole-gut irrigation') and antibiotics. The antibiotic regime must be active against both aerobic and anaerobic organisms. At present a suitable prescription would be cefuroxime 750 mg plus metronidazole 500 mg 1 hour before surgery, plus another two doses of each drug at 6 and 12 hours after the operation. If a patient comes to surgery with a loaded colon, perioperative wash outs can be performed provided the rest of the wound is scrupulously protected. Detergent preparations are available for this.

Blood and electrolyte deficiencies are corrected. Before commencing the operation, an indwelling catheter is inserted into the bladder.

Combined (abdominal and perineal) excision of the rectum. This operation is still required for large extensive tumours of the lower third of the rectum, which are unsuitable for a sphincter-saving procedure. It has the advantage for difficult tumours of the lower rectum of two surgeons operating from the abdominal and perineal approaches simultaneously. This considerably reduces the time expended in performing the operation, and obviates turning the patient. A large catheter is passed and with the patient in Trendelenburg lithotomy position, the legs being supported in special crutches designed by Lloyd-Davies, access is afforded to the abdomen and the perineum at the same time.

The abdominal surgeon makes a midline incision, extending it well above the umbilicus. The liver and the peritoneum are examined for metastases and the degree of fixity of the growth is established. The small intestine is packed away from the pelvis. A self-retaining retractor is placed in the wound and the pelvic colon freed by dividing any congenital adhesions on the left side. The peritoneum and the pelvic floor are divided with a knife by an incision which runs from the colon at the proposed site of division over the mesocolon and across the base of the bladder or near the cervix on the pelvic floor and then upwards on the right side of the mesocolon. The peritoneum is now raised, using the points of the scissors to expose the ureters and testicular or ovarian artery. The mesocolon is now divided at the site of the proposed division of the colon and the trunk of the inferior mesenteric artery (Fig. 60.25), is ligated and divided distal to the first branch. (Some surgeons emphasise 'flush ligation' of the artery at its origin from the aorta.) The rectosigmoid mesentery is further divided and separated from the sacrum by blunt dissection with the fingers. In this way, the sacrum is cleared almost down to the coccyx. The peritoneal incision anterior to the rectum is now deepened and the seminal vesicles or the vaginal wall are identified so that Denonvilliers' fascia behind them is cleared by a dissection leading down to the prostate or perineal body. The middle rectal vessels usually lying anterior to the lateral ligaments on each side are now divided and ligated with diathermy. The site of division of the pelvic colon is cleared of fat and the colon divided between clamps with diathermy.

By this time, the perineal surgeon working from below has mobilised the anus and the lower rectum so that the whole of the bowel together with a clamp can be passed through the perineal wound by the abdominal surgeon. Haemostasis over the sacrum may be difficult, but it is achieved by diathermy and a hot saline pack left in position for a few minutes. The pelvic peritoneum is now united by continuous catgut stitches from the bladder right back over the promontory of the sacrum (Fig. 60.26).

The site in the left iliac fossa for the colostomy should have been marked preoperatively by the stoma care nurse in consultation with the
patient. If this has not been possible it should be sited equidistant from the umbilicus and the left anterior superior iliac spine at the linea semilunaris about 2.5 cm above the spinoumbilical line. A circular piece of skin and fascia, about 3 cm in diameter, is excised and this hole deepened to excise similar areas of fascia and peritoneum. The protected end of the colon with the clamp is now passed through this incision and the colostomy performed by suturing the colon to the peritoneum and the mucosa directly to the skin. The paracolic gutter is closed with sutures — this will close the 'lateral space'. The abdomen is closed and the layers of the incision are protected from the colostomy. An adherent plastic colostomy bag is then fitted in position and the dressings are placed on the abdominal wound.

When the abdominal surgeon has made certain that the condition is operable, the perineal surgeon closes the anus with pursestring sutures of stout silk. An elliptical incision between the tip of the coccyx and the central perineal point is made around the anus and deepened. The left forefinger is insinuated into the levator ani which is divided lateral to the finger first on one side and then on the other. The dissection is deepened posteriorly by incising Waldeyer's fascia which is a thick condensation of pelvic fascia lying between the rectum and the sacrum. Contact is made with the abdominal surgeon. The apex of skin anterior to the anus is grasped in a haemostat, which serves as a retractor, and by scissors or gauze dissection the wound is deepened, when the catheter within the membranous urethra will be felt. In both the male and the female, a plane of cleavage will be found between the rectum and the prostate of the rectum and the vagina, respectively. This plane having been carefully determined, Denonvilliers' fascia is divided, after which the rectum can be stripped from the prostate or the vagina. The posterior wall of the vagina is frequently excised with the rectum. When the abdominal surgeon has cleared the rectum laterally, the whole of the anus and rectum can be drawn downwards and removed. Haemostasis must be secured and the perineal wound closed anteriorly and posteriorly in layers with a large drainage tube or closed entirely around suction drains. Large dressings of gauze and wool are applied over the area and a triangular bandage is used to keep the dressing in place. It is usual to employ primary closure of the perineal wound, and to use laterally situated suction drains brought out through each ischiorectal fossa to keep the large perineal cavity from filling up with blood and serous exudate. These drains can be removed after 5 days.

After treatment. The patient is returned to bed, blood transfusion being continued as necessary. The catheter is connected to a closed drainage system and left in for 5 days. It may have to be reinserted if voluntary micturation is not re-established.

Reactionary haemorrhage from the perineal wound may demand return to the theatre to open and pack the wound with gauze. The colour of the colostomy must be watched to make sure that the blood supply is adequate. Small-bowel obstruction may occur by herniation through the lateral space of the colostomy or through the pelvic peritoneal closure line. Discharge of urine from the perineal wound demands immediate investigation for bladder, ureteric or urethral damage.

Care of the colostomy. This is much the same as the care of an ileostomy (Chapter 57). Within a very short time, the colostomy acts once or twice a day. The patient soon learns which foods cause diarrhoea and therefore avoids them. Many patients are now taught to empty their lower colon by irrigations through the colostomy: this has many advantages for the patient who requires an inactive colostomy while at work. Occlusive caps are also available which fit in the end of the stoma and allow some degree of continence.

Stenosis of colostomy is usually avoided by the removal of the circle of skin and subcutaneous tissues at the colostomy site. Dilators may be necessary if there is any tendency for stenosis to occur.

Laparoscopic abdominoperineal excision. Recently, it has been demonstrated that the operation can be carried out laparoscopically. The rectum is mobilised completely from above using the laparoscope. A small circular perineal incision is made around the anal canal, and via a limited perineal dissection the rectum and anal canal are completely mobilised. After transecting the mid-sigmoid colon with an Endo GIA instrument, the specimen containing the carcinoma is delivered through the perineal wound. A trephine incision is made in the left iliac fossa and the sigmoid colon is brought out as an end colostomy. Although the operative technique has been shown to be quite feasible and reduces postoperative pain and time in hospital, there is concern that it may not be as curative as the standard ‘open’ technique. The concern surrounds the degree of clearance that can be achieved via the laparoscope, and the risk of free cancer cells being disseminated around the peritoneal cavity and implanting, particularly at the ‘port’ sites. Controlled trials will be needed to determine whether the laparoscopic approach is safe.

Anterior resection

In cases of carcinoma of the rectum situated above the peritoneal reflection, lymphatic spread is virtually confined to the upward path. Here a wide resection of the bowel with its lymphatic field, followed by end-to-end anastomosis and preservation of the sphincter mechanism is both justifiable and highly desirable.

As discussed previously, in the last two decades there has been a move to extend sphincter-saving operations to treat most tumours of the middle third of the rectum, and indeed many of the lower third. The introduction of the stapling instruments, particularly the new Premium CEEA instrument with its detachable head, has made such procedures far more feasible.

The operation of low anterior resection proceeds in the same manner as the abdominal part of abdominoperineal excision. The rectum is mobilised to such an extent that a right-angled clamp can be placed at least 2 cm below the tumour. The rectal stump can then be stapled transversely, using a TA instrument. After the rectum and sigmoid colon have been excised, continuity is re-established by the method depicted in Fig. 60.27. Some surgeons are concerned that the anastomotic leakage rate will be increased if the technique of cross-stapling of the rectal stump is used. They prefer to place a pursestring suture in the rectal stump lumen, as well as in the proximal colon. After the stapling gun is fired and removed, it is essential that the head of the instrument is detached and the ‘doughnuts’ are examined. A break in the circumference of one or both ‘doughnuts’ signifies a defect in the anastomosis, and the latter should be sought and repaired with interrupted sutures. In these circumstances, a covering stoma will also be required to allow safe healing of the anastomosis. Some surgeons believe that such a stoma is required for all colorectal and coloanal anastomoses which are constructed below the peritoneal reflection.

Occasionally, although the rectum, together with its tumour, can be removed adequately, continuity cannot be restored by a stapling technique. In such cases, it may still be possible to restore continuity by bringing the colon down to the anal canal and constructing a coloanal anastomosis via the transanal route (Fig. 60.29) (the so-called abdominotransanal—coloanal operation first described by Parks).

In each of the procedures, it is essential to ensure that any free tumour cells released by mobilisation of the rectum are destroyed by irrigation of the colonic and rectal lumens with a cancercidal solution such as 1 per cent centrimide. By so doing, the implantation of such cells and subsequent local recurrence is prevented. However, it should be realised that, although a small percentage of local recurrences is due to implantation of shed cells, the majority is due to inadequate removal of the tumour at the time of the initial operation. Although it is usual for the surgeon to remove all macroscopic tumour, he or she is often unable to remove all microscopic tumour. Particular interest has recently focused on local microscopic spread. It is now known that micrometastases are present in the mesorectum, and these are the most likely cause of local recurrence after rectal excision (Quirke). Heald has emphasised how important it is to remove all of the mesorectum during anterior resection or abdomino-penineal excision. TME is now being practised world-wide and appears to reduce the risks of local recurrence substantially (Fig. 60.30). However, it is unlikely that surgery alone will deal adequately with the micrometastases in the pelvis. Consequently, adjuvant
radiotherapy may have added benefit (see below).

Laparoscopic anterior resection

It is now possible to perform a high anterior resection using the laparoscope, the anastomosis being performed intraperitoneally using a slightly modified circular stapling gun. Laparoscopic anastomoses below the peritoneal reflection are feasible, but are much more difficult. However, with improvements in technology such procedures may become more commonplace. Nevertheless, like laparoscopic abdominopерineal excision, there is concern that these operations may be less curative than the standard operations.

Hartmann’s operation. This is an excellent procedure in an old and feeble patient who would not stand a lengthy anterior resection or an abdominopерineal procedure. Through an abдinal incision the rectum is excised, if possible, to within 2.5 cm of the anus, the anorectal stump is transected usually with a stapler, a colostomy is performed and the peritoneum oversewn to cover the pelvic defect in the usual way. In an old patient, where the neoplasm is usually slow growing and spread is late, this is a most useful operation.

Palliative colostomy. This is indicated only in cases giving rise to intestinal obstruction, or where there is gross infection of the neoplasm. It is often possible to resect the growth later, and in some cases cure, rather than palliation, is achieved.

Local operations. For small, low-grade mobile lesions, which are often Dukes’ A tumours, local removal should be curative. For these tumours, especially in the unfit or patients who will not accept a colostomy, local removal has been used. Such operations are only suitable for lesions within 10 cm of the anal verge. Turnbull advocated local diathermy removal while York-Mason developed a trans-sphincteric approach, but a peranal approach is usually possible, with full-thickness excision of the lesion. More recently, the TEM technique has been used for these tumours. There is considerable doubt whether such techniques should be used for potential curable lesions as they do not deal with the mesorectal or lymphatic spread of the tumour.

More extensive operations. When the carcinoma of the rectum has spread to contiguous organs, the radical operation can often be extended to remove these structures. Thus in the male, where the spread is usually to the bladder, a cystectomy and resection of the rectum can be effected. In the female, the uterus acts as a barrier preventing spread from the rectum to the bladder. Accordingly, a hysterectomy should be undertaken in addition to excision of the rectum. Should the bladder base be involved, then pelvic exenteration must include that structure. Pelvic excision for carcinoma of the rectum is justifiable only when the surgeon is reasonably confident that the growth can be removed in toto.

Pelvic exenteration (Brunsчwig’s operation). The aim is to remove all of the pelvic organs, together with the internal iliac and the obturator groups of lymph nodes (Fig. 60.30). The Trendelenburg lithotomy position facilitates the procedure, and ligation of both internal iliac arteries diminishes the blood loss. The small intestine fills the empty pelvis. Special care must therefore be taken to suture accurately the perineal skin, and to avoid pressure necrosis of the perineal incision by nursing the patient on alternate sides. Some form of urinary diversion is necessary (Chapter 65), usually an ileal conduit.

Radiotherapy. With modern techniques (MV cobalt therapy or neutron beam irradiation) some adenocarcinomas now respond to radiotherapy. Various controlled trials have recently been performed to investigate the effect of adjuvant radiotherapy given either preoperatively or postoperatively. The overall results of these trials suggest that provided an adequate dose is given (4000—5000 Gy) adjuvant radiotherapy can reduce the incidence of local recurrence; however, long-term survival is not affected. Surprisingly, with modern techniques morbidity from the radiation is not a major problem. Another advantage of preoperative radiotherapy is often its ability to reduce the size of a large tumour and make its subsequent removal easier. Palliative irradiation can be given for inoperable primary tumours or local recurrence, especially when painful. Papillon perfected a technique of intravaginal radiation which applies the treatment direct to the tumour from the rectal lumen. In a selected series of early cases, the results were good (more than 70 per cent 5-year survival rates). Intraoperative irradiation is also being evaluated.

Chemotherapy and immunotherapy. A variety of drugs has been tried both as an adjuvant therapy and for the treatment of disseminated disease. The most frequently used drug is 5-fluorouracil (SFU). Up until recently, the results of various trials using SFU either alone or in combination were disappointing. However, some optimism has recently been aroused by studies which have infused SFU into the portal vein during and immediately after the primary operation (Taylor). Such adjuvant therapy is thought to kill malignant cells which are released into the circulation during operative manipulation of tumour, and thus prevent the formation of metastases. Initial results suggest that such therapy does reduce the incidence of metastases and can prolong survival.

There is also evidence that systemic folic acid (Leucovorin) has an effect as an adjuvant therapy when used in combination with SFU. Similarly, studies from both the UK and the USA suggested that the combination of SFU and levamisole (a nonspecific stimulator of the immune process) was effective as an adjuvant therapy for Dukes’ C carcinomas. A variety of studies is now being conducted world-wide to examine which are the best forms of adjuvant therapy that should be used for both rectal and colon cancer. At the present it is generally accepted that the combination of SFU and folic acid given for a 6-month period in patients who are at high risk of recurrence can reduce cancer specific mortality.

There is considerable interest at present in immunotherapy for the treatment of disseminated colorectal cancer. Various monoclonal antibodies to carcinoembryonic antigen have been developed, which theoretically can be targeted to malignant deposits. When these antibodies are conjugated to cacncerial agents, they have the ability to destroy the cancerous cells. Unfortunately, the antibodies are not sufficiently specific and, therefore, normal tissue is likely to be damaged. Nevertheless, the search continues for more selective antibodies.

Results of surgery for rectal cancer. In specialised centres, the resectability rate may be as high as 95 per cent, with an operative mortality of less than 5 per cent. Overall, 5-year survival rates in these centres is about 50 per cent, but the rate falls to approximately 25 per cent when the results of nonspecialised centres are included. The most likely reason for this difference is the higher proportion of advanced and emergency cases treated in nonspecialised hospitals. However, another contributing reason is that in specialised centres there is a concentration of expertise which is not readily available in district hospitals. Survival rates are influenced by Dukes’ stage, with C cases doing worse than A and B lesions (Fig. 60.31). The degree of mobility also influences survival, with fixed lesions having a worse prognosis than mobile lesions. The lower the tumour is in the rectum, the worse the outlook. Histological grade also influences outcome, anaplastic lesions having the worse prognosis. Interestingly, despite the more frequent use of sphincter-saving resection compared with abdominopерineal excision, survival has not been affected.

Local recurrence. Local recurrence after rectal excision is a major problem. The patient often presents with persistent pelvic pain, which radiates down the legs if sacral roots have been involved. Bladder problems may occur. If recurrence develops after abdominopерineal excision, a swelling or induration may be present in the perineum, or an abscess or discharging sinus may develop. Occasionally, the presence of a large recurrence in the pelvis may lead to bilateral leg oedema, from either from pressure or invasion of lymphatics or veins. After sphincter-saving resection, local recurrence may produce a change in bowel habit, or the passage of blood per rectum. Sigmoidoscopic examination after sphincter-saving resection may reveal friable tissue at the anastomosis which, when biopsied, confirms the diagnosis.
However, usually the recurrence is situated extrarectally, and is detected either as induration on digital examination or by endoluminal ultrasonography or CT. These investigations can also detect recurrence before it causes symptoms. Local recurrence rates vary between 2 and 25 per cent and seem to occur with equal frequency after sphincter-saving resection and abdominoperineal excision. The most common cause is inadequate removal of all the tumour at the initial operation. This is due to the presence of microscopic tumour deposits in the tissues surrounding the rectum. Heald has shown that if the mesorectum is removed in its entirety, the local recurrence rate can be reduced to less than 5 per cent.

Other possible causes for local recurrence include implantation of viable cells on the suture line and the development of a new primary tumour. Although both mechanisms may occur, inadequate removal of the tumour is by far and away the most important reason for recurrence. Eighty per cent of all local recurrences develop within 2 years following surgery and are very difficult to treat. The best prospect of salvage is by surgical resection. However, it is only possible to achieve apparent complete removal in a minority of cases. It was hoped that serial measurements of carcinoembryonic antigen might identify those patients who might benefit by early radical surgery, but this has been found not to be the case (Northover).

The mainstay of therapy for local recurrence is radiotherapy, which is invariably palliative. Occasionally, a neodymium: yttrium-aluminium-garnet (Nd:Yag) laser can be used to deal with an obstructing or bleeding lesion.

**Carcinoid tumour.** Carcinoid tumour of the rectum, as far as its lethal properties are concerned, can be looked upon as a gradation between a benign tumour and a carcinoma. A latter-day aphorism is ‘keep carcinoid in mind when an atypical neoplasm (ulcer) of the rectum is encountered’. Like benign lymphoma, carcinoid tumour originates in the submucosa, the mucous membrane over it being intact. Consequently, it seldom produces evidence of its presence in the early stages, when it presents as a small plaque-like elevation. The incidence of clinical malignancy, i.e., the occurrence of metastases, is 10 per cent. This is much less than that for carcinoid tumour of the small intestine, but it is greater than that of carcinoid tumour of the vermiform appendix. Multiple primary carcinoid tumours of the rectum are not infrequent. The neoplasm is of slow progression, and usually metastasises late. Large carcinoids (over 2 cm) are almost always malignant.

**Treatment.** Local excision is sufficient treatment. Resection of the rectum is advisable if the growth is more than 2.5 cm in diameter, if recurrence follows local excision or if the growth is fixed to the perirectal tissues. Even when metastases are present, resection may prolong life.

Venous drainage

Arterial supply of the puborectalis muscle sling.

Arterial supply

Surgical anatomy

The anal canal commences at the level where the rectum passes through the pelvic diaphragm and ends at the anal verge (the external or distal boundary of the anal canal). The muscular junction between the rectum and anal canal can be felt with the finger as a thickened ridge the anorectal bundle or 'ring'.

Anal canal musculature (Fig. 61.1)

The internal sphincter is a thickened continuation of the circular muscle coat of the rectum. This involuntary muscle commences where the rectum passes through the pelvic diaphragm and ends at the anal orifice, where its lower border can be felt. The internal anal sphincter is 2.5 cm long and 2–5 mm thick. When exposed during life, it is pearly white in colour, and its individual, transversely placed fibres can be seen clearly. Spasm and contracture of this muscle play a major part in fissure and other anal affections.

The longitudinal muscle is a continuation of the longitudinal muscle coat of the rectum intermingled with fibres from the puborectalis. Its fibres fan out through the lowest part of the external sphincter, to be inserted into the true anal and perianal skin. The longitudinal muscle fibres that are attached to the epithelium provide pathways for the spread of perianal infections, and mark out tight 'compartments that are responsible for the intense pressure and pain that accompany many localised perianal lesions.

Beneath the anal skin lie the scanty fibres of the corrugator cuts ani muscle.

The external sphincter, formerly subdivided into a deep, superficial and subcutaneous portion is now considered to be one muscle (Goligher). Some of its fibres are attached posteriorly to the coccyx, while anteriorly they are inserted into the midperineal point in the male, whereas in the female they fuse with the sphincter vaginae. In life the external sphincter is pink in colour and homogeneous. Unlike the pale internal sphincter muscle, which is involuntary, the red external sphincter is composed of voluntary (somatic) muscle.

Between the internal (involuntary) sphincter and the external (voluntary) sphincter muscle mass is found a potential space, the intersphincteric plane. This plane is important as it contains the basal parts of eight to 12 apocrine glands, which can cause infections, and it is also a route for the spread of pus. It can also be opened up by a surgeon to provide access for operations on the sphincter muscles.

The pubeorectal plays a key role in maintaining the angle between the anal canal and rectum and, hence, is essential for the preservation of continence (Fig. 61.2). There is a close association between the pubeorectal portion of the levator ani and the external sphincter muscle.

The mucous membrane. The pink columnar epithelium lining the rectum extends through the anorectal ring into the surgical anal canal. The mucosa of the upper anal canal is attached loosely to the underlying structures, and covers the internal rectal plexus. Passing downwards where it clothes the series of eight to 12 longitudinal folds known as the columns of Morgagni, the mucus membrane becomes cubical, and red in colour (Fig. 61.3); above the anal valves the mucous membrane becomes plum coloured. Just below the level of the anal valves there is an abrupt, albeit wavy, transition to squamous epithelium, which is parchment colour. This wavy junction constitutes the dentate line. The squamous epithelium lining the lower anal canal is thin and shiny, and is known as the anoderm. This squamous epithelium differs from the true skin in that it has no epidermal appendages, i.e. hair and sweat glands. The anoderm passes imperceptibly into the pigmented skin of the anus. At the dentate line the anoderm is attached very firmly indeed to deeper structures.

The dentate line is a most important landmark both morphologically and surgically. It represents the site of fusion of the proctodeaum and post-allantoic gut, and the position of the anal membrane, remnants of which may frequently be seen as anal papillae situated on the free margin of the anal valves. The dentate line separates:

above
- cubical epithelium;
- autonomic nerves (insensitive);
- portal venous system;
below
- from squamous epithelium;
- from spinal nerves (very sensitive);
- from systemic venous system.

The anal valves of Ball are a series of transversely placed semilunar folds linking the columns of Morgagni. They lie along and actually con-stitute the waviness of the dentate line. They are functionless remnants of the fusion of the post-allantoic gut with the proctodeaum.

The crypts of Morgagni (syn. anal crypts) are small pockets between the inferior extremities of the columns of Morgagni. Into several of these crypts, mostly those situated posteriorly, opens one anal gland by a nar-row duct. This duct bifurcates, and the branches pass outward to enter the internal sphincter muscle, in 60 per cent of people (Fig. 61.4). Issuing from this ampula there are three to six tubular sub-branches that extend into the intermuscular connective tissue, where they end blindly. In some lower animals, these glands secrete an odoriferous substance during the rutting season; in humans, their function, if any, is obscure. Some of their cells have been shown to give a positive staining reaction for mucin, but as the lining epithelium is mainly cubical, the mucus secreting propensity of the anal glands must be extremely small. Infection of an anal gland can give rise to an abscess, and in the opinion of a number of surgeons, infection of an anal gland is the most common cause of infection of an anal abscess and fistulae.

The anorectal ring marks the junction between the rectum and the anal canal. It is formed by the joining of the puborectalis muscle (Fig. 61.2), the deep external sphincter, conjoined longitudinal muscle and the highest part of the internal sphincter. The anorectal ring can be clearly felt digitally, especially on its posterior and lateral aspects. Division of the anorectal ring results in permanent incontinence of faeces. The position and length of the anal canal, as well as the angle of the anorectal junction, depend to a major extent on the integrity and strength of the puborectalis muscle sling.

Arterial supply

The anal canal is supplied by branches from the superior, middle and inferior haemorrhoidal arteries. The most important is the superior haemorrhoidal, whose left branch sup-pplies the left half of the canal by a single terminal branch, while its right has two terminal branches. All of the arteries contribute to a rich submucous and intramural plexus, so that interruption of the arterial supply from above by division of the superior and middle rectal arteries does not deprive the anus of its blood supply.

Venous drainage

Anatomy and physiology

Anal canal musculature (Fig. 61.1)

In women the external sphincter is pink, in men red. Guide by palpating the patient's perianal skin. There is a close association between the puborectalis portion of the levator ani and the external sphincter muscle. Some of its fibres are attached posteriorly to the coccyx, while anteriorly they are inserted into the mid-perineal point in the male, whereas in the female they fuse with the sphincter vaginae. In life the external sphincter is pink in colour and homogeneous. Unlike the pale internal sphincter muscle, which is involuntary, the red external sphincter is composed of voluntary (somatic) muscle.

The intersphincteric plane is important as it contains the basal parts of eight to 12 apocrine glands, which can cause infections, and it is also a route for the spread of pus. It can also be opened up by a surgeon to provide access for operations on the sphincter muscles.

The pubeorectal plays a key role in maintaining the angle between the anal canal and rectum and, hence, is essential for the preservation of continence (Fig. 61.2). There is a close association between the pubeorectal portion of the levator ani and the external sphincter muscle.

The mucous membrane. The pink columnar epithelium lining the rectum extends through the anorectal ring into the surgical anal canal. The mucosa of the upper anal canal is attached loosely to the underlying structures, and covers the internal rectal plexus. Passing downwards where it clothes the series of eight to 12 longitudinal folds known as the columns of Morgagni, the mucus membrane becomes cubical, and red in colour (Fig. 61.3); above the anal valves the mucous membrane becomes plum coloured. Just below the level of the anal valves there is an abrupt, albeit wavy, transition to squamous epithelium, which is parchment colour. This wavy junction constitutes the dentate line. The squamous epithelium lining the lower anal canal is thin and shiny, and is known as the anoderm. This squamous epithelium differs from the true skin in that it has no epidermal appendages, i.e. hair and sweat glands. The anoderm passes imperceptibly into the pigmented skin of the anus. At the dentate line the anoderm is attached very firmly indeed to deeper structures.

The dentate line is a most important landmark both morphologically and surgically. It represents the site of fusion of the proctodeaum and post-allantoic gut, and the position of the anal membrane, remnants of which may frequently be seen as anal papillae situated on the free margin of the anal valves. The dentate line separates:

The crypts of Morgagni (syn. anal crypts) are small pockets between the inferior extremities of the columns of Morgagni. Into several of these crypts, mostly those situated posteriorly, opens one anal gland by a narrow duct. This duct bifurcates, and the branches pass outward to enter the internal sphincter muscle, in 60 per cent of people (Fig. 61.4). Issuing from this ampula there are three to six tubular sub-branches that extend into the intermuscular connective tissue, where they end blindly. In some lower animals, these glands secrete an odoriferous substance during the rutting season; in humans, their function, if any, is obscure. Some of their cells have been shown to give a positive staining reaction for mucin, but as the lining epithelium is mainly cubical, the mucus secreting propensity of the anal glands must be extremely small. Infection of an anal gland can give rise to an abscess, and in the opinion of a number of surgeons, infection of an anal gland is the most common cause of infection of an anal abscess and fistulae.

The anorectal ring marks the junction between the rectum and the anal canal. It is formed by the joining of the puborectalis muscle (Fig. 61.2), the deep external sphincter, conjoined longitudinal muscle and the highest part of the internal sphincter. The anorectal ring can be clearly felt digitally, especially on its posterior and lateral aspects. Division of the anorectal ring results in permanent incontinence of faeces. The position and length of the anal canal, as well as the angle of the anorectal junction, depend to a major extent on the integrity and strength of the puborectalis muscle sling.

Arterial supply

The anal canal is supplied by branches from the superior, middle and inferior haemorrhoidal arteries. The most important is the superior haemorrhoidal, whose left branch supplies the left half of the canal by a single terminal branch, while its right has two terminal branches. All of the arteries contribute to a rich submucous and intramural plexus, so that interruption of the arterial supply from above by division of the superior and middle rectal arteries does not deprive the anus of its blood supply.

Venous drainage
The anal veins are distributed in similar fashion to the arterial supply. The superior and middle haemorrhoidal veins drain via the inferior mesenteric vein into the portal system, having become the superior rectal vein en route. The superior haemorrhoidal vein drains the upper half of the anal canal. The inferior haemorrhoidal veins drain the lower half of the anal canal and the subcutaneous perianal plexus of veins: they eventually join the external iliac vein on each side.

**Lymphatic drainage**

Lymph from the upper half of the anal canal flows upwards to drain into the post-rectal lymph nodes and from there goes to the para-aortic nodes via the inferior mesenteric chain. Lymph from the lower half of the anal canal drains on each side first into the superficial and then into the deep inguinal group of lymph glands. However, if the normal flow is blocked, e.g. by tumour, the lymph can be diverted into the alternative route.

**Surgical physiology of the anal muscles and pelvic floor**

The function of the anal canal and pelvic floor muscles is not only to contain the contents of the rectum, but also to allow effortless, unimpeded voiding at defecation. Interference with the integrity of the anatomy or physiology of the muscles of the anus and pelvic floor can lead to the extremes of intractable constipation or incontinence. If the muscles of the pelvic floor become too floppy, the entire anorectal mechanism can drop down (‘perineal descent’), or alternatively can gape open, so allowing intussusception and prolapse of the rectum.

If the puborectalis and anorectal ring of muscles fail to relax appropriately (so-called ‘inappropriate function’ or anismus) to allow the rectum to empty at defecation, obstructed defecation ensues: this can usually be overcome by excessive voluntary straining efforts, but frequently ends in intractable constipation. Excessive straining can cause both partial and complete rectal prolapse. When a patient presents with incontinence caused by weak or damaged anorectal musculature, or if bizarre or extreme complaints of constipation are elicited, it is now possible to investigate these symptoms to obtain objective data on which to base a management protocol (Swash and Henry). The length, resting tone and the power to relax and contract the anal sphincter muscles can be assessed by manometry and electromyography (Figs 61.5, 61.6 and 61.7); these studies can be combined with delineation of rectal sensibility and function by balloon distension and radiology (‘defecatory proctography’) and the abnormalities identified. In addition to the intrinsic defects, mechanical deviations can be mapped: the level and angle of the anorectal junction can be established by clinical observation and by an appliance (‘perineometer’). Further-more, it is possible to take radiographs of the acts of straining and evacuation while simultaneously recording electromyographs of the sphincter muscles and intrarectal pressure (Williams) (Figs 61.8). This technique is known as dynamic integrated proctography. Endoluminal ultrasound can also be used to visualise the integrity of both the internal and external anal sphincters (Fig. 61.9). The above techniques provide information which enables many patients with incontinence and constipation to be treated effectively.
Examination of the anus

This requires careful attention to circumstances. The examining couch should be of sufficient height to allow easy inspection and access for any necessary manoeuvres. A good light is mandatory. The Sims (left lateral) or the lithotomy position is satisfactory: the latter is less convenient for an elderly patient and can cause social embarrassment to young women. A protective glove should be worn. The patient should be relaxed and able to co-operate. A few quiet words from the doctor can prevent many loud ones from the patient.

Inspection

With the buttocks opened, the anus is inspected. Note is made of any lesions, e.g. inflammatory skin changes, haemorrhoids, fissure (‘sentinel pile’) or fistula. The patient is asked to strain down before inspection is concluded.

Digital examination with the index finger

A good lubricant is necessary neither too little nor too much. Any secretions should be sampled before applying lubricant to the anal verge.

Extreme gentleness should be the rule so that pain is not caused. Painful spasm of the anal sphincters is confirmation of a hidden fissure if the history is suggestive.

The examination should check normal, as well as abnormal, structures according to the following plan:

- intraluminal:
  - normal: faeces,
  - abnormal: polyp or carcinoma;
- intramural:
  - normal: sphincter muscles and anorectal angle,
  - abnormal: carcinoma or leiomyoma;
- extramural:
  - normal: perianal structures,
  - abnormal: abscess.

At the same examination, the rectum is examined according to the same system. Before withdrawing the finger, the patient is asked again to strain down, and a note is made regarding the prostate in a male patient and the cervix, uterus and pouch of Douglas in a female.

Discharge

After withdrawal, the finger is examined for mucus, pus, blood and abnormal faecal material.

Proctoscopy (Fig. 61.10)

This examination is of great importance. Either the Sims position with the buttocks elevated on a small cushion, or the knee—elbow position (Fig. 61.11) may be used. The lower third of the rectum, the anorectal junction and the anal canal can be inspected as the instrument is withdrawn slowly. The patient should also be asked to strain during withdrawal as by so doing an internal intussusception may be made visible. Minor procedures can be carried out through this instrument, e.g. treatment of haemorrhoids by injection or banding (see below) and biopsy.

Sigmoidoscopy (Chapter 60)

Although this is a strictly an examination of the rectum and lower sigmoid colon, it should be carried out even when an anal lesion has been confirmed. Rectal pathology, e.g. colitis or carcinoma, is frequently the cause of an anal lesion, e.g. fissure or haemorrhoids. Not infrequently, rectal pathology is found that is independent of the anal lesion and which requires treatment.

Special investigations

These are discussed above.

Physiological studies
Manometry
Electrophysiology
Proctography
Endoluminal ultrasound
Congenital abnormalities

Early in embryonic life there is a common chamber — the cloaca — into which open the hind gut and the allantois. The cloaca becomes separated into the bladder and post-allantoic gut (rectum) by the down growth of a septum. About this rime an epiblastic bud, the proctodaeum, grows in towards the rectum. Normally fusion between these two structures occurs during the third month of intrauterine life.

Imperforate anus

(The term is used as a well-recognised description. Strictly it should be ‘agenesis’ and ‘atresia’ of the rectum and anus.) One infant in 4500 is born with an imperforate anus, or with imperfect fusion of the post-allantoic gut with the proctodaeum. The condition is divided into two main groups: the high and the low, depending on whether the termination of the bowel is above or below the pelvic floor. The low varietes are easy to diagnose and relatively simple to treat, and the outlook is good. The high varieties often have a fistula into the urinary tract together with a deficient pelvic floor, and are difficult to treat.

Low abnormalities (Fig. 61.12)

Covered anus. The underlying anal canal is covered by a bar of skin with a track running forwards to the perineal raphe. The track should be opened with scissors, followed by routine dilatation of the anus.

Ectopic anus. The anus is situated anteriorly and may open in the perineum in boys, or more commonly in the vulva in girls, or rarely into the vagina. A plastic ‘cut back’ operation is required (Pena).

Stenosed anus. The anus is microscopic, but careful examination usually reveals a minute opening which responds to regular dilatation.

Membranous stenosis. Here the anus is normally sited, but is covered with a thin membrane which bulges with retained meconium. It is rare, and an incision will cure the condition.

High abnormalities (Fig. 61.13)

These are often associated with a fistulous connection between the blind rectal stump and the bladder, or other abnormalities of the pelvic structures.

Anorectal agenesia. A blind rectal pouch lies just above the pelvic floor — its anterior aspect in the male is attached to the bladder and often there is a rectovesical fistula manifested by the passage of gas or meconium in the urine. In the female, the fistula is usually into the posterior fornix.

Rectal atresia. The anal canal is normal but ends blindly at the level of the pelvic floor. The bowel also ends blindly above the pelvic floor without a fistulous opening. This anomaly is rare but must be treated by mobilisation of the rectum and excision of the stricture. After that, end-to-end anastomosis of the anus and rectum must be attempted. More conservative measures are followed by an intractable stricture.

Cloaca. This occurs only in females and here the bowel, urinary and genital tracts all open into a common wide cavity. Commonly severe malformations of the area are associated with other developmental abnormalities, e.g. tracheobronchial fistula.

Clinical management

As congenital abnormalities are frequently multiple, very careful general examination of the baby must be made to exclude any other anomalies. It is urgent and important to determine whether the abnormality is high or low, and a radiograph will help.

Radiologicalexamination

Six hours after birth sufficient air may have collected in the large intestine to cast an X-ray shadow. With a metal button or a coin strapped to the site of the anus, or a metal bougie inserted into the blind anal canal, the infant is held upside down for 3–4 minutes and radiographed in the inverted position (Fig. 61.14). The gas in the rectum will rise to the top and indicates the distance between the site of the metal indicator and the blind end of the rectum. If the distance is over 2.5 cm, the abnormality is ‘high’. This method, although useful, is sometimes vitiated by a plug of meconium in the rectum causing an apparent gap far in excess of that actually present. It may be necessary to wait until the baby is 24 hours old before rectal gas appears.

Whereas ‘high’ lesion is suspected, an effort must be made to obtain a specimen of urine — the presence of *proteus* or *pyocyanus* usually signifies that a fistula is present. An intravenous (i.v.) urogram is recommended by some, even though there is a definite radiation risk. There may be gas in the bladder. A diagnostic perineal examination is usually unwise — it may prejudice the chances of further surgery.

Treatment

In the low abnormalities, this is usually simple and has been outlined when each condition was described above. The high abnormalities present a very difficult problem and each case must be considered on its merits. On the whole, newborn babies stand surgery very well, provided compatible blood is available, a clear airway is maintained postoperatively and inhalation of vomit prevented by nasogastric suction.

In the absence of complications, the general management of imperforate anus is as follows:

- **Laparotomy, division of rectourethral fistula and transverse colostomy.** A rectal ‘pull-through’ operation can be done later;
- **Laparotomy, division of fistula and ‘pull-through’ opera-ion.** One stage; division of the fistula and rectal ‘pull-down’ operation through the perineum (this method is now rarely used);
- **Post-sagittal rectoplasty (PSARP)** (Pena). Similar to above but via posterior approach;
- **Colostomy** only (for the cloacal variety).

For the ‘pull-through’ operation the lower bowel is mobilised, and a new passage is created through the pelvic floor by passing a pair of curved forceps through it, keeping close to the urethra, to the site of the future anus. This is dilated by Hegar’s dilators so that the bowel can he pulled down and its mucosa stitched to the skin of the newly formed anus. (For details the reader is referred to the standard textbooks of operative surgery and the publications of Swenson, Duhamel and Nixon.)

In general, daily dilatation will be required for at least 3 months and it may be necessary for years.

In a high percentage of cases, imperforate anus is associated with other congenital abnormalities, especially of the urinary organs, and
nearly half the deaths in cases of imperforate anus are due to other malformations.

**Sacrococcygeal teratoma**

Sacrococcygeal teratoma, although rare, is among the most common of the large tumours seen during the first 3 months of life. The frequency of the precoccygeal region for the development of a teratoma is explained by the fact that this area is the site of the ‘primitive knot’, a group of totipotent cells that retain their totipotentiality longer than any others save the sex anlage. Females are more often affected than males.

The tumour, which arises between the sacrum and the rectum, is firmly attached to the coccyx and, occasionally, to the last piece of the sacrum. At the time of birth some of these tumours are huge, and in 20 per cent of cases the infant is stillborn. The tumour tends to be large (Fig. 61.15), but it can be small enough to pass unnoticed until it enlarges or a complication ensues. It is this variety that is prone to become malignant, usually at about 10 months of age.

**Treatment.** Removal should be soon after birth; delay is liable to result in fatal ulceration, infection, rectal or urinary obstruction, or malignant change.

**Operation:** excision. Cs undertaken through a longitudinal elliptical incision, the coccygeal attachment being left until the last. The coccyx must always be excised; occasionally the last piece of the sacrum must be removed also. There may be a fistula between the tumour and the rectum, but as a rule this is small, and can be closed safely without performing a colostomy. The dead space in the pelvis is drained, the skin united and a pressure dressing applied.

When the operation is undertaken soon after birth, the prognosis is good.

**Postanal dermoid**

The space in front of the lower part of the sacrum and coccyx is occupied by a soft, cystic swelling — a postanal dermoid cyst — which is regarded as a simple form of teratoma. Hidden in the hollow of the sacrum, it is unlikely to be discovered unless a sinus communicating with the exterior is present, or develops as a result of inflammation. Such a cyst usually remains symptomless until adult life, when it is prone to become infected. Exceptionally, by its very size, it gives rise to difficulty in defecation. The cyst is easily palpable on rectal examination.

**Differential diagnosis.** Especially in a child, an anterior sacral meningocele must be excluded. The latter enlarges when the child cries, and is frequently associated with paralysis of the lower limbs and incontinence. When a discharging sinus is present, a post anal dermoid will probably be mistaken for a pilonidal sinus, unless pressure over the sacrococcygeal region with a finger in the rectum causes a flow of sebaceous material, and injection of contrast and radiography reveals a bottle-necked cyst in front of the coccyx.

Treatment is complete excision of the cyst, and sinus if present. In the case of large cysts it is necessary to remove the coccyx in order to gain access.

**Postanal dimple (syn. fovea coccygea)**

A dimple, sometimes amounting to a short blind pit, in the skin beneath the tip of coccyx, is noticed from time to time in the course of a clinical examination.

**Pilonidal sinus**

Pilonidal means ‘appertaining to a nest of hair’ (Latin: *pilus* = hair, *nidus* = nest).

**A etiology**

The army of supporters of the congenital theory of the origin of pilonidal sinus has become reduced to a corporal’s guard. That, in rare instances, a sinus in the anococcygeal area is congenital must be allowed, but in these cases of proven congenital origin the sinus is not necessarily pilonidal. It could be a sinus connected with a postanal dermoid, referred to above, or a sinus resulting from a persistent caudal remnant of the original neural canal. The latter occurs in the sacral rather than the coccygeal region, and is definitely connected with the spinal theca. On this account, meningiats from an extradural abscess may occur in a child.

The reasons which support the acquired theory of origin of pilonidal sinus can be summarised as follows.

- Interdigital pilonidal sinus is an occupational disease of hairdressers, the hair within the interdigital cleft or clefts being the customers’.
- Pilonidal sinuses of the axilla and umbilicus have also been reported.
- The age incidence of the appearance of pilonidal sinus (82 per cent occur between the ages of 20 and 29 years) is at variance with the age of onset of congenital lesions.
- Hair follicles have almost never been demonstrated in the walls of the sinus.
- The hairs projecting from the sinus are dead hairs, with their pointed ends directed towards the blind end of the sinus.
- The disease mostly affects men, and hairy men most frequently.
- Recurrence is common, even though adequate excision of the track is carried out.

The mode of origin of a pilonidal sinus is now believed to be as follows: on sitting, the buttocks take the weight of the body, and move independently, or together. Hairs broken off by friction against clothing, and shed short hairs, whether originating from the nape of the neck, back, or buttocks, tend to collect in the cleft of the nates and/or a postanal dimple. Furthermore, it is suggested that the use of toilet paper may contribute to hair entangled in faecal matter being swept into the cleft; pilonidal sinus is extremely rare in those races that employ ablution after defecation. By reason of the shearing action of the buttocks, which is increased by sitting on a hard seat, and especially by vibration of a vehicle, loose hair travels down the intergluteal furrow, to penetrate the skin or the open mouth of a sudoriferous gland, such glands being more active in early manhood. It is not yet clear whether the initial entry of hairs through the skin is a primary event, or follows the softening of the skin due to pusular or other forms of dermatitis. Once a sinus has formed, intermittent negative pressure of the area may suck other loose hairs into the pit. So common was pilonidal sinus among jeep riders in the 1935—45 war, that it became known as ‘jeep bottom’.

**Pathology**

The sinus extends into the subcutaneous planes as an infected track. Branching side channels are not infrequent. A stratified squamous epithelial lining, of varying degrees of integrity, is found in about half the cases. Hair shafts are found either lying loose in the sinus, embedded
in granulation tissue, or deep in mature scar tissue in three-quarters of the cases. Foreign-body giant cells are common.

**Clinical features**

There is a chronic or recurring sinus in the midline about the level of the first piece of the coccyx. Typically, a tuft of hair projects from its mouth. The discharge from the sinus or sinuses is often bloodstained, and contains foul sebum and sometimes hairs. Secondary openings may be present on either side of the midline, often far out on to the buttocks or in the perineum.

As has been indicated already, symptoms usually commence during the third decade; patients presenting later in life nearly always give a history dating back to this period.

Males with this condition outnumber females by four to one, the females being on an average 3 years younger than the males; this corresponds to the earlier maturation of the female. The condition rarely occurs in blonds; many of the patients are exceptionally hairy and are usually obese. In spite of the preponderance in dark-haired persons, whose hair is stiffer than the silky blond (Oldham), the condition is practically confined to white races. The complaint is of a discharge, pain or a tender swelling at the bottom of the spine. Even at the height of an attack of inflammation the constitutional symptoms are slight. Often there is a history of repeated abscesses in the region that have discharged spontaneously or have been incised. The primary sinus may have one, or as many as six openings, all of which are strictly in the midline between the level of the sacrococcygeal joint and the tip of the coccyx. Unlike a fistula in ano, the sinus passes upwards and forwards towards the sacrum. It does not reach bone, but ends blindly near the bone. When an abscess forms it may discharge through a primary sinus; more frequently it points and bursts, or is incised to one side of the midline (usually the left), thus forming a secondary sinus.

**Conservative treatment**

Patients reporting for the first time with mild symptoms can sometimes be cured by conservative measures, which consist of cleaning out the track, removing all hairs from the area, followed by frequent washing of the parts with a detergent and water, and applying equal parts of witch hazel (liq. ext. hamamelis) and alcohol. Long sitting, e.g., driving a car, is avoided if possible. These measures, tried on a large scale in the US Army, proved tolerably successful — more successful than similar attempts in civil life, because the sufferer could be relegated to duties that were unlikely to aggravate the condition.

**Treatment of an acute exacerbation (abscess)**

If rest, baths, local antiseptic dressings and the administration of a broad-spectrum antibiotic fail to bring about resolution, the abscess should be opened through a comparatively small incision. Provided all hairs and granulation tissue are removed from the abscess cavity, there is some prospect of curing the lesion (Millar). After it has been cleaned out, the track can be destroyed by careful instillation of pure phenol solution (Maurice). In all other circumstances, an elective operation must be planned.

**Operation** should be performed only when the inflammation has been controlled by the measures indicated already.

The patient is placed on the operating table, for preference in the ‘jack-knife’ position. Methylene blue is injected into the sinus to colour all the tracks, the nozzle of the syringe being pressed against the opening to obtain some pressure. Variations in operative technique include the following.

- Lay open the tracks, remove all debris and hair, and suture the edges to the skin, thus marsupialising the sinus. This procedure yields a good, hairless scar.
- Excise all of the tracks, as stained by blue dye, meticulously secure haemostasis by diathermy and catgut ligature and, using sutures, coapt the subcutaneous fat and skin very accurately and institute a drain and suction (i.e. Redivac) for 48 hours to remove blood and serum. In cases of extensive sinus formation, primary cover may be achieved by rotating a flap of skin and fat.
- Excise all of the tracks as stained by the blue dye and, after securing haemostasis as above, pack the wound. The following day the whole dressing is removed, and daily baths and moist dressing are instituted until the wound heals by granulation. A silastic elastomer pack is particularly useful for dressing the wound as it can be removed, washed and reinserted by the patient, and ensures that the wound heals from below. Epithelialisation can sometimes be speeded up by skin grafting. Immediately after operation, the patient should avoid sitting on the wound. Subsequently, the scar may require protection from further incursions of hair by selective hair-trimming. The recurrence rate after primary closure may be as high as 50 per cent without meticulous technique.

**Recurrent pilonidal sinus.** Three possibilities account for this disappointment:

- a diverticulum of the main channel has been overlooked at the primary operation;
- new hairs enter the skin or the scar;
- when the natal fold is deformed by scarring, the least trauma causes tearing of the scar, and the resulting crevice becomes contaminated with coliform and cutaneous bacteria.

An alternative approach to circumvent the incident of recurrence has been to ensure that the sound closure is to one side of the midline (Karydakis); this method has been reported as having a high rate of success. Yet another recently described technique said to have a high incidence of success is that described by Bascom. The procedure involves an incision lateral to the midline which allows the chronic abscess cavity robe scrubbed free of hair and granulation tissue (Fig. 61.16). Removal of the small midline pits is carried out with small (7 mm) incisions (Fig. 61.17). The lateral wound is then left open, but the midline incisions are closed (Fig. 61.18).
Anal incontinence

Aetiology
Aetiology of incontinence
Descent
Destruction
Debility
Deficiency
Damage
Denervation
Dementia

The origins of anal incontinence may derive from causes relating to:

- descent:
  - perineal descent,
  - rectal prolapse;
- destruction:
  - malignant tumours,
  - irradiation;
- debility:
  - illness,
  - old age;
- deficiency:
  - congenital abnormalities;
- damage:
  - wounds,
  - surgical procedures,
  - childbirth;
- denervation:
  - spinal injuries,
  - neurosurgical procedures,
  - spina bifida,
  - neurological disorders, e.g. multiple sclerosis;
- dementia:
  - senility,
  - psychological abnormality.

Of these causes, geriatric, traumatic and obstetric cases predominate with anal surgical procedures an important contributor to the traumatic group. Another major cause in women is pudendal nerve neuropathy which results from chronic straining, perineal descent and a traction injury to the nerve. This type of incontinence used to be termed idiopathic but neurophysiological studies have determined its true nature. In particular, the latency of pudendal nerve transmission can now be measured by stimulating the pudendal nerve per rectum and measuring the time taken for an electromyographic (EMG) response to be detected in the external and sphincter. A latency above 2 ms is usually diagnostic of pudendal nerve neuropathy.

Once the cause of the incontinence has been precisely defined by a careful history and meticulous examination, supported by special investigations as indicated (see above), treatment may be possible. Surgical procedures have been developed to repair and support damaged or weak sphincter muscles. These may be classified as follows.

Operations to reunite divided sphincter muscles

The sphincter muscles may have been divided as a result of direct trauma, operations for fissure and fistula or by obstetrical injury. The ends of the divided muscle are found and reunited by a double overlap repair (Fig. 61.19).

Operations to reef the external sphincter and puborectalis muscle

If the sphincter muscles are stretched and patulous (as they often are in old age and cases of rectal prolapse) they may be tightened by a postanal repair. These operations use darns of absorbable material to narrow down and plicate the external sphincter and the puborectalis sling (Fig. 61.20). They restore length to the anal canal, strength to the anal sphincter and angulation to the anorectal junction. The approach is usually through the intersphincteric plane.

Operations to support the anal canal

If the anal canal is gaping and has feeble muscles that cannot be strengthened by direct means, support can be given by encircling stitches or Mersilene strands after the Thiersch operation pattern (Chapter 53). However, these techniques are not popular since the sutures may erode into the, anal canal or cause an impediment to satisfactory evacuation and have now been abandoned. Recently, attempts have been made to create a new anal sphincter by transposing the gra-cilis muscle around the anal canal and stimulating it electrically by a pacemaker (Williams) (Fig. 61.21). This appears a promising technique and is effective in approximately 60 per cent of patients who have previously had more conventional operations.

More recently an artificial sphincter has been developed from that used in urology. It consists of a silastic cuff which is inflated around the anal canal and occludes it. When evacuation is required, the cuff is deflated by squeezing a small balloon attached to a reservoir (Fig. 61.22). Since this device is a foreign body which exerts pressure on the bowel wall, there is concern that erosion and infection will be a common problem.

All of these procedures achieve best results if the bowel habit is regulated and a normal defecatory pattern established over the preoperative and postoperative periods. The opera-tions should be covered by antibiotics active against both aerobic and anaerobic organisms to reduce the risk of septic complications. If any of these procedures fail or are contraindicated, the patient may require a permanent colostomy.
Anal fissure

Definition

An anal fissure (syn. fissure in ano) is an elongated ulcer in the long axis of the lower anal canal.

Location

The site of election for an anal fissure is the midline posteriorly (90 per cent overall). The next most frequent situation is the midline anteriorly.

Aetiology

The cause of anal fissure, and particularly the reason why the midline posteriorly is so frequently affected, is not completely understood. A probable explanation is as follows: the posterior wall of the rectum curves forwards from the hollow of the sacrum to join the anal canal, which then turns sharply backwards. During defecation the pressure of a hard faecal mass is mainly on the posterior anal tissues, in which event the overlying epithelium is greatly stretched and, being relatively unsupported by muscle, is placed in a vulnerable position when a scybalous mass is being expelled. Possibly some cases are due to tearing down of an anal valve of Ball. An anterior anal fissure is much more common in women, particularly in those who have borne children. This can be explained by the lack of support of the anal mucous membrane by a damaged pelvic floor and an attenuated perineal body. A more recent suggestion supported by Doppler flow studies is that a fissure is due to ischaemia. It may be that the cause is a combination of trauma initially perpetuated by a poor blood supply.

Some causes of anal fissure are certain:

- an incorrectly performed operation for haemorrhoids in which too much skin is removed. This results in anal stenosis and tearing of the sear when a hard motion is passed;
- inflammatory bowel disease — particularly Crohn’s disease;
- sexually transmitted diseases.

Pathology

An anal fissure is either acute or chronic. The upper internal end of the fissure stops at the dentate line. Because the fissure occurs in the stratified sensitive epithelium of the lower half of the anal canal, pain is the most prominent symptom (see below).

Acute anal fissure is a deep tear through the skin of the anal margin extending into the anal canal. There is little inflammatory induration or oedema of its edges. There is accompanying spasm of the anal sphincter muscle.

Chronic anal fissure is characterised by inflamed indurated margins, and a base consisting of either scar tissue or the lower border of the internal sphincter muscle. The ulcer is canoe-shaped, and at the inferior extremity there is a tag of skin, usually oedematous. This tag is known picturesquely as a sentinel pile — ‘sentinel’ because it guards the fissure. There may be spasm of the involuntary musculature of the internal sphincter. In long-standing cases, this muscle becomes organically contracted by infiltration of fibrous tissue. Infection is common and may be severe, ending in abscess formation. A cutaneous fistula may follow.

Chronic fissure in ano may have a specific cause — often a granulomatous infection, e.g. Crohn’s disease. Biopsy examination is advisable of any tissue removed at operation for a chronic fissure. Specific fissures of this type are often less painful than the appearances of the lesion would suggest.

Clinical features

1 Symptoms of anal fissure
2 Pain on defecation
3 Bright red bleeding
4 Mucus discharge
5 Constipation

The condition is more common in women and generally occurs during the meridian of life. It is uncommon in the aged, because of muscular atony, whereas anal fissure is not rare in children, is sometimes encountered during infancy and may cause acquired megacolon (Chapter 57).

- Pain is the symptom — sharp, agonising pain starting during defecation, often overwhelming in intensity and lasting for an hour or more. As a rule, it ceases suddenly, and the sufferer is comfortable until the next action of the bowel. Periods of remission occur for days or weeks. The patient tends to become constipated rather than go through the agony of defecation. (One patient accustomed himself to take a generous dose of senna on Saturday night, and retire to the toilet on Sunday morning with a bottle of whisky and the newspaper.)

- Bleeding — this is usually slight and consists of bright streaks on the stools or the paper.

- Discharge. A slight discharge accompanies fully established cases.

On examination

In cases of some standing, a sentinel skin tag can usually be displayed. This, together with a typical history and a tightly closed, puckered anus, is almost pathognomonic of the condition. By gently parting the margins of the anus, the lower end of the fissure can be seen (Fig. 61.23).

Because of the intense pain it causes, digital examination of the anal canal should not be attempted at this stage unless the fissure cannot be seen, or it seems imperative to exclude major intrarectal pathology. In these circumstances, the local application of a surface anaesthetic such as 5 per cent xylocaine on a pledget of cotton wool, left in place for about 5 minutes, will enable the necessary examination to be made. In early cases, the edges of the fissure are impalpable; in fully established cases, a characteristic crater which feels like a vertical buttonhole can be palpated. The diagnosis must be established beyond doubt, for which a general anaesthetic may be required.
Differential diagnosis

Carcinoma of the anus in its very early stages easily simulates a fissure. If real doubt exists, the lesion must be excised under general anaesthesia and submitted to histological examination.

Multiple fissures in the perianal skin are commonly seen as a complication of skin diseases, scratching and inflammatory bowel disease, as well as homosexual practices (sodomy, fluting and the use of anorectal sex toys; Fig. 60.8) and analrectal sexually transmitted disease such as herpes. Admitted homosexuals, should, after appropriate counselling, be offered a human immunodeficiency virus (HIV) test as they may have acquired immunodeficiency syndrome (AIDS) (Chapter 9).

Tuberculous ulcer has an undermined edge.

Proctalgia fugax (see below) causes severe episodic pain.

Treatment

The pain of an anal fissure is so great that usually the patient demands relief, and consequently many patients with an acute fissure present early. The object of all treatment for this condition is to obtain complete relaxation of the internal sphincter. Provided the complications are dealt with, the fissure will slowly heal as soon as all spasm has disappeared.

Conservative treatment

Because of the risks of incontinence associated with sphincterotomy, it is now usual practice to treat anal fissures conser-vatively in the first instance using a chemical sphincterotomy. Nitric oxide has been shown to be the neurotransmitter which induces relaxation of the internal sphincter. Glyceryl trinitrate, being a nitric acid donor, when applied as an ointment (0.2 per cent by weight) to the anal canal produces sufficient relaxation of the sphincter to allow the fissure to heal in up to two-thirds of patients (Scholefield). In addition, glyceryl trinitrate ointment improves blood flow to the area, and this aids healing. Unfortunately, glyceryl trinitrate may produce severe headaches and other agents with fewer side effects should be available soon. Other measures include laxatives to ensure the motions are soft, but the stools should not be made watery. Celsolax tablets give a soft stool of good bulk which is ideal. Anal dilators used in con-junction with xyloca ine ointment are difficult to insert because of pain and are rarely effective.

Operative measures. The simplest procedure in the past has been gentle dilatation of the sphincter. Under general anaesthesia, the index and middle finger of each hand were inserted simultaneously into the anus and carefully pulled apart dilating the anus so that its diameter was no greater than four finger breadths. Great care and judgement had to be exercised, so that the anal sphincter was not overstretched. The risks of incontinence following this procedure have now made it unpopular. Although it might still be used for young men with high pressure sphincters who understand the slight risk, it is definitely contraindicated in those patients with weak sphincters.

Should these measures prove ineffective, or if the fissure is chronic with fibrosis, a skin tag or a mucous polyp, then surgical measures are advisable. General anaesthesia is best, although some surgeons use a local anaesthetic in the form of xyloca ine or lignocaine introduced into the ischiorectal fossa on each side, in order to anaesthetise the nerves passing towards the rectum. In other situations, a caudal anaesthetic is suitable.

Lateral anal sphincterotomy (Notaras). In this operation, the internal sphincter is divided away from the fissure itself — usually either in the right or the left lateral positions. The procedure can be done by an open or a closed method. Healing is usually complete within 3 weeks. The operation is more successful for acute than chronic fissures. Seventy-five per cent of cases are suitable for treatment by this method, which can be done as an out-patient procedure under local anaesthesia by an experienced surgeon. However, there is a definite yet small risk of incontinence and it is imperative that patients are appraised of this risk preoperatively.

Dorsal fissurectomy and sphincterotomy. The essential part of the operation is to divide the transverse fibres of the internal sphincter in the floor of the fissure. If a sentinel pile is present, this is excised. The ends of the diverticulum retract and a smooth wound is left. The after-treatment consists of attention to bowels, a daily bath and the passage of an anal dilator until the wounds have healed, which usually takes about 3 weeks. Despite the presence of the wound, there is little or no pain and the results are good. The disadvantage of this operation is the prolonged healing time — usually not less than 3 weeks and often longer — and, occasionally, a mild, persistent and permanent mucus discharge. It is now reserved only for the most chronic or recurrent anal fissures, the majority being treated by lateral sphincterotomy. Once again incontinence might be a postoperative complication.

Hypertrophied anal papilla

Anal papillae occur at the dentate line, and are remnants of the ectoderma) membrane that separated the hindgut from the proctodaeum. As these papillae are present in 60 per cent of patients examined proctologically, they should be regarded as normal structures. Anal papillae can become elongated, as they frequently do in the presence of an anal fissure. Occasionally, an elongated anal papilla may be the cause of pruritus. An elongated anal papilla associated with pain and/or bleeding at defecation is sometimes encountered in infancy. Haemorrhage into a hypertrophied anal papilla can cause sudden rectal pain. A prolapsed papilla may become ripped by contraction of the sphincter mechanism after defecation. Occasionally, a red oedematous papilla is encountered with local pain and a purulent discharge from the associated crypt. This condition of ‘cryptitis’ may be cured by laying open the mouth of the infected anal gland and removing the papilla.

Treatment. Using a slotted proctoscope, elongated papillae without haemorrhoids should be crushed and excised after injecting the base with local anaesthetic. When large papillae complicate internal haemorrhoids, this is an indication for operative treatment of the haemorrhoids, as well as excision of the elongated papillae.

Proctalgia fugax

This disease is characterised by attacks of severe pain arising in the rectum, recurring at irregular intervals and apparently unrelated to organic disease. The pain is described as cramp-like, often occurs when the patient is in bed at night, usually lasts only for a few minutes and disappears spontaneously. It may follow straining at stool, sudden explosive bowel action or ejaculation. It seems to occur more commonly in patients suffering from anxiety or undue stress, and also it is said to afflict young doctors. The pain may be unbearable — it is possibly due to segmental cramp in the pubococcygeus muscle. It is unpleasant, incurable, but fortunately harmless and gradually subsides. A mote chronic form of the disease has been termed the ‘levator syndrome’ and can he associated with severe constipation. Biofeedback techniques have been used to help such patients: some surgeons have been willing to sever the puborectalis muscle, but this can cause incontinence.
Haemorrhoids

Haemorrhoids (Greek: haima blood, rhoos = flowing) syn. piles (Latin: pila= a ball) are dilated veins occurring in relation to the anus. Such haemorrhoids may be external or internal, i.e. external or internal to the anal orifice. The external variety lies beneath the anal mucous membrane. When the two varieties are associated, they are known as interoexternal haemorrhoids.

The veins which form internal haemorrhoids become engorged as the anal lining descends and is gripped by the anal sphincters. The mucosal lining is gathered prominently in three places (the ‘anal cushions’), which can be in the areas of the three terminal branches of the superior haemorrhoidal artery, but this is exceptional (Thomson). The anal cushions are present in embryonic life and are necessary for full continence. Straining causes these cushions to slide downwards and internal haemorrhoids develop in the prolapsing tissues.

Haemorrhoids may be symptomatic of some other condition, and this important fact must be remembered. Symptomatic haemorrhoids may appear:

• in carcinoma of rectum. This, by compressing or causing thrombosis of the superior rectal vein, gives rise to haemorrhoids (Fig. 61.24) sufficiently often to warrant examination of the rectum and the rectosigmoid junction for a neoplasm in every case of haemorrhoids;

• during pregnancy. Pregnancy piles are due to compression of the supereior rectal veins by the pregnant uterus and the relaxing effect of progesterone on the smooth muscle in the walls of the veins, plus an increased pelvic circulating volume;

• from at raining at micturition consequent upon a stricture of the ure-thra — or an enlarged prostate;

• from chronic constipation.

NB. Contrary to the usual belief, in 128 consecutive cases of portal hypertension, Macpherson did not encounter a single example of haemorrhoids that could be attributed to portal cirrhosis, although bleeding oesophageal varices often complicate portal hypertension.

The great majority of haemorrhoids is not symptomatic. The description that follows concerns symptomatic haemorrhoids that are notsecondary to an underlying cause.

Internal haemorrhoids

Internal haemorrhoids, which include intero-external haemorrhoids, are exceedingly common. Essentially, the condition is a dilatation of the internal venous plexus with an enlarged displaced anal cushion. Because of the communication between the internal and external plexuses, if the former becomes engorged, the latter is liable to become involved also.

Aetiology

Hereditary. The condition is so frequently seen in members of the same family that there must be a predisposing factor, such as a congenital weakness of the vein walls or an abnormally large arterial supply to the rectal plexus.

Varicose veins of the legs and haemorrhoids often occur concurrently. Morphological. In quadrupeds, gravity aids, or at any rate does not retard, return of venous blood from the rectum. Consequently venous valves are not required. In humans, the weight of the column of blood unassisted by valves produces a high venous pressure in the lower rectum, unparalleled in the body. Except in a few fat old dogs, haemorrhoids are exceedingly rare in animals.

Anatomical. The collecting radicles of the superior haemorrhoidal vein lie unsupported in the very loose submucous connective tissue of the anorectum. These veins pass through muscular tissue and are liable to be constricted by its contraction during defecation. The superior rectal veins, being tributaries of the portal vein, have no valves.

Exacerbating factors. Straining accompanying constipation or that induced by over purgation is considered to be a potent cause of haemorrhoids. Less often, the diarrhoea of enteritis, colitis or the dysenteries aggravates latent haemorrhoids. In both instances, descent and swelling of the anal cushions are prominent features.

Pathology

Internal haemorrhoids are frequently arranged in three groups at 3, 7, and 11 o’clock with the patient in the litho-tomy position [in which patients used to be put for the classical operation of ‘cutting’ for bladder stone via the urethral or the perineal route (Chapter 62)]. This distribution has been ascribed to the arterial supply of the anus whereby there are two subdivisions of the right branch of the superior rectal artery, but the left branch remains single (Fig. 61.25), but this is now known to be atypical. In between these three primary haemorrhoids there may be smaller secondary haemorrhoids. Each principal haemorrhoid can be divided into three parts.

• The pedicle is situated at the anorectal ring. As seen through a proctoscope, it is covered with pale pink mucosa. Occasionally, a pulsating artery can be felt in this situation.

• The internal haemorrhoid, which commences just below the anorectal ring. It is bright red or purple, and covered by mucous membrane. It is of variable size.

• An external associated haemorrhoid lies between the den-tate line and the anal margin. It is covered by skin, through which blue veins can be seen, unless fibrosis has occurred.

• This associated haemorrhoid is present only in well-established cases.

Entering the pedicle of an internal haemorrhoid may be a branch of the superior rectal artery. Very occasionally there is a haemangiomatous condition of this artery — an ‘arterial pile’—which leads to ferocious bleeding at operation.

Clinical features

Symptoms of haemorrhoids

Bright red painless bleeding
**Bleeding**, as the name haemorrhoid implies, is the principal and earliest symptom. At first the bleeding is slight; it is bright red and occurs during defecation (a 'splash in the pan'), and it may continue intermittently thus for months or years. Haemorrhoids that bleed but do not prolapse outside the anal canal are called **first-degree haemorrhoids**.

**Prolapse** is a much later symptom. In the beginning the protrusion is slight and occurs only at stool, and reduction is spontaneous. As time goes on the haemorrhoids do not reduce themselves, but have to be replaced digitally by the patient. Haemorrhoids that prolapse on defecation but return or need to be replaced manually and then stay reduced are called **second-degree haemorrhoids**. Still later, prolapse occurs during the day, apart from defecation, often when patients are tired or exert themselves. Haemorrhoids that are permanently prolapsed are called **third-degree haemorrhoids** (Fig. 61.26). By now, the haemorrhoids have become a source of great discomfort and cause a feeling of heaviness in the rectum but are not usually acutely painful.

**Discharge.** A mucoid discharge is a frequent accompani-ment of prolapsed haemorrhoids. It is composed of mucus from the engorged mucous membrane, sometimes augmented by leakage of ingested liquid paraffin. **Pruritus** will almost certainly follow this discharge.

Pain is absent unless complications supervene. For this reason, any patient complaining of 'painful piles' must be suspected of having another condition (possibly serious) and examined accordingly.

Anaemia can be caused very rarely by persistent profuse bleeding from haemorrhoids.

**Investigation**

On inspection there may be no evidence of internal haemorrhoids. In more advanced cases, redundant folds or tags of skin can be seen in the position of one or more of the three primary haemorrhoids. When the patient strains, internal haemorrhoids may come into view transiently or, if they are of the third degree, they are, and remain, prolapsed.

Digital examination. Internal haemorrhoids cannot be felt unless they are thrombosed.

**Proctoscopy.** A proctoscope is passed to its fullest extent and the obturator is removed. The instrument is then slowly with-drawn. Just below the anorectal ring internal haemorrhoids, if present, will bulge into the lumen of the proctoscope.

**Sigmoidoscopy** should be done as a precaution in every case (Chapter 60 and Fig. 60.5).

**Complications**

**Profuse haemorrhage** is not rare. Most often it occurs in the early stages of the second degree. The bleeding occurs mainly externally, but it may continue internally after the bleeding haemorrhoid has retracted or has been returned. In these circumstances, the rectum is found to contain blood.

**Strangulation.** One or more of the internal haemorrhoids prolapse and become gripped by the external sphincter. Further congestion follows because the venous return is impeded. Second-degree haemorrhoids are most often complicated in this way. Strangulation is accompanied by considerable pain, and is often spoken of by the patient as an 'acute attack of piles' [a phrase that also embraces a thrombotic pile (see below) or an inflamed anal skin tag]. Unless the internal haemorrhoids can be reduced within an hour or two, strangulation is followed by thrombosis.

**Thrombosis.** The affected haemorrhoid or haemorrhoids become dark purple or black (Fig. 61.27) and feel solid. Considerable oedema of the anal margin accompanies thrombosis. Once the thrombosis has occurred, the pain of strangulation largely passes off, but tenderness persists.

**Ulceration.** Superficial ulceration of the exposed mucous membrane often accompanies strangulation with thrombosis.

**Gangrene** occurs when strangulation is sufficiently tight to constrict the arterial supply of the haemorrhoid. The resulting sloughing is usually superficial and localised. Occasionally, a whole haemorrhoid sloughs off, leaving an ulcer which heals gradually. Very occasionally, massive gangrene extends to the mucous membrane within the anal canal and rectum, and can be the cause of spreading anaerobic infection and portal pyaemia.

**Fibrosis.** After thrombosis, internal haemorrhoids sometimes become converted into fibrous tissue. The fibrosed haemorrhoid is at first sessile, but by repeated traction during prolapse at defecation, it becomes pedunculated and constitutes a fibrous polyp that is readily distinguished by its white colour from an adenoma, which is bright red. Fibrosis following transient strangulation commonly occurs in the subcutaneous part of a primary haemorrhoid. Fibrosis in an external haemorrhoid favours prolapse of an associated internal haemorrhoid.

**Suppuration** is uncommon. It occurs as a result of infection of a thrombosed haemorrhoid. Throbbing pain is followed by perianal swelling, and a perianal or submucous abscess results.

**Pylephlebitis** (syn. portal pyaemia). Theoretically, infected haemorrhoids should be a potent cause of portal pyaemia and liver abscesses (Chapter 52). Although cases do occur from time to time, this complication is surprisingly infrequent. It can occur when patients with strangulated haemorrhoids are subjected to ill advised surgery and has even been reported to follow banding (see below).

**Treatment**

Treatment of haemorrhoids

Symptomatic Injection of sclerosant Banding Photocoagulation Haemorrhoidectomy
**Nonoperative treatment** is recommended when the haemorrhoids are a symptom of some other condition or disease except, of course, when a carcinoma is present. The bowels are regulated by hydrophilic colloids (Isogel, etc.) and if necessary a small dose of Senokot at night. Various proprietary creams can be inserted into the rectum from a collapsible tube fitted with a nozzle, at night and before defecation. Suppositories are also useful.

**Active treatment.** This consists of injection or treatment by elastic band applications to the base of each haemorrhoid or formal operation, each with specific indications. Treatment should not be withheld because the patient is elderly or infirm.

**Injection treatment** (Mitchell). **Indications.** This is ideal for first-degree internal haemorrhoids which bleed. Early second-degree haemorrhoids are often cured by this method but a proportion relapses.

**Technique.** The patient should have an empty rectum, but no special preparation is necessary. A proctoscope is introduced and the haemorrhoids are displayed. The proctoscope is further introduced in until the haemorrhoid has almost disappeared from the lumen and only its upper end is visible. The injection is made at this point above the main mass of each haemorrhoid (Fig. 61.28) into the submucosa at, or just above, the anorectal ring. Using Gabriel’s syringe or more commonly a disposable instrument (Fig. 61.29) with the bevel of the needle directed towards the rectal wall, from 3 to 5 ml of 5 per cent phenol in almond oil is injected. The injection should produce elevation and pallor of the mucosa. The solution spreads in the submucosa upwards to the pedicle, and downwards to the internal haemorrhoid and to secondary haemorrhoids if present, but it is prevented by the intermuscular septum from reaching the external haemorrhoid. There is slight, transient bleeding from the point of puncture. The injection is painless, but a dull ache is common for a few hours. There is no special after-treatment. If there is only one haemorrhoid present, it may be cured by one injection; if all three haemorrhoids are equally enlarged, each is injected at the same session. Often three sessions at 6-weekly intervals are required. Care should be taken not to inject into the prostate anteriorly, for the resulting prostatitis can be crippling.

**Banding treatment** (Barron)

For second-degree haemorrhoids which are too large for successful handling by injections, treatment is available by slipping tight elastic bands on to the base of the pedicle of each haemorrhoid with a special instrument (Fig. 61.30). The bands cause ischaemic necrosis of the piles, which slough off within a few days. The procedure should be painless if done properly, and can be performed in the out-patient department. Not more than two haemorrhoids should be banded at each session and 3 weeks at least should elapse between each treatment.

**Cryosurgery**

The application of liquid nitrogen has been evaluated in some centres. The extreme cold (-196°C) of the application causes coagulation necrosis of the piles, which subsequently separate and drop off. Although some encouraging early results were reported (Lloyd-Williams), the technique often caused troublesome mucus discharge and pain, and has now been abandoned.

**Photocoagulation**

The application of infrared coagulation by a specially designed instrument has recently been advocated for the treatment of haemorrhoids that do not prolapse (Leicester). This is said to be an effective and painless method of treatment.

**Operation. Indications.** Cases unsuitable for injection or banding treatment are:

- third-degree haemorrhoids;
- failure of nonoperative treatments of second-degree haemorrhoids;
- fibrosed haemorrhoids;
- intero-external haemorrhoids when the external haemorrhoid is well defined.

These are indications for haemorrhoidectomy.

**Haemorrhoidectomy**

Some preoperative treatment is necessary. An aperient is given on the evening before the operation and an enema is administered. The anal region is shaved. On the morning of the operation the rectum is evacuated with the aid of a disposable enema.

Haemorrhoidectomy can be performed using an open or a closed technique. The open technique is most commonly used in the UK, and is known as the Milligan-Morgan operation — named after the surgeons who described it. The closed technique is the popular technique in the USA. Both involve ligation and excision of the haemorrhoid, but in the open technique the anal mucosa and skin are left open to heal by secondary intention, and in the closed technique, the wound is sutured.

**Open technique.** With the patient in the lithotomy position, the sphincter is gently stretched, and the internal haemorrhoids are then prolapsed by traction on the skin tags, or on the skin of the anal margin. Each haemorrhoid is dealt with as follows: it is picked up with dissecting forceps and traction is exerted. Traction displays a longitudinal fold (the pedicle) above the haemorrhoid. Each pedicle is grasped in a fine-pointed haemostat, as also is each external haemorrhoid or skin tag connected with each internal haemorrhoid. These pairs of haemostats, when held out by the assistants, form a triangle. The operator takes the left lateral pair of haemostats in the palm of his hand and places the extended forefinger in the anal canal to support the internal haemorrhoid. In this way traction is applied to the skin of the anal margin. With scissors, a shaped cut is made (Fig. 61.31a), each limb of which is placed on either side of the skin holding haemostat. This cut transverses the skin and the corrugator cons ani. Exerting further traction a little blunt dissection exposes the lower border of the internal sphincter. A transfixing ligature of no. 3 chromic catgut is applied to the pedicle at this level (Fig. 61.31b). Each haemorrhoid, having been dealt with in this manner (Fig. 61.31c), is excised 1.25 cm distal to the ligature, the ends of which are cut about 1 cm from the knot. The stumps of the ligated haemorrhoids are returned to the rectum by tucking a piece of gauze into the anal canal.

The margins of the skin wounds are trimmed so as not to leave overhanging edges (Fig. 61.32). Bleeding subcutaneous arteries having been secured, the corners of three pieces of petroleum-jelly gauze are tucked into the anus so as to cover the areas denuded of skin. A pad of gauze and wool and a firmly applied T-bandage complete the operation.

**Closed technique** (Fig. 61.33). The patient is placed in the prone jack-knife position with the buttocks strapped apart. A suitable retractor, such as the Hill—Ferguson type, is placed within the anal canal, and the anus is infiltrated with 20 ml of a 1 in 300 000 adrenaline—saline solution. The haemorrhoid is excised, together with the overlying mucous, as illustrated in Fig. 61.33a. The haemorrhoid is dissected carefully from the underlying sphincter and haemostasis is achieved. The pedicle is transfixed and ligated with 3.0 chromic catgut or Dexon. Any
residual small haemorrhoids should be removed by filleting them out after undermining the edges of the cut mucosa. The mucous 1 defect is then closed completely with a continuous suture using the same stitch that was employed to ligate the haemorrhoid pedicle. The remaining haemorrhoids are excised and ligated in similar fashion, ensuring there are adequate mucosal and skin bridges between each area of excision, so as to avoid a subsequent stenosis.

Postoperative care. In these days of economic stringencies, the patient is discharged from hospital within a day or two of the operation. In the USA, the procedure is often performed on a day-care basis. The patient is instructed to take two warm baths a day, and is given a bulk laxative to take twice daily, together with appropriate analgesia. Dry dressings are applied as necessary, a sterile sanitary towel usually being ideal. The patient is seen again 3—4 weeks after discharge and a rectal examination is performed. If there is evidence of stenosis, the patient is encouraged to use a dilator.

Postoperative complications may be early or late.

Complications of haemorrhoidectomy

**Early**
- Pain Secondary haemorrhage
- Acute retention of urine Anal stricture
- Reactionary haemorrhage Anal fissure

**Late.** Pain may demand repeated pethidine. Xylocaine jelly introduced through a fine nozzle into the rectum, as necessary, is of considerable value.

Retention of urine is not unusual after haemorrhoidectomy in male patients, and frequently it is precipitated by the presence of a rectal tube or pack, or both. Before resorting to catheterisation, the patient should be reassured, given an analgesic, allowed to stand at the side of the bed in privacy or be assisted to a hot bath into which he may be able to void urine.

Reactionary haemorrhage is much more common than secondary haemorrhage. The haemorrhage may be mainly or entirely concealed, but will become evident on examining the rectum.

Treatment. A suitable dose of morphine is given intravenously. If the bleeding persists, the patient must be taken to the operating theatre and the bleeding point secured by diathermy or under-running with a ligature on a needle. Should a definite bleeding point not be found, suspected areas are under-run in this way and the anal canal and rectum are packed.

Late. Secondary haemorrhage is uncommon; when it occurs, it does so about the 7th or 8th day after operation. It is usually controlled by morphia but, if the haemorrhage is severe, an anaesthetic should be given and a catgut stitch inserted to occlude the bleeding vessel.

Anal stricture. This must be prevented at all costs (Fig. 61.32 and legend). A rectal examination at the 10th day will indicate whether strictureing is to be expected. It may then be necessary to give a general anaesthetic and dilate the anus. After that, daily use of the dilator should give a satisfactory result.

Anal fissure and submucous abscesses may also occur.

Treatment of complications

Strangulation, thrombosis and gangrene. In these cases, it was formerly believed that surgery would promote pylephlebitis. If adequate antibiotic cover is given from the start, this is not found to be so and immediate surgery can be justified in many patients. Besides adequate pain relief, bed rest with frequent, hot sitz baths and warm saline compresses with firm pressure usually cause the pile mass to shrink considerably in 3—4 days when standard ligation and excision of the piles can be carried out. Some surgeons consider that the operation at this stage increases the risk of postoperative stenosis and delay surgery for a month or so. They then review the situation and only carry out haemorrhoidectomy if necessary. In spite of the low risk of pylephlebitis, caution should dictate a 'noninterventionist' policy whenever this is practical. An anal dilation technique has in the past been used as an alternative treatment to surgery for painful 'strangulated' haemorrhoids. However, the stretching should be far more circumspect than that recommended by Lord in his original description and the patient must be warned about other risks of incontinence. Once again an anal stretch must be avoided in patients with a weak or potentially weak anal sphincter. Many colorectal surgeons have abandoned the use of anal stretch in any circumstances.

Severe haemorrhage. The cause usually lies in a bleeding diathesis or the use of anticoagulants. If such are excluded, a local compress containing adrenaline solution, with an injection of morphone and blood transfusion if necessary, will usually control the haemorrhage. After blood replacement is adequate, ligation and excision of the piles may be required.

External haemorrhoids

Unlike internal haemorrhoids, external haemorrhoids con-sists of a conglomerate group of distinct clinical entities.

A thrombosed external haemorrhoid is commonly termed a perianal haematoma. It is a small clot occurring in the pen-anal subcutaneous connective tissue, usually superficial to the corrugator cutis ani muscle. The condition is due to back pressure on an anal venule consequent upon straining at stool, coughing or lifting a heavy weight.

The condition appears suddenly and is very painful, and on examination a tense, tender swelling which resembles a semi ripe blackcurrant is seen. The haematoma is usually situated in a lateral region of the anal margin. Untreated it may resolve, suppurate, fibrosed and give rise to a cutaneous tag, or burst and extrude the clot, or continue bleeding.

In the majority of cases resolution or fibrosis occurs. Indeed, this condition has been called 'a 5-day, painful, self-curing lesion' (Milligan).

Provided it is seen within 36 hours of the onset, a perianal haematoma is best treated as an emergency. Under local anaesthesia the haemorrhoid is bisected and the two halves are excised together with 1.25 cm of adjacent skin. This leaves a pear-shaped wound which is allowed to granulate. The relief of pain is immediate and a permanent cure is cera-tip. On the rare occasions in which a perianal haematoma is situated anteriorly or posteriorly, it should be treated con-servatively because of the liability of a skin wound in these regions to become an anal fissure.
Associated with internal haemorrhoids = intero-external haemorrhoids. These have been discussed.

Dilatation of the veins of the anal verge becomes evident only if the patient strains, when a bluish, cushion-like ring appears. This variety of external haemorrhoid is almost a perquisite of those who lead a sedentary life. The only treatment required is an adjustment in habits of the patient.

A 'sentinel' pile is associated with an anal fissure (see above).

Genital warts — see Chapter 67.
Pruritis ani

This is intractable itching around the anus. Usually the skin is reddened hyperkeratotic and may become cracked and moist. The causes are numerous. A useful mnemonic is: ‘pus, polypus, parasites, piles, psyche’.

• Lack of cleanliness, excessive sweating, and wearing rough or woollen underclothing are common causes.

• An anal or perianal discharge which renders the anus moist. The causative lesions include an anal fissure, fistula in ano, prolapsed internal or external haemorrhoids, genital warts and excessive ingestion of liquid paraffin. A mucous discharge is an intense pruritic agent and a polyp can be the cause.

• A vaginal discharge, especially due to the *Trichomonas vaginalis*.

• **Parasitic causes.** Threadworms should be excluded, especially in young subjects. Children suffering from threadworms should wear gloves at night, less they scratch the perianal region and are reinfested with ova by nail biting — ‘parasites lost, parasites regained’. Scabies and pediculosis pubis may infest the anal region.

• **Epidermophytosis** is a common cause especially if the skin between the toes is also infected. Microscopic and cultural examinations are essential. Half-strength Whitfield’s ointment quickly gives relief and is the sheet anchor of treatment.

• **Allergy** is sometimes the cause, in which case there is likely to be a history of other allergic manifestations, such as urticaria, asthma or hay fever. Antibiotic therapy may be the precipitating factor.

• **Skin diseases** localised to the perianal skin — psoriasis, lichen planus and contact dermatitis.

• **Bacterial infection.** Intertrigo due to a mixed bacterial infection. Erythrasma due to *Corynebacterium minutissimum* is responsible for some cases and its presence is detected by ultraviolet light which induces a pink fluorescence.

• **A psychoneurosis.** It is alleged that in a few instances neurotic individuals become so immersed in their complaint that a pain—pleasure complex develops, the pleasure being the scratching. Possibly this is true, but such a syndrome should not be assumed without firm grounds for coming to this conclusion.

• **Diabetes.** Diabetes can sometimes present with pruritus ani and the urine should be tested in all patients.

**Treatment.** The cause is treated. Other methods include the following.

• **Hygienic measures.** Cotton wool should be substituted for toilet paper. Soap is avoided and replaced by a detergent. These measures alone, combined with wearing cotton cellular underwear and applications of calamine lotion, are all that is necessary to cure some cases. If there is much anal hair trapping the moisture and discharge, shaving can be very helpful.

• **Hydrocortisone.** In cases with dermatitis, and only in cases with dermatitis, prednisolone, applied topically in a cream of 1 per cent is often beneficial; sometimes after discontinuation of the therapy, the pruritus is liable to return, in which event 5 per cent xylocaine ointment can be substituted for a time.

• **Strapping the buttocks apart is a most useful procedure,** especially when the pruritus is acute, and in chronic cases when the opposing surfaces are moist. The strapping is worn so long as the patient finds it beneficial.

**Operative treatment**

This may be necessary for a concomitant lesion of the anorectum which is thought to initiate or contribute to the pruritis. Otherwise, surgery is not indicated.
Anorectal abscesses

In 60 percent of cases the pus from the abscess yields a pure culture of *Escherichia coli*; in 23 per cent a pure culture of *Staphylococcus aureus* is obtained. In diminishing frequency, pure cultures of *Bacteroides*, *Streptococcus* or *Proteus* strain are found. In many cases the infection is mixed. In a high per-cent-age of cases — some estimate it as high as 90 per cent — the abscess commences as an infection of an anal gland (Figs 61.34 and 61.35). Other causes are penetration of the rectal wall, e.g. by a fish bone, a blood-borne infection or an extension of a cutaneous boil. Underlying rectal disease, such as neoplasm and particularly Crohn’s disease, may be the cause. Similarly patients with generalised disorders, such as diabetes and more recently AIDS, may present with an anorectal abscess. The latter patients usually have abscesses which run an aggressive course.

A large percentage of anorectal abscesses coincides with a fistula in ano. For this reason, anorectal abscess becomes a highly important subject. Moreover, as antibiotics cannot reach the contents of an abscess in adequate concentration, no reliance can be placed on antibiotic therapy alone. A fistula is much more likely if bacterial culture of the pus discloses bowel (as opposed to skin) organisms (Grace).

**Differential diagnosis**

The only conditions with which an anorectal abscess is likely to be confused are an abscess connected with a pilonidal sinus, Bartholin’s gland or Cowper’s gland.

**Classification**

A clear understanding of suppuration in this area is dependent on a concise knowledge of the anatomy (Figs 61.34 and 61.35). There are four main varieties: perianal, ischiorectal, submucous and pelvirectal.

**Perianal (60 per cent)**

This usually occurs as the result of suppuration in an anal gland, which spreads superficially to lie in the region of the subcutaneous portion of the external sphincter (Fig. 61.35a).

It may also occur as a result of a thrombosed external pile. If the haematoma is not evacuated, it may become infected and perianal abscess results. This is the most common abscess of the region. Persons of all ages are affected and the condition is not uncommon, even in infancy and childhood. The constitutional symptoms and the pain are less pronounced than in the ischiorectal abscess because the pus can expand the walls of this part of the intermuscular space comparatively easily. Early diagnosis is made by inspecting the anal margin, when an acutely tender, rounded, cystic lump about the size of a cherry is seen and felt at the anal verge below the dentate line.

**Treatment**. No time should be lost in evacuating the pus.

**Operation.** Thorough drainage is achieved by making a cruciate incision over the abscess and excising the skin edges this completely removes the ‘roof’ of the abscess.

**Ischiorectal abscess (30 per cent)**

Commonly, this is due to an extension laterally through the external sphincter of a low intermuscular anal abscess (Fig. 61.35b). Rarely, the infection is either lymphatic or blood borne. The fat, which fills the ischiorectal fossa (Fig. 61.36), is particularly vulnerable because it is poorly vascularised; consequently it is not long before the whole space becomes involved. The ischiorectal fossa communicates with that of the opposite side via the post sphincteric space, and if an ischiorectal abscess is not evacuated early, involvement of the contralateral fossa is not uncommon. Should an internal opening into the anal canal ensue, a ‘horseshoe’ abscess develops enveloping the whole of the posterior part of the circumference of the anal canal (cf. horseshoe fistula).

An ischiorectal abscess gives rise to a tender, brawny induration palpable on the corresponding side of the anal canal and the floor of the fossa. Constitutional symptoms are severe, the temperature often rising to 38—39°C. Men are affected more often than women.

**Treatment.** Operation should be undertaken early — as soon as it is certain that an abscess is present in this area — remembering that antibiotic therapy often masks the general signs.

**Operation. Stage 1.** A cruciate incision (Fig. 61.37 inset) is made into the abscess. A portion of skin is sometimes excised (Fig. 61.37) but deroofing is not necessary in every case.

**Stage 2.** As soon as the acute infection has subsided, the wound should be re-examined, preferably under general anaesthesia. A careful search is made for a fistulous opening communicating with the anal canal. If such is found, the treatment should be as for fistula. If no fistula is found, the cavity should be lightly packed with gauze wrung out in any weak antiseptic favoured by the operator. A T-bandage is applied. When the cavity has become covered with granulation tissue, skin grafting may help to expedite final epithelialisation.

**Submucous abscess**

Submucous abscess (5 per cent) occurs above the dentate line (Fig. 61.35c). When it occurs after the injection of haemorrhoids, it always resolves. Otherwise, it can be opened with sinus forceps when adequately displayed by a proctoscope.

**Pelvirectal abscess**

Pelvirectal abscess is situated between the upper surface of the levator ani and the pelvic peritoneum (Fig. 61.35d). It is nothing more or less than a pelvic abscess and, as such, is usually secondary to appendicitis, salpingitis, diverticulitis or parametritis. *Abdominal Crohn’s disease is an important cause of pelvic disease that can present as perianal sepsis* (cf. fistula in ano). A relevant point to remember is that, rarely, a supra-levator abscess/fistula may be due to overenthusiastic attempts to drain an ischiorectal abscess or to display a fistula, when a probe is forced through the levator ani/rectal wall from below.

**Fissure abscess**

This is the name given to a subcutaneous abscess lying in immediate association with an anal fissure. Drainage is achieved at the same time as the fissure is treated by sphincterotomy.
**Fistula in ano**

A fistula in ano is a track, lined by granulation tissue, which connects deeply in the anal canal or rectum and superficially on the skin around the anus. It usually results from an anorectal abscess which burst spontaneously or was opened inadequately (Fig. 61.34). The fistula continues to discharge and, because of constant reinfection from the anal canal or rectum, seldom, if ever, closes permanently without surgical aid. An anorectal abscess may produce a track, the orifice of which has the appearance of a fistula, but it does not communicate with the anal canal or the rectum. By definition this is not a fistula, but a sinus.

**Types of anal fistulae**

These are divided into two groups, according to whether their internal opening is below or above the anorectal ring.

**Low-level fistulae** open into the anal canal below the anorectal ring.

**High-level fistulae** open into the anal canal at or above the anorectal ring.

As an alternative to the common anatomical classification illustrated in Fig. 61.38, Parks produced another based on the origin of the fistula from an abscess in an anal gland situated in the plane between the internal and external sphincters (the ‘anal intersphincteric plane’) (Fig. 61.39).

The importance of deciding whether a fistula is a low or a high-level type is that a low-level fistula can be laid open usually without fear of permanent incontinence (from damage to the anorectal bundle), while a high-level fistula can be treated only by ‘staged’ operations, often with the use of a protective colostomy to prevent septic complications and to shorten healing time between the stages. In probing a high fistulous track, great care must be taken not to create an internal opening into the rectum where none existed previously. Such a disaster could convert a relatively straightforward ‘intersphincteric’ track into a high ‘pelvirectal’ fistula that might prove very difficult to cure.

By the standard classification, a high fistula refers to both a high anal [Fig. 61.38(4)] and a pelvirectal fistula [Fig. 61.38(5)]. By the Parks’ classification, both a high trans sphincteric and a supralevalator fistula would qualify as high, with the intersphincteric falling into either category depending on whether an internal opening was present at all, and at what level it entered the anal canal [see Fig. 61.39(4)].

**Low-level fistulae**

**Clinical features.** Commonly, the principal symptom is a per-sistent seropurulent discharge that irritates the skin in the neighbourhood and causes discomfort. Often the history dates back for years. So long as the opening is large enough for the pus to escape, pain is not a symptom, but if the orifice is occluded pain increases until the discharge erupts. Frequently, there is a solitary external opening, usually situated within 3.5—4 cm of the anus, presenting as a small elevation with granulation tissue pouting from the mouth of the opening. Sometimes superficial healing occurs, pus accumulates and an abscess reforms and discharges through the same opening or a new opening. Thus there may be two or more external openings, usually grouped together on the right or left of the midline but, occasionally, when both ischiorectal fossae are involved, an opening is seen on each side, in which case there is often intercommunication between them (Fig. 61.40). As a rule there is much induration of the skin and subcutaneous tissues around the fistula.

**Goodsall’s rule.** Fistulae with an external opening in relation to the anterior half of the anus tend to be of the direct type (Fig. 61.41). Those with an external opening or openings in relation to the posterior half of the anus, which are much more common, usually have curving tracks, and may be of the horseshoe variety. Note that posteriorly situated fistulae may have multiple external openings which always connect to a solitary internal orifice, usually midline (Fig. 61.41).

**Digital examination.** Not infrequently an internal opening can be felt as a nodule on the wall of the anal canal. Irrespective of the number of external openings, there is almost invariably only one internal opening.

**Proctoscopy** sometimes will reveal the internal opening of the fistula. A hypertrophied papilla is suggestive that the internal orifice lies within the crypt related to the papilla (Fig. 61.42). Probing. In the past, it was the universal practice to probe a fistula in the ward or the out-patient department. Such manoeuvres accomplish nothing, are painful and are liable to reawaken dormant infection. Furthermore, if probing is performed without the utmost gentleness, or if the patient, experiencing pain, makes a sudden jerk, a false passage may result which complicates the condition still further. Probing should be postponed until the patient is under an anaesthetic in the operating theatre.

The injection of lipiodol, or other opaque medium, along the sinus, before radiography has little to recommend it. The radiographs thus obtained are seldom illuminating, and the procedure is likely to cause a recrudescence of inflammation. Endoluminal ultrasonography and magnetic resonance imaging are being developed as techniques for ‘mapping’ complex fistulae.

**Radiography of** the thorax should be undertaken and the possibility of pulmonary tuberculosis considered, despite the fact that today it will be found in only a small proportion of patients with fistula in ano — usually of Asian origin (see below).

I— Special clinical types of fistulae in ano

Fistula connected with an anal fissure. Unlike the usual fistula in ano, pain (due to the fissure) is a leading symptom. The fistula is very near the anal orifice, usually posterior, and the external opening is often hidden by the sentinel pile.

Fistula with an internal opening above the anorectal ring is due, almost invariably, to penetration by a foreign body or probing and interference with a high abscess. A supralevalot fistula arising spontaneously will be seen only once or at most twice in a surgical career.

Granulomatous infections and Crohn’s disease. If induration around a fistula is lacking, if the opening is ragged and flush with the surface, if the surrounding skin is discoloured and the discharge is watery, or if the external openings are multiple, tuberculous or Crohn’s disease should be considered. In more than 30 per cent of patients suffering from pul-monary tuberculosis, virulent tubercle bacilli are present in the rectum. About 2—3 per cent of fistulae in the UK are due to Crohn’s disease or tuberculosis. In Asian communities, the incidence of tuberculosis is higher. Crohn’s disease should also be suspected if there are other stigmata, and a small bowel meal may be necessary. If tuberculosis is suspected, a chest radiograph and sputum cultures are mandatory. However, the diagnosis can usually only be made on histological examination of biopsy material from the track. If due to tuberculosis, the fistula will usually respond to antituberculous drugs alone.

Fistulae with many external openings may arise from tuberculous proctitis, Crohn’s disease of colon or ileum, bilharziasis and lymphogranuloma inguinale with a fibrous rectal stricture. Crohn’s disease is the most frequent cause seen in this country from this group.
Carcinoma arising within perianal fistulae. Colloid carcinoma may complicate fistulae in ano and a colloid carcinoma of the rectum is notoriously liable to be complicated by perianal fistulae. In some instances, the fistulous condition, with its discharge of colloid material, overshadows the primary carcinoma, and not a few unfortunate patients have had their condition diagnosed for a time as an inflammatory fistula in ano. If a primary tumour is present in the rectum, usually it can be detected and its nature established by biopsy. Dukes established conclusively that colloid carcinomatous fistulae can develop without a primary neoplasm in the rectum. He regarded such cases as examples of colloid carcinoma developing in a reduplicated portion of the intestinal tract. Both adenocarcinoma and squamous-cell carcinoma are known to arise within chronic fistulous tracks. The former can develop from the anal granular tissue; the latter is an example of true malignant change of squamous epithelium lining the wall of the track.

**Hidradenitis suppurativa.** This is a chronic infection of apocrine glands around the anal margin giving rise to numerous sinuses. The mons pubis and groin can also be affected. After excision of the area, granulation and healing are accelerated by using Silastic foam dressing (Hughes).

**Treatment.** That the fistulous track must be laid open from its ter-mination to its source was a rule promulgated by John of Arderne more than 600 years ago.

The operation can best be described in stages:

**Step 1.** Preoperative cleaning enemas are necessary. When the patient has been anaesthetised, he or she is placed in the lithotomy position or in the prone jack-knife position, according to the preference of the operator. Using bidigital palpation under anaesthesia, it is often possible to obtain more information concerning a fistula than can be learned from probing; it is surprisingly easy to push a probe through the wall of the track. Unfortunately, many inexperienced operators find it more reassuring to create a false passage than to risk criticism for not being able to demonstrate the internal opening. Careful bidigital palpation of the perianal tissue will often reveal a cord-like induration, representing the track, which will lead the intra anal finger towards the proximal opening. Rather than insert a probe through the distal orifice at this stage, it is better to endeavour to find the internal opening via a proctoscope. If the internal opening still cannot be seen, the insertion of a probe termgradely into an anal crypt, especially one with a nearby hypertrophied papilla, often reveals the internal portion of the track (Fig. 61.42). The injection of dilute methylene blue or other dye into the external mouth of the fistula to establish the site of the internal opening is occasionally necessary, but is not recommended as a routine.

**Step 2.** A probe-pointed director (Fig. 61.43) is inserted into the distal orifice, and it is advanced delicately until it reaches a point where it does not pass readily. The track is opened along the director and bleeding is controlled.

**Step 3.** If it is not at once evident in which direction the track passes, granulations are wiped away with gauze (it is seldom necessary to use a curette). Often this will leave a granulation-filled spot at one site only. Gentle probing at this spot frequently will give the clue to the continuation of the fistula. The director is reinserted, and again followed with the knife for a short distance. This procedure is repeated until the entire track, and any side channels, are laid open. As far as possible, all muscle is divided at right angles to its fibres. In the rare event of the track passing above the anorectal ring, cutting should cease as the level of the dentate line, and from thenceforth the operation is conducted as sug-gested below. In most instances, probing and laying open the track can be repeated until the entire track is laid open. Pursuing this course, if there is no internal opening, the track will become bereft of granulations on wiping it. As a rule, the internal opening can be demonstrated either by direct inspection through a proctoscope, or by a bent probe inserted into an anal crypt. In the latter circumstance, the internal portion of the track is excised in continuity.

**Step 4.** The edges of the track are trimmed, 1—3 mm of tissue being removed — a step that makes postoperative packing unnecessary after the first 24—36 hours. Hughes advocated primary split skin grafting of the wound resulting from fistulotomy. The grafts are taken from the inner aspect of the thigh and applied to the anal wound, being stitched to the skin edges and to each other in the depths of the wound. Tulle gras is then superimposed and a firm pack of cotton wool applied. The first dressing is done on the 5th postoperative day.

When skin grafting is not employed, digital dilatation of the anus, or the passage of a St Mark’s Hospital3 dilator every other day, prevents pocketing or bridging of the granulating wound.

**Biopsy.** Always send a piece of track for biopsy.

**High-level fistulae**

The treatment of these cases is difficult. If the track is laid open as for low-level fistulae, incontinence will follow. There are four types (Parks).

**Supralevator fistula — secondary to local disease** [Fig. 61.39(3)]. It occurs as a result of Crohn’s disease, ulcerative colitis, carcinoma, a foreign body perforating the rectal ampulla from above or trauma. This fistula is quite unrelated to the ordinary type and the treatment is that of the cause. A traumatic fistula usually needs a colostomy. None of these fistulae requires to be laid open, which would in any case cause incontinence.

**Trans-sphincteric fistula** [Fig. 61.39(2)] with perforating secondary track. The condition starts as an intersphincteric track [Fig. 61.39(1)], often with a high secondary track in the ischiorectal fossa up to the levator ani. Here lies the danger. Although the anal opening may be low, during exploration of the high track, unless great care is taken, the probe can be pushed through the levator ani into the rectal ampulla, thus converting a low fistula into a high-level type. Treatment should first of all be directed to the low trans-sphincteric fistula and healing of the upper track may follow. If it fails to do so, or if the opening into the rectum is of any size or near the anorectal bundle, a colostomy must sometimes be done before sound healing will take place. High tracks often require staged operations.

**A seton — a time-honoured device —** (i.e. a ligature of silk, nylon, silastic or linen) is helpful when the internal opening is near the anorectal ring. Insertion of a seton and subsequent re-examination of the patient without anaesthesia will establish whether the internal opening is situated so near to the anorectal ring that incontinence would result if the track were laid open. Under these conditions, a staged operation and a covering colostomy would be the proper treatment. While the seton remains in situ it acts as a wick/drain and allows the acute inflammatory reaction around the track to subside: this can greatly simplify subsequent surgery. In expert hands, primary repair of divided sphincter muscle can preserve continence when a high-level track is laid open.

**Intersphincteric fistula.** The track is formed as a primary anal gland abscess (Fig. 61.34a), and it runs between the internal and external sphincter along the plane of the longitudinal muscle fibres (see Fig. 61.39, Type 1). It may have an opening into the rectum above the anorectal ring and below at the site of a perianal abscess (Fig. 61.34b). Providing it is recognised it is easy to treat. The internal sphincter is divided and the whole track is laid open without fear of incontinence.
**Suprasphincteric fistula.** Occasionally, the intersphincteric track passes over the top of the sphincter before passing down again in the ischiorectal fossa. Treatment of this type is very difficult and is sometimes best done by an indwelling seton.
Nonmalignant strictures  

**Congenital**

- A stricture at the level of the anal valves, due to incomplete obliteration of the proctodeal membrane, sometimes does not give rise to symptoms until early childhood.

- Patients who have had an operation for imperforate anus in infancy may require periodic anorectal dilatation.

**Spasmodic**

- An anal fissure causes spasm of the internal sphincter.

- Rarely, a spasmodic stricture accompanies secondary megacolon (Chapter 57), possibly due to chronic use of laxatives.

**Organic**

- **Postoperative stricture** sometimes follows haemorrhoidectomy performed incorrectly. Low coloanal anastomoses, especially if a stapling gun is used, can narrow down postoperatively.

- **Irradiation** stricture is an aftermath of irradiation.

- **Senile anal stenosis** — a condition of chronic internal sphincter contraction is sometimes seen in the aged. Increasing constipation is present with pronounced straining at stool. Faecal impaction is liable to occur. The muscle is rigid and feels like a tight umbrella ring. There is no evidence of a fissure in ann. The treatment is internal sphincterotomy or dilatation at frequent intervals.

- **Lymphogranuloma inguinale** (Chapter 67). This is by far the most frequent cause of a tubular inflammatory stricture of the rectum and 80 per cent of the sufferers are women. Frei’s reaction is usually positive. This variety of rectal stricture is particularly common in black races, and may be accompanied by elephantiasis of the labia majora. In the early stages, antibiotic treatment may lead to cure. In advanced cases excision of the rectum is required.

- **Inflammatory bowel disease.** Stricture of the anorectum also complicates ulcerative proctocolitis and most commonly large-bowel Crohn’s disease; in this instance the stricture as annular and often more than one is present. A carcinoma should be suspected if a stricture is found, until a biopsy is obtained.

- **Endometriosis** of the rectovaginal septum may present as a stricture. There is usually a history of frequent menstrual periods with the appearance of severe pain during the first 2 days of the menstrual flow.

- **Neoplastic.** When free bleeding occurs after dilatation of a supposed inflammatory stricture, carcinoma should be suspected (Grey Turner) and a portion of the stricture should be removed for biopsy. Sometimes in these cases repeated biopsies show inflammatory tissue only. If, however, the symptoms show a marked progression, malignancy should be strongly suspected.

**Clinical features**

Increasing difficulty in defecation is the leading symptom. The patient finds that increasingly large doses of aperients are required, and if the stools are formed, they are ‘pipe-stem’ in shape. In cases of inflammatory stricture, tenesmus, bleeding and the passage of mucopus are superadded. Sometimes the patient comes under observation only when subacute or acute intestinal obstruction has supervened.

**Rectal examination.** The finger encounters a sharply defined shelf-like interruption of the lumen. If the calibre is large enough to admit the finger, it should be noted whether the stricture is annular or tubular. Sometimes this point can be determined only after dilatation. A biopsy of the stricture must be taken.

**Treatment**

**Prophylactic**

The passage of an anal dilator during convalescence after haemorrhoidectomy greatly reduces the incidence of post-operative stricture. Efficient treatment of lymphogranuloma inguinale in its early stages should lessen the frequency of stricture from that cause.

**Dilatation by bougies**

For anal and many rectal strictures dilatation by bougies at regular intervals is all that is required.

**Anoplasty**

The stricture is incised and a rotation or advancement flap of skin and subcutaneous tissue replaces the defect and enlarges the anal orifice (Fig. 61.44). This technique is particularly useful for postoperative strictures.

**Colostomy**

Colostomy must be undertaken when a stricture is causing intestinal obstruction, and in advanced cases of stricture complicated by fistulae in ann. In selected cases, this can be followed by restorative resection of the stricture-bearing area. If this step is anticipated, the colostomy is placed in the transverse colon.

**Rectal excision and coloanal anastomosis**

When the strictures are at or just above the anorectal junction, and are associated with a normal anal canal, but irreversible changes necessitate removal of the area, excision can be followed by a coloanal anastomosis with good functional results. A similar procedure can be done for an otherwise incurable supralevator fistula, especially post irradiation.
Malignant tumours

Malignant lesions of the anus and anal canal

Squamous cell carcinoma
Basaloid carcinoma
Mucoepidermoid carcinoma
Basal cell carcinoma
Malignant melanoma
Anal intraepithelial neoplasia (AIN)

Carcinoma of the anus differs from carcinoma of the rectum in histological structure, behaviour and types of treatment. This is mainly because of its accessibility, its sensitivity and its abundant lymph drainage, both superficial and deep. Seventy per cent of anal tumours arise in the anal canal: 30 per cent are squamous cell carcinomas of the anal verge.

Squamous cell carcinoma

Because of its superficial situation, the presence of this lesion is frequently recognised by the patient, who often presents early. However, there are exceptions.

• Radiation carcinoma sometimes develops in the anal and perianal skin of a patient unwisely treated with lightly filtered radiographs for pruritus ani. The chronic radiation dermatitis becomes so familiar to the patient that too often he or she does not perceive the superimposition of carcinoma.
• Anal warts sometimes take on a carcinomatous change (Fig. 61.45). This is particularly likely in HIV-positive individuals.
• Occasionally, a squamous cell carcinoma develops in the track of a long-standing fistula in ano.

The following malignant tumours of the anal canal are also found, but they are rare.

Basaloid carcinoma

This is also known as cloacogenic carcinoma and is a form of nonkeratinising squamous carcinoma. It can metastasise to lymph nodes and can be highly malignant. It is not very sensitive to irradiation.

Mucoepidermoid carcinoma

This tumour arises near the squamocolumnar cell junction and is of average malignancy. It is not well keratinised and is radiosensitive.

Basal cell carcinoma

Like the true squamous cell carcinomas of the anal verge and lower anal canal these are ‘skin tumours’ and behave accordingly.

Melanoma

Melanoma of the anus presents as a bluish-black soft mass that is apt to be confused with a thrombotic pile, and therefore unfortunately incised. Such trauma, followed -by the trauma of defecation, incites the tumour to rapid metastasis. Left undisturbed, it ulcerates and the colour of the tumour changes from blue to black. The inguinal lymph nodes are soon involved. Unless a melanoma is excised at an early stage, it disseminates by the bloodstream. The tumour is radioresistant and has a very poor prognosis (Fig. 61.46).

Lymphoma

This may rarely affect the anal region and may be part of a more widespread lymphomatous condition.

Clinical features

Anal cancer can occur at almost any age, but is usually found in the 6th and 7th decades. It is a rare condition, accounting for approximately 2 per cent of all colorectal cancers. Symptoms include rectal bleeding, mucus discharge, tenesmus, the sensation of a lump in the anus and a change in bowel habit. Occasionally, a patient may present with a mass in the inguinal region due to metastatic lymph nodes.

Rectal examination may reveal an ulcerating, hard, tender, bleeding mass in the anal canal or at the anal verge. The lesion may fungate through the anal canal and appear on the pen-anal skin, or present through a chronic draining anal fistula.

Predisposing conditions

There appears to be a relationship between anal condylomata caused by the human papilloma virus, particularly type 16, and anal cancer. Similarly, the disease is more prevalent in patients infected with the human immunodeficiency virus and those with anal intraepithelial neoplasia (AIN) (see later). Several reports suggest a significantly higher incidence of anal cancer in patients with Crohn’s disease.

Treatment of squamous carcinoma of the anus and anal canal

Tumours of the anal verge

For small squamous cell lesions of the anal verge, wide local excision leaving a margin of at least 2.5 cm of tissue all round is often sufficient to effect a cure. Lymphatic dissemination will be to the inguinal nodes, which should be watched carefully. If they become involved, block dissection removal of the glands of one or both groins will be necessary and carries a fair prognosis for cure.

Tumours of the anal canal

The traditional treatment for carcinoma of the anal canal has been abdominopenineal excision, removing the growth and perianal area widely. If and when the inguinal lymph nodes became involved, a radical dissection of the groins was carried out. Although this operation is based on sound pathological principles, the need for a permanent colostomy and the morbidity associated with it have encouraged surgeons to try a
Radiotherapy alone was used for selected small tumours for a long time. This was applied by external beam, interstitial and intracavitary techniques (Pack). Approximately 50 per cent of tumours treated in this way were said to be eradicated, making subsequent abdominoperineal excision unnecessary (Quan). In patients who presented with inguinal lymph node metastases, block dissection of the groin was indicated in addition to the radiotherapy.

A combination of chemotheraphy and radiotherapy, so-called chemo radiation (Nigro) has now become the preferred initial therapy for all anal canal tumours. The patient is given a combination of 5-fluomouracil (5-FU) and mitomyein for approximately 1 week. Some authors have used a combination of bleomycin, cisplatinum and adriamycin. The chemotherapy is followed by radiotherapy given over 3—7 weeks. The patient is then examined 4—6 weeks after cessation of treatment. If there is obvious tumour remaining, an abdominoperineal excision is performed. If there has been a good response to therapy, the scar is excised; and if no microscopic carcinoma is present, the patient is followed up carefully. The therapy does have unpleasant side effects: most patients suffer proctitis and perineal dermatitis from the radiotherapy, and leucopenia and thrombocytopenia are frequent with the chemotherapy; all patients must be warned about the possibility of alopecia. Nevertheless, approximately two-thirds of patients respond to chemoradiation and avoid a major surgical procedure, and 90 per cent of patients are alive and well 2 years after treatment. This therapy is applicable for all tumours, but those with a diameter of 5 cm or more have a higher failure rate. Although many of these are likely to result in eventual abdominoperineal excision, it is probably best to treat them initially by chemoradiation, as this may make subsequent surgery easier.

In the frail patient with an advanced lesion, a defunctioning colostomy may be the only therapy available to relieve the patient of distressing symptoms such as incontinence.

**Anal intraepithelial neoplasm**

AIN appears to be a premalignant lesion of the anal region. The term describes a dysplastic change which is histologically characterised by a loss of epithelial cellular maturation with associated nuclear hyperchromasia, pleomorphism, cellular crowding and abnormal mitoses within the anal epithelium. These features are identical to those of similar cervical and vulval lesions, and AIN is classified according to nomenclature used for genital intraepithelial neoplasia. Thus:

- **AIN I** — cellular and nuclear abnormalities are restricted to the lower third of the epithelium;
- **AIN II** — the lower two-thirds of the epithelium are affected;
- **AIN III** — the full thickness of the epithelium is affected. This is synonymous with carcinoma in situ of the anus (sometimes termed Bowen’s disease).

AIN seems to be aetiologically linked with human papilloma virus (HPV), type 16, and is more prevalent in women with genital intraepithelial neoplasia and those individuals who are systemically immunosuppressed (Scholefield). The natural history is unknown, but there is circumstantial evidence that in certain cases AIN may lead to invasive squamous cell carcinoma.

AIN I and II are considered low grade and probably have minimal malignant potential and therefore do not require treatment. In contrast, AIN III is considered high grade, but treatment is difficult because the surgeon is often dealing with a wide field change. Options include simple excision, excision with grafting, laser ablation, cryoablation or the application of cytotoxic creams (such as 5 FU).
Further reading

No disease of the human body, belonging to the province of the surgeon, requires in its treatment a better combination of accurate anatomical knowledge with surgical skill than Hernia in all its varieties.  (Sir Astley Paston Cooper, 1804)

A hernia is a protrusion of a viscus or part of a viscus through an abnormal opening in the walls of its containing cavity. The external abdominal hernia is the commonest form, the most frequent varieties being the inguinal, femoral and umbilical, respectively, 75, 8.5 and 15 per cent (Fig. 62.1). The rarer forms comprise 1.5 per cent, excluding incisional hernias.
General features common to all hernias

Aetiology

Any condition which raises intra-abdominal pressure, such as a powerful muscular effort, may produce a hernia. Whooping cough is a predisposing cause in childhood, whilst a chronic cough, straining on micturition or straining on defecation may precipitate a hernia in an adult. Hernias are more common amongst smokers, which may be the result of an acquired collagen deficiency increasing an individual's susceptibility to the development of hernias. It should be remembered that the appearance of a hernia in an adult can be a sign of intra-abdominal malignancy. Stretching of the abdominal musculature because of an increase in contents, as in obesity, can be another factor. Fat acts to separate muscle bundles and layers, weakens aponeurosis and favours the appearance of paraumbilical, direct inguinal and hiatus hernias. A femoral hernia is rare in nulliparous women and men, but more common in multiparous women owing to stretching of the pelvic ligaments. An indirect hernia may occur in a congenital preformed sac — the remains of the processus vaginalis.

Peritoneal dialysis can cause the development of a hernia from a previously occult weakness or enlargement of a patent processus vaginalis.

Composition of a hernia

As a rule, a hernia consists of three parts — the sac, the coverings of the sac and the contents of the sac.

The sac

The sac is a diverticulum of peritoneum consisting of mouth, neck, body and fundus. The neck is usually well defined, but in some direct inguinal hernias and in many incisional hernias there is no actual neck. The diameter of the neck is important because strangulation of bowel is a likely complication where the neck is narrow, as in femoral and paraumbilical hernias.

The body of the sac

The body of the sac varies greatly in size and is not necessarily occupied. In cases occurring in infancy and childhood the sac is gossamer thin. In long-standing cases the wall of the sac may be comparatively thick.

The covering

Coverings are derived from the layers of the abdominal wall through which the sac passes. In long-standing cases they become atrophied from stretching and so amalgamated that they are indistinguishable from each other.

Contents

These can be:

- omentum = omentocele (syn. epiplocele);
- intestine = enterocoele. More commonly small bowel, but may be large intestine or appendix;
- a portion of the circumference of the intestine Richter's hernia;
- a portion of the bladder (or a diverticulum) may constitute part of or be the sole contents of a direct inguinal, a sliding inguinal or a femoral hernia;
- ovary with or without the corresponding fallopian tube;
- a Meckel's diverticulum = a Littre's hernia;
- fluid — as part of ascites or as a residuum thereof.

Classification

Irrespective of site, a hernia can be classified into five types.

Classification of hernias

1. Reducible
2. Irreducible
3. Obstructed
4. Strangulated (complication of irreducible hernias)
5. Inflamed

The hernia either reduces itself when the patient lies down, or can be reduced by the patient or the surgeon. The intestine usually gurgles on reduction and the first portion is more difficult to reduce than the last. Omentum, in contrast, is described as doughy and the last portion is more difficult to reduce than the first. A reducible hernia imparts an expansile impulse on coughing.

Irreducible hernia

Here the contents cannot be returned to the abdomen, but there is no evidence of other complications. It is usually due to adhesions between the sac and its contents or from over-crowding within the sac. Irreducibility without other symptoms is almost diagnostic of an omentocele, especially in femoral and umbilical hernias. Note: any degree of irreducibility predisposes to strangulation.

Obstructed hernia

This is an irreducible hernia containing intestine which is obstructed from without or within, but there is no interference to the blood supply to the bowel. The symptoms (colicky abdominal pain and tenderness over the hernia site) are less severe and the onset more gradual than is the case in strangulation, but more often than not the obstruction culminates in strangulation. Usually there is no clear distinction clinically between obstruction and strangulation, and the safe course is to assume that strangulation is imminent and treat accordingly.

Incarcerated hernia. The term 'incarceration' is often used loosely as an alternative to obstruction or strangulation, but is correctly employed only when it is considered that the lumen of that portion of the colon occupying a hernial sac is blocked with faeces. In that event the scybalous contents of the bowel should be capable of being indented with the finger, like putty.
**Strangulated hernia**

A hernia becomes strangulated when the blood supply of its contents is seriously impaired, rendering the contents ischaemic. Gangrene may occur as early as 5—6 hours after the onset of the first symptoms. Although inguinal hernia may be 10 times more common than femoral hernia, a femoral hernia is more likely to strangulate because of the narrowness of the neck and its rigid surrounds.

Pathology. The intestine is obstructed and its blood supply impaired. Initially, only the venous return is impeded, the wall of the intestine becoming congested and bright red with the transudation of serous fluid into the sac. As congestion increases, the wall of the intestine becomes purple in colour. The intestinal pressure increases distending the intestinal loop and impairing venous return further. As venous stasis increases, the arterial supply becomes more impaired. Blood is extravasated under the serosa and is effused into the lumen. The fluid in the sac becomes blood stained and the shining serosa dull due to a fibrinous, sticky exudate. At this stage the walls of the intestine have lost their tone and become friable. Bacterial transudation occurs secondary to the lowered intestine viability and the sac fluid becomes infected. Clinical features. Sudden pain at first situated over the hernia is followed by generalised abdominal pain, colicky in character and often located mainly at the umbilicus. Nausea and subsequently vomiting ensue. The patient may complain of an increase in hernia size. On examination, the hernia is tense, extremely tender and irreducible, and there is no expansile cough impulse.

Unless the strangulation is relieved by operation, the spasms of pain continue until peristaltic contractions cease with the onset of ischaemia when paralytic ileus (often the result of peritonitis) and septicaemia develop. Spontaneous cessation of pain must be viewed with caution as this may be a sign of perforation.

**Richter's hernia**

Richter's hernia is a hernia in which the sac contains only a portion of the circumference of the intestine (usually small intestine). It usually complicates femoral and, rarely, obturator hernias.

**Strangulated Richter's hernia**

Strangulated Richter's hernia (Fig. 62.3) is particularly note-worthy as operation is frequently delayed because the clinical features mimic gastroenteritis. The local signs of strangulation are often not obvious, the patient may not vomit and, while colicky pain is present, the bowels are often opened normally or there may be diarrhoea; absolute constipation is delayed until paralytic ileus supervenes. For these reasons, gangrene of the knuckle of bowel and perforation have often occurred before operation is undertaken.

Strangulated omentocele. The initial symptoms are in general similar to those of strangulated bowel. Vomiting and constipation may be absent as omentum, unlike intestine, can exist on a very meager blood supply. The onset of gangrene is therefore delayed, occurring first in the centre of the fatty mass. Unrelieved, a bacterial invasion of the ischaemic contents of the sac will occur and an abscess eventually develops. In an inguinal hernia, infection usually terminates as a scrotal abscess, but extension from the sac to the general peritoneal cavity is always a possibility.

Inflamed hernia. Inflammation can occur from inflammation of the contents of the sac (e.g. acute appendicitis or salpingitis) or from external causes (e.g. the trophic ulcers which develop in the dependent areas of large umbilical or incisional hernias). The hernia is usually tender but not tense, and the overlying skin red and oedematous. Treatment is based on treatment of the underlying cause.
Individual features of hernias

Inguinal hernia

Surgical anatomy

The superficial inguinal ring is a triangular aperture in the aponeurosis of the external oblique and lies 1.25 cm above the pubic tubercle. The ring is bounded by a superomedial and an inferolateral crus joined by the criss-cross intercru- nal fibres. Normally, the ring will not admit the tip of the little finger.

The deep inguinal ring is a U-shaped condensation of the transversalis fascia and lies 1.25 cm above the inguinal (Poupart’s) ligament, midway between the symphysis pubis and the anterior superior iliac spine. The transversalis fascia is the fascial envelope of the abdomen and the competency of the deep inguinal ring depends on the integrity of this fascia.

The inguinal canal. In infants the superficial and deep inguinal rings are almost superimposed and the obliquity of the canal is slight. In adults the inguinal canal, which is 3.75 cm long, is directed downwards and medially from the deep to the superficial inguinal ring. In the male the inguinal canal transmits the spermatic cord, the ilio-inguinal nerve and the genital branch of the genitofemoral nerve. In the female the round ligament replaces the spermatic cord.

Boundaries of the canal. Figure 62.4 illustrates the canal, viewing the structures from superficial to deep as is seen at operation. The anterior boundary comprises mainly the external oblique aponeurosis with the conjoined muscle laterally. The posterior boundary is formed by the fascia transversalis and the conjoined tendon (internal oblique and transversus abdominis medially). The inferior epigastric vessels lie posteriorly and medially to the deep inguinal ring.

The superior boundary is formed by the conjoined muscles (internal oblique and transversus) and the inferior boundary is the inguinal ligament.

An indirect hernia travels down the canal on the outer (lateral and anterior) side of the spermatic cord. A direct hernia comes out directly forwards through the posterior wall of the inguinal canal. While the neck of the indirect hernia is lateral to the inferior epigastric vessels, the direct hernia usually emerges medial to this except in the saddle-bag or pantaloons type, which has both a lateral and a medial component. An inguinal hernia can be differentiated from a femoral hernia by ascertaining the relation of the neck of the sac to the medial end of the inguinal ligament and the pubic tubercle, i.e. in the case of an inguinal hernia the neck is above and medial, while that of a femoral hernia is below and lateral (Fig. 62.4). Digital control of the internal ring may help in distinguishing between an indirect and a direct inguinal hernia, although some reports have found the preoperative diagnosis to be incorrect as often as correct.

Indirect (syn. oblique) inguinal hernia

This is the most common of all forms of hernia (see ‘Aetiology’). It is most common in the young, whereas a direct hernia is most common in the old. In the first decade of life inguinal hernia is more common on the right side in the male. This is no doubt associated with the later descent of the right testis and a higher incidence of failure of closure of the processus vaginalis. In adult males, 65 per cent of inguinal hernias are indirect and 55 per cent are right-sided. The hernia is bilateral in 12 per cent of cases. Three types of indirect inguinal hernia occur (Fig. 62.5).

Bubonocele

When the hernias limited to the inguinal canal

Funicular

the processus vaginalis is closed just above the epididymis the content of the sac can be felt separately from the testis, which lies below the hernia

Completes (syn. scrotal) — a complete inguinal hernia is rarely present at birth but is commonly encountered in infancy. It also occurs in adolescence or adult life. The testis appears to lie within the lower part of the hernia.

Clinical features

Occurring at any age, males are 20 times more commonly affected than females. The patient complains of pain in the groin or pain referred to the testicle when performing heavy work or taking strenuous exercise. When asked to cough a small transient bulging may be seen and felt together with an expansile impulse. When the sac is still limited to the inguinal canal, the bulge may be better seen by observing the inguinal region from the side or even looking down the abdominal wall while standing behind the respective shoulder of the patient.

As an indirect inguinal hernia increases in size it becomes apparent when the patient coughs and persists until reduced (Fig. 62.6). As time goes on the hernia comes down as soon as the patient stands up. In large hernias there is a sensation of weight, and dragging on the mesentery may produce epigastric pain. If the contents of the sac are reducible, the inguinal canal will be found to be commodious.

In infants the swelling appears when the child cries. It can be translucent in infancy and early childhood, but never in an adult. In girls an ovary may prolapse into the sac.

Differential diagnosis in the male.

• A vaginal hydrocele (Fig. 62.7);

• an encysted hydrocele of the cord;

• a spermatocele;

• a femoral hernia;

• an incompletely descended testis in the inguinal canal — an inguinal hernia is often associated with this condition;

• a lipoma of the cord — this is often a difficult, but unimportant, diagnosis. It is usually not settled until the parts are displayed by operation.

NB. Examination using finger and thumb across the neck of the scrotum will help to distinguish between a swelling of inguinal origin and one which is entirely intrascrotal.
Differential diagnosis in the female.

- A hydrocele of the canal of Nuck is the commonest differential diagnostic problem;
- A femoral hernia.

**Treatment of indirect inguinal hernia**

Operative treatment. **Operation is the treatment of choice.** It must be remembered that patients who have a bad cough from chronic bronchitis should not be denied an operation, for these are the very people who are in danger of getting a strangulated hernia. In adults, local, epidural or spinal, as well as general, anaesthesia can be used.

Inguinal herniotomy. This is the basic operation which entails dissecting out and opening the hernial sac, reducing any contents, and then transfixing the neck of the sac and removing the remainder. It is employed either by itself or as the first step in a repair procedure (herniorrhaphy). By itself it is sufficient for the treatment of hernia in infants, adolescents and young adults. Any attempts at repair in such cases may, in fact, do more harm than good.

In infants it is not necessary to open the canal, as the internal and external rings are superimposed. Excellent results are obtained. The operation is usually now performed as a day case unless there are additional medical or social problems.

Herniotomy and repair (herniorrhaphy). This operation consists of: (1) excision of the hernial sac; plus (2) repair of the stretched internal inguinal ring and the transversalis fascia; and (3) further reinforcement of the posterior wall of the inguinal canal. (2) and (3) must be achieved without tension resulting in the wound and various techniques exist to achieve this, e.g. Shouldice operation, fascial flaps or polypropylene mesh implants.

**Operative procedures**

1. **Excision of the sac.** The indirect sac may be distinguished as a pearly white structure lying on the outer side of the cord and, when the internal spermatic fascia has been incised longitudinally, it can usually be dissected out and then opened between haemostats.

2. **Reduction of contents.** Intestine or omentum is returned to the peritoneal cavity. Omentum is often adherent to the neck or fundus of the sac: if to the neck, it is freed, and if to the fundus of a large sac, it may be transfixied, ligated and cut across at a suitable point. The distal part of the omentum, like the distal part of a large scrotal sac, can be left in situ (the fundus should, however, not be ligated).

3. **Isolation and ligation of the neck of the sac.** Whatever type of sac is encountered, it is necessary to free its neck by blunt dissection until the parietal peritoneum can be seen on all sides. The dissection is only considered complete when the extraperitoneal fat has been encountered and the inferior epigastric vessels are seen on the medial side. It used to be considered essential to open the sac to ensure that no bowel or omentum was adherent to the neck. If the sac is obviously empty, it is sufficient simply to reduce it, close the internal ring and perform a herniorrhaphy if required. If the sac is opened, all contents should be reduced and the neck transfixied as high as possible before excising the sac.

4. **Repair of the transversalis fascia and the internal ring.** When the internal ring is weak and stretched, and the transversalis is bulging, the repair should include a technique of narrowing the deep ring, for example the Lyric method of narrowing the ring with lateral dis-placement of the cord (Fig. 62.8) or the Shouldice method, whereby the ring and fascia are incised and carefully separated from the deep inferior epigastric vessels and extraperitoneal far before an overlapping repair (‘double breasting’) of the lower flap behind the upper flap is performed. In the classic Shouldice operation, a third and fourth layer of tension free suturing, using monofilament materials, polypropylene, polyamide or wire, is placed between the internal oblique aponeurosis arch and the inguinal ligament (Fig. 62.9).

5. **Reinforcement of the posterior inguinal wall.** This is achieved by suturing without tension between the tendinous aponeurotic arch of internal oblique to the under surface of the inguinal ligament and to the pubic tubercle (as described above in the Shouldice operation) or by reinforcing the posterior wall of the canal with a prosthetic mesh. Care is taken when suturing not to pick up the same tendinous bundle for each suture. Suturing of muscle bundles is of no value. The suturing method can include a rectus-relaxing incision (Haltared—Tanner). The Lichtenstein tension-free hernioplasty involves placement of an approximately 16 x 8 cm tailored to the individual patient’s requirements) mesh as an extra lamina, anterior to the posterior wall and overlapping it generously in all directions, including medially over the pubic tubercle. Other historical techniques, which should now be abandoned because of poor results, include overlapping the extraperitoneal oblique behind the cord (making it lie subcutaneously). Special care was needed to avoid excessive narrowing of the new external ring which could jeopardise the vascular supply to and the venous return from the testis.

6. **Completion of operation.** If desired, the cremasteric muscle can be reconstituted: the external oblique is directly sutured or overlapped leaving a new external ring which should accommodate the tip of a finger (Fig. 62.10).

**A truss.** A truss may be used when operation is contraindicated or when operation is refused. Its use should be mainly historical as there are very few contraindications to surgery with today’s variety of anaesthetic techniques. If a truss is to be worn, the hernia must be reducible.
A rat tailed spring truss with a perineal band to prevent the truss slipping will, with due care and attention, control a small or moderate size inguinal hernia. A truss must be worn continuously during waking hours, keeplean and in proper repair, and renewed when it shows signs of wear. It must be applied before the patient gets up and while the hernia is reduced. A properly fitting truss must control the hernia when the patient stands, with his legs apart, stoops and coughs violently. If it does not it is a menace, for it increases the risk of strangulation. There is no place for trusses in the management of infant hernias. If an infant hernia becomes suddenly irreducible, urgent operative repair is indicated. Otherwise, the infant hernia can be left alone until the child is over 3 months old when routine day-case repair can be performed.

**Direct inguinal hernia**

In adult males, 35 per cent of inguinal hernias are direct. At presentation, 12 per cent of patients will have a contralateral hernia in addition and there is a four-fold increased risk of future development of contralateral hernia if one is not present at the original presentation.

A direct inguinal hernia is always acquired. The sac passes through a weakness or defect of the transversalis fascia in the posterior wall of the inguinal canal. In some cases the defect is small and is represented by a discrete defect in the transversalis fascia, while in others there is a generalised bulge. Often the patient has poor lower abdominal musculature, as shown by the presence of elongated bulgings (Malgaigne’s bulges). Women practically never develop a direct inguinal hernia (Brown). Predisposing factors are smoking, and occu-patons that involve straining and heavy lifting. Damage to the ilio-inguinal nerve (previous appendicectomy) is another cause, due to resulting weakness of the conjoined tendon.

Direct hernias do not often attain a large size or descend into the scrotum (Fig. 62.11). In contrast to an indirect inguinal hernia, a direct inguinal hernia lies behind the spermatic cord. The sac is often smaller than the hernial mass would indicate, the protruding mass mainly consisting of extraperitoneal fat. As the neck of the sac is wide, direct inguinal hernias do not often strangulate.

Funicular direct inguinal hernia (syn. prevesical hernia). This is a narrow-necked hernia with prevesical fat and a portion of the bladder that protrudes through a small oval defect in the medial part of the conjoined muscle just above the pubic tuber-cle. It occurs principally in elderly males and occasionally becomes strangulated. Unless there are definite contraindications, operation should always be advised.

Dual (syn. saddle bag; pantaloon) hernia. This type of hernia consists of two sacs which straddle the inferior epigastric artery, one sac being medial and the other lateral to this vessel. The condition is not rare and is a cause of recurrence, one of the sacs having been overlooked at the time of operation.

Operation for direct hernia. The principles of repair of direct hernias are the same as those of an indirect hernia with the exception that the hernia sac can usually be simply inverted after the sac has been dissected free and the transversalis fascia reconstructed in front of it. This reconstruction of the posterior wall of the inguinal canal should be undertaken by the Shouldice repair or mesh implant using the Lichtenstein technique (Figs 62.9 and 62.10). The darn operation is no longer acceptable because of its high recurrence rate and slow rehabilitation.

**Strangulated inguinal hernia**

Pathological and clinical features are described earlier in this chapter. Strangulation of an inguinal hernia occurs at any time during life and in both sexes. Indirect inguinal hernias strangulate more commonly, the direct variety not so often owing to the wide neck of the sac. Sometimes a hernia strangulates on the first occasion that it descends; more often strangulation occurs in patients who have worn a truss for a long time, and in those with a partially reducible or irreducible hernia.

In order of frequency, the constricting agent is: (a) the neck of the sac; (b) the external inguinal ring in children; and (c), rarely, adhesions within the sac.

**Contents**

Usually, the small intestine is involved in the strangulation; the next most frequent is the omentum; sometimes both are involved. It is rare for the large intestine to become strangulated in an inguinal hernia, even when the hernia is of the sliding variety.

**Strangulation during infancy**

The incidence of strangulation is 4 per cent (Gross) and the ratio of females to males is 5:1. More frequently the hernia is irreducible but not strangulated. In most cases of strangulated inguinal hernia occurring in female infants the content of the sac is an ovary or an ovary plus its fallopian tube.

**Treatment of strangulated inguinal hernia**

The treatment of strangulated hernia is by emergency operation ('The danger is in the delay not in the operation', Sir Astley Paston Cooper). Vigorous resuscitation with intravenous fluids, nasogastric aspiration and antibiotics is essential, although operation should not be unduly delayed in moribund patients. It is also advisable to empty the bladder, if necessary by catheterisation.

Inguinal herniectomy for strangulation. An incision is made over the most prominent part of the swelling. The external oblique aponeurosis is exposed and the sac, with its coverings, is seen issuing from the superficial ring. In all but very large hernias, it is possible to deliver the body and fundus of the sac together with its coverings and (in the male) the testis on to the surface. Each layer covering the anterior surface of the body of the sac near the fundus is incised and, if possible, stripped off the sac. The sac is then incised and any fluid, which may be highly infective, drained effectively. The external oblique aponeurosis and the superficial inguinal ring are divided. A finger is then passed into the opening in the sac and, employing the finger as a guide, the sac is slit along its length. If the constriction lies at the superficial inguinal ring, or within the canal, it is readily divided by this procedure. When the constriction is at the deep ring, by applying haemostats to the cut edge of the neck of the sac and drawing them downwards, and at the same time retracting the internal oblique upwards, it may be possible to continue slitig the sac over the finger towards the point of constriction. When the constriction is too tight to admit a finger, a grooved dissector is inserted and the neck of the sac is divided with a knife in an upward and inward direction, i.e. parallel to the inferior epigastric vessels, under vision. Once the constriction has been divided, the strangulated contents can be drawn down. Devitalised omentum is excised after being securely ligated. Viable intestine is returned to the peritoneal cavity. Doubtfully viable and gangrenous intestine is excised by localised resection. If the hernial sac is of moderate size and can be separated easily from its coverings, it is excised and closed by a purse-string suture. When the sac is large and adherent, much time is saved by cutting across the sac as described earlier. Having tied or sutured the neck of the sac, a repair can be made if the condition of the patient permits. In those circumstances where the incision has been soiled or gangrenous bowel resected, prosthetic mesh is best avoided, although some authorities have successfully used polypropylene mesh with antibiotic cover.

Conservative measures. These are only indicated in infants. The child is given analgesias and placed in gallow's traction (the judgement of Solomon position). In 75 per cent of cases reduction is effected and there
patients are usually between 30 and 40 years of age. The condition is more prevalent in women who have borne children than in nulliparae.

Sex incidence. The female to male ratio is about 2:1, but it is interesting that whereas the female patients are frequently elderly, the male patients are usually between 30 and 40 years of age. The condition is more prevalent in women who have borne children than in nulliparae.

Femoral hernia

Femoral hernia is the third most common type of primary hernia. It accounts for about 20 per cent of hernias in women and 5 per cent in men. The overriding importance of femoral hernia lies in the facts that it cannot be controlled by a truss and that of all hernias it is the most liable to become strangulated, mainly because of the narrowness of the neck of the sac and the rigidity of the femoral ring. Strangulation is the initial presentation of 40 per cent of femoral hernias.

Surgical anatomy. The femoral canal occupies the most medial compartment of the femoral sheath and it extends from the femoral ring above to the saphenous opening below. It is 1.25 cm long and 1.25 cm wide at its base, which is directed upwards. The femoral canal contains fat, lymphatic vessels and the lymph node of Cloquet. It is closed above by the septum crurale, a condensation of extraperitoneal tissue and that it is replaced deep to the repaired fascia transversalis. In many circumstances it is desirable to perform orchidectomy in order to effect a secure repair. No attempt should be made to dissect the caecum or colon free from the peritoneum under the impression that these are adhesions, in which case peritonitis or a faecal fistula resulting from necrosis of a devascularised portion of the bowel may occur. This is especially liable to occur on the left side, as vessels in the mesocolon may be injured.

Operation. It is unnecessary to remove any of the sliding hernial sac provided that it is freed completely from the cord and the abdominal wall, and that it is replaced deep to the repaired fascia transversalis. In many circumstances it is desirable to perform orchidectomy in order to effect a secure repair. No attempt should be made to dissect the caecum or colon free from the peritoneum under the impression that these are adhesions, in which case peritonitis or a faecal fistula resulting from necrosis of a devascularised portion of the bowel may occur. This is especially liable to occur on the left side, as vessels in the mesocolon may be injured.

Clinical features

A sliding hernia is impossible to control with a truss, and as a rule the hernia is a cause of considerable discomfort. Consequently, operation is indicated and the results are very good.

Operation. It is unnecessary to remove any of the sliding hernial sac provided that it is freed completely from the cord and the abdominal wall, and that it is replaced deep to the repaired fascia transversalis. In many circumstances it is desirable to perform orchidectomy in order to effect a secure repair. No attempt should be made to dissect the caecum or colon free from the peritoneum under the impression that these are adhesions, in which case peritonitis or a faecal fistula resulting from necrosis of a devascularised portion of the bowel may occur. This is especially liable to occur on the left side, as vessels in the mesocolon may be injured.

Femoral hernia

Femoral hernia is the third most common type of primary hernia. It accounts for about 20 per cent of hernias in women and 5 per cent in men. The overriding importance of femoral hernia lies in the facts that it cannot be controlled by a truss and that of all hernias it is the most liable to become strangulated, mainly because of the narrowness of the neck of the sac and the rigidity of the femoral ring. Strangulation is the initial presentation of 40 per cent of femoral hernias.

Surgical anatomy. The femoral canal occupies the most medial compartment of the femoral sheath and it extends from the femoral ring above to the saphenous opening below. It is 1.25 cm long and 1.25 cm wide at its base, which is directed upwards. The femoral canal contains fat, lymphatic vessels and the lymph node of Cloquet. It is closed above by the septum crurale, a condensation of extraperitoneal tissue pierced by lymphatic vessels, and below by the cribriform fascia.

The femoral ring is bounded:

- anteriorly by the inguinal ligament;
- posteriorly by Astley Cooper’s (iliopectineal) ligament, the pubic bone and the fascia over the pectineus muscle;
- medially by the concave knife-like edge of Gimbernat’s (lacunar) ligament, which is also prolonged along the iliopectineal line as for Astley Cooper’s ligament;
- laterally by a thin septum separating it from the femoral vein.

Sex incidence. The female to male ratio is about 2:1, but it is interesting that whereas the female patients are frequently elderly, the male patients are usually between 30 and 40 years of age. The condition is more prevalent in women who have borne children than in nulliparae.

Pathology. A hernia passing down the femoral canal descends vertically as far as the saphenous opening. While it is confined to the inelastic
walls of the femoral canal the hernia is necessarily narrow but, once it escapes through the saphenous opening into the loose areolar tissue of the groin, it expands, sometimes considerably. A fully distended femoral hernia assumes the shape of a retort and its bulbous extremity may be above the inguinal ligament. By the time the contents have pursued so tortuous a path they are usually irreducible and apt to strangulate.

Clinical features. Femoral hernia is rare before puberty. Between 20 and 40 years of age the prevalence rises and continues to old age. The right side (Fig. 62.13) is affected twice as often as the left, and in 20 per cent of cases the condition is bilateral. The symptoms to which a femoral hernia bears rise are less pronounced than those of an inguinal hernia; indeed, a small femoral hernia may be unnoticed by the patient or disregarded for years, perhaps until the day it strangulates. Adherence of the greater omentum sometimes causes a dragging pain. Rarely, a large sac is present.

Differential diagnosis. A femoral hernia has to be distinguished from the following.

**An inguinal hernia.** The neck of the sac lies above and medial to the medial end of the inguinal ligament at its attachment to the pubic tuber-cle. The neck of the sac of a femoral hernia lies below this (Fig. 62.14). The fundus of an inguinal or a femoral hernia may follow the line of least resistance and occupy a variety of places, for instance, occasionally the fundus of a femoral hernia sac overlies the inguinal ligament.

**A saphena varix.** A saccular enlargement of the termination of the long saphenous vein, usually accompanied by other signs of varicose veins. The swelling disappears completely when the patient lies flat, while a femoral hernia sac is usually still palpable. In both, there is an impulse on coughing. A saphena varix will, however, impart a fluid thrill to the examining fingers when the patient coughs or when the saphenous vein below the varix is tapped with the fingers of the other hand. Sometimes a venous hum can be heard when a stethoscope is applied over a saphena varix.

**An enlarged femoral lymph node.** There may be other enlarged lymph nodes to aid the diagnosis. If Cloquet’s lymph node alone is affected, it may be impossible to distinguish from a femoral hernia sac unless there are other clues, such as an infected wound or abrasion on the corresponding limb or on the perineum.

**Lipoma.**

**A femoral aneurysm.** See Chapter 15.

**A psoas abscess.** There is often a fluctuating swelling — an iliac abscess

— which communicates with the swelling in question. If suspected, an examination of the spine and an X-ray will confirm the diagnosis.

**A distended psoas bursa.** The swelling diminishes when the hip is flexed and osteoarthritis of the hip is present.

**Rupture of the adductor longus.** Rupture of the adductor longus with haematoma formation — suspected on clinical history.

Hydrocele of a femoral hernia sac. The neck of the sac becomes plugged with omentum or by adhesions, and a hydrocele of the sac results.

Laugier’s femoral hernia. This is a hernia through a gap in the lacunar (Gimbernat’s) ligament. The diagnosis is based on unusual medial position of a small femoral hernia sac. The hernia has nearly always strangulated.

Narath’s femoral hernia. This occurs only in patients with congenital dislocation of the hip and is due to lateral displacement of the psoas muscle. The hernia lies hidden behind the femoral vessels.

Cloquet’s hernia. Cloquet’s hernia is one in which the sac lies under the fascia covering the pectineus muscle. Strangulation is likely. The sac may coexist with the usual type of femoral hernia sac.

**Strangulated femoral hernia**

A femoral hernia strangulates frequently and gangrene rapidly develops. This is explained by the narrow, unyielding femoral ring. In 40 per cent of cases the obstructing agent is not the lacunar ligament but the neck of the femoral sac itself. A Richter’s hernia is a frequent occurrence (see above).

Treatment of a femoral hernia. The constant risk of stran-gulation is sufficient reason to recommend operation, which should be carried out soon after the diagnosis has been made. A truss is contraindicated because of this risk.

**Operative treatment.** Several approaches to the femoral hernia have been advocated including the low operation (Lockwood), the high operation (McEvedy) and the inguinal operation (Lotheissen). In all cases the bladder must be emptied by catheterisation immediately before commencing surgery.

The high (McEvedy) operation. Classically, a vertical incision is made over the femoral canal and continued upwards above the inguinal ligament. An acceptable alternative that heals well and with less pain is to use a ‘unilateral’ Pfannenstiel incision, which can be extended to form a complete Pfannenstiel incision if formal Laparotomy is required. This incision provides good access to the preperitoneal space. Through the lower part of the incision the sac is dissected Out. The upper part of the incision exposes the inguinal ligament and the rectus sheath. The superficial inguinal ring is identified and an incision 2.5 cm above the ring and parallel to the outer border of the rectus muscle is deepened until the extraperitoneal space is identified. By gauze dissection in this space the hernial sac entering the femoral canal can be easily identified. Should the sac be empty and small, it may be drawn upwards; if it is large, the fundus is opened below and its contents, if any, dealt with appropriately before delivering the sac upwards from its canal. The sac is then freed from the extraperitoneal tissue and its neck ligated. An excellent view of the ilio-pectineal ligament is obtained and the conjoined tendon is sutured to it with nonabsorbable sutures. An alternative repair, particularly suitable for recurrent femoral hernias, is to suture a sheet of polypropylene mesh over the femoral canal orifice, anchoring the mesh inferiorly to the ilio-pectineal ligament and medially to the rectus sheath.

An advantage of this approach is that if resection of intestine is required, ample room can be obtained by opening the peritoneum. The
disadvantage of this approach is that if infection occurs, an incisional hernia may develop.

Lotheissenn's operation. The inguinal canal is opened as for inguinal herniorrhaphy. The transversalis fascia is incised to the medial side of the epigastric vessels and the opening is enlarged. The peritoneum is now in view; one must be certain that it is the peritoneum and not the bladder or a diverticulum thereof. The peritoneum is picked up with dissecting forceps and incised. It is now possible to ascertain whether any intraperitoneal structure is entering the femoral sac. Should the sac be empty, haemostats are placed upon the edges of the opening into the peritoneum and, by gauze dissection, the sac is withdrawn from the femoral canal. An empty sac can be delivered easily. If strangulation is suspected, as soon as the external oblique has been exposed, the inferior margin of the wound is retracted, thereby displaying the swelling. The coverings of the sacs are incised and peeled off, until the sac, dark from contained blood stained fluid, is apparent. The sac is incised and the fluid that escapes is mopped up with care. The retractor is removed and the operation is continued above the inguinal ligament as described above. Once the peritoneum has been opened above the inguinal ligament, one can see exactly what is entering the sac. Should the obstruction lie in a narrow neck of the sac, the neck of the sac may be gently stretched by insertion of a haemostat. (An abnormal obturator artery is present either on the medial or the lateral side of the neck of the sac in 28 per cent of cases.) The contents of the sac are delivered and dealt with appropriately. Sometimes, in order to facilitate reduction of the hernial contents, it becomes necessary to divide or digitally dilate part of the lacunar (Gimbernat's) ligament.

The Lotheissen repair is effected by suturing the conjoined tendon to the iliopectineal line to form a shutter. While protecting the external iliac/femoral vein with the forefinger, nonabsorbable sutures are passed through the peritoneum and Cooper's ligament overlying the ilio-pectineal line. The retractor is removed and the long ends of the sutures are passed from within, outwards, through the conjoined tendon and tied, thus approximating the conjoined tendon to the ilipectineal line. If there is any tension, a Tanner's slide will facilitate this step. The incised external oblique is sutured.

An alternative repair is to buttress the femoral canal with a sheet of polypropylene mesh. Once the sac has been dealt with, a sheet of mesh is inserted into the preperitoneal space and anchored inferiorly to the ilipectineal line, inf eromedially to Cooper's ligament and superomedially to the rectus sheath. The transversalis fascia may then be approximated in front of the mesh and the incised external oblique repaired. It should be noted that the peritoneum must be closed before placement of the mesh.

NB. Throughout operations for the repair of a femoral hernia, on the lateral side, the external iliac/femoral vein must be protected, and on the medial side, great care must be taken not to injure the bladder, particularly as a portion of the bladder may form part of the wall of the sac (a sliding femoral hernia).

Umbilical hernia

Exomphalos (syn. omphalocele) occurs once in every 6000 births; it is due to failure of all or part of the midgut to return to the coelom during early foetal life. There is some debate as to whether gastrochisis represents a separate entity or is simply an exomphalos with ruptured membranes, but the debate has little practical importance because the principles of treatment are similar. When the sac remains unruptured, it is semitranslucent (Fig. 62.15) and, although very thin, it consists of two layers — an outer layer of amniotic membrane and an inner layer of peritoneum. Omphalocoles may be divided into those with a fascial defect of less than or greater than 4 cm. The former are termed herniation of the umbilical cord. In smaller defects, a single loop of intestine may not be obvious and ligation of what was thought to be a normal umbilical cord will result in transection of the intestine, leaving the embarrassing problem of an umbilico-enteric fistula.

In large defects the liver, spleen, stomach, pancreas, colon or bladder may be seen through the membrane. The intestine lies freely mobile within the intact sac without evidence of adhesions or inflammation. In contrast, the liver has dense adhesions to the sac, a fact which must be remembered during surgical repair.

Treatment

Small defects may be closed primarily soon after birth as there is usually no difficulty with disproportion between the size of the abdominal cavity and the volume of the sac contents.

Large defects present a more substantial problem and four techniques have been described: nonoperative therapy, skin flap closure, staged closure, and primary closure

Nonoperative therapy. This is appropriate for premature infants with a gigantic intact sac or those in whom associated anomalies make survival of a major operation unlikely. The intact sac is painted daily with a desiccating antiseptic solution and, if successful, an eschar forms over the sac. Eventually granulisation grows in from the periphery and the subsequent ventral hernia can be repaired later.

Skin flap closure. The sac is gently trimmed away enabling inspection of the abdominal contents. The skin is freed from the fascial edges and undermined laterally. The umbilical vessels are ligated or one artery is cannulated for monitoring. The skin flaps are approximated in the midline with simple sutures and the ventral hernia is then closed at a later date (months to years later).

Staged closure. The sac is gently trimmed away from the skin edge and the skin further freed from the fascial attachments. The prosthetic material [polypropylene mesh or expanded polytetrafluoroethylene (PTFE)] is sutured with interrupted nonabsorbable sutures circumferentially to the full thickness of the muscular fascial abdominal wall to form a sifo. The top of the sifo is gathered and tied with umbilical tape. At daily intervals, the sifo is opened under strict aseptic conditions and the contents are examined for infection or dehiscence. The viscera are pushed back into the abdominal cavity and the infant is observed for signs of raised intra-abdominal pressure. The sifo is then tied at a reduced level and the cycle repeated until the sac is flush with the abdominal wall. At this stage, the fascia may be closed with interrupted sutures and skin closed over the top.

Primary closure. The sac is gently dissected away from the skin edge and the underlying fascia. The intestine is then evacuated completely of meconium and fluid distally and proximally through a nasogastric tube. The abdominal wall is stretched gradually and repeatedly in quadrants, usually achieving a doubling of volume. The viscera are then replaced and the fascial layer is closed primarily, usually under moderate tension. Intragastric pressure monitoring is helpful to prevent undue vena caval compression.

Congenital umbilical hernia. Rarely, a fully developed umbilical hernia present at birth, presumably due to intrauterine epithelialisation of a small exomphalos.

Umbilical hernia of infants and children

This is a hernia through a weak umbilicus which may partial-ly result from failure of the round ligament (obliterated umbilical vein) to cross the
umbilical ring and partially from absence of the Richet fascia. Both sexes seem to be equally affected, although there are significant racial differences, with the incidence in black infants reported as up to eight times higher than in white infants. The hernia is often symptomless but increases in size on crying and assumes a classical conical shape (Fig. 62.16). Obstruction or strangulation below the age of 3 years is extremely uncommon.

Treatment. Conservative treatment is indicated under the age of 2 years. When the hernia is symptomless, reassurance of the parents is all that is necessary and 95% of hernias will disappear spontaneously. If the hernia persists at 2 years of age or older, it is unlikely to resolve and herniorrhaphy is indicated. Operation. A small curved incision is made immediately below the umbilicus. The skin cicatrix is dissected upwards and the neck of the sac isolated. After ensuring that the sac is empty of contents, it is either inverted into the abdomen or ligated by transfixion and excised. The defect in the linea alba is closed with interrupted absorbable sutures.

Paraumbilical hernia (syn. supraumbilical or infraumbilical hernia)

In adults the hernia does not occur through the umbilical scar. It is a protrusion through the linea alba just above or sometimes just below the umbilicus (Fig. 62.17). As it enlarges it becomes rounded or oval in shape, with a tendency to sag downwards. Paraumbilical hernias can become very large. The neck of the sac is often remarkably narrow compared with the size of the sac and the volume of its contents, which usually consist of greater omentum often accompanied by small intestine and, alternatively or in addition, a portion of transverse colon. In long-standing cases the sac sometimes becomes loculated owing to adherence of omentum to its fundus.

Clinical features. Women are affected five times more frequently than men. The patient is usually overweight, and between the ages of 35 and 50 years. Increasing obesity, with flabbiness of the abdominal muscles, and repeated pregnancy are important aetiological factors. These hernias may become irreducible owing to the formation of omental adhesions within the sac. Symptomatically, a large umbilical hernia causes a dragging pain by its weight. Gastrointestinal symptoms are common and are probably due to traction on the stomach or transverse colon. Often there are transient attacks of intestinal colic due to partial intestinal obstruction. In long-standing cases Intertrigo of the adjacent surfaces of skin and trophic ulcers of the fundus are troublesome complications.

Treatment. Untreated, the hernia increases in size and more and more of its contents become irreducible. Eventually, strangulation may occur. Therefore operation should be advised in nearly all cases. If the patient is obese and the hernia is symptomless, operation can be postponed until the patient has lost weight.

Epigastric herniorrhaphy. If the defect is small, a primary herniorrhaphy can be performed. If the defect is large, the repair is best performed with prosthetic rettressing of the abdominal wall. The classic primary repair is that described by Mayo. A transverse elliptical incision is made around the umbilicus and the subcutaneous tissues are dissected off the rectus sheath to expose the neck of the sac. The neck is incised to expose the contents. Intestine is returned to the abdomen and any adherent omentum freed. Excess adherent omentum can be removed with the sac if necessary. The sac is then removed and the peritoneum closed with an absorbable suture. The aponeurosis on both sides of the umbilical ring is mobilised from underlying tissue sufficiently to allow an overlap of 5 or 7.5 cm. Interrupted mattress sutures are then inserted into the aponeurosis, as shown in Fig. 62.18. When this row of mattress sutures has been tied, the overlapping upper margin is stitched to the sheath of the rectus abdominis and the midline aponeurosis. A suction drain should be placed in the wound in fat patients, who ooze blood and liquid fat. The subcutaneous fat and skin are then approximated with deep sutures.

Paraumbilical hernioplasty. In the case of very large primary para-umbilical hernias (fascial defect > 4 cm) or for recurrent paraumbilical hernias, the use of prosthetic material (polypropylene mesh) is recommended.

Additional lipectomy. In patients with a paraumbilical hernia associated with a large, pendulous, fat-laden abdominal wall the operation can, with great advantage, be combined with panilcipectomy by fashioning the incisions to embrace a larger area of the fat-laden superficial layers of the abdominal wall.

Strangulation is a frequent complication of a large paraumbilical hernia in adults. Owing to the narrow neck and the fibrous edge of the linea alba, gangrene is liable to supervene unless early operation is carried out. It should also be remembered that in large hernias the presence of loculi may result in a strangulated knuckle of the bowel in one part of an otherwise soft and nontender hernia.

Operation. In early cases, the operation does not differ from that for nonstrangulated cases. Gangrenous contents are dealt with as in other situations. If a portion of the transverse colon is gangrenous, it should be exteriorised by the Paul—Mikuticz method and the gangrenous portion excised. If the ring is large enough to transmit the colon unhampere, it is left alone; otherwise it is enlarged. It is important that the small intestine be thoroughly scrutinised as a small loop may have been trapped and slipped back when the constriction was relieved. If nonviable gut is overlooked, peritonitis quickly supervenes and the symptoms are ascribed to postoperative discomfort. The condition of the patient steadily deteriorates until they succumb after a few days.

Epigastric hernia (syn. fatty hernia of the linea alba)

An epigastric hernia occurs through the linea alba anywhere between the xiphoid process and the umbilicus, usually midway between these structures. Such a hernia commences as a protrusion of extraperitoneal fat through the linea alba, and it was hypothesised that this protrusion occurs at the site where small blood vessels pierced the linea alba. However, only a minority of epigastric hernias is accompanied by blood vessels, and it is more likely that the defect occurs as a result of a weakened linea alba due to abnormal decussation of the fibres of the aponeurosis. More than one hernia may be present and the commonest cause of ‘recurrence’ is failure to identify a second defect at the time of original repair.

A swelling the size of a pea consists of a protrusion of extraperitoneal fat only (fatty hernia of the linea alba). If the protrusion enlarges, it drags a pouch of peritoneum after it and so becomes a true epigastric hernia. The mouth of the hernia is rarely large enough to permit a portion of hollow viscus to enter it; consequently, either the sac is empty or it contains a small portion of greater omentum.

It is probable that an epigastric hernia is the direct result of a sudden strain tearing the interfacing fibres of the linea alba. The patients are often manual workers between 30 and 45 years of age.

Clinical features

• Symptomless — a small fatty hernia of the linea alba can be felt better than it can be seen and may be symptomless, being discovered only in the course of routine abdominal palpation.

• Painful — sometimes such a hernia gives rise to attacks of local pain, worse on physical exertion, and tenderness to touch and light clothing.
This may be because the fatty contents become nipped sufficiently to produce partial strangulation.

- **Referred pain** — it is not uncommon to find that the patient, who may not have noticed the hernia, complains of pain suggestive of a peptic ulcer. However, as the majority of these hernias is asymptomatic, symptoms should not be ascribed to the hernia until any gastrointestinal pathology has been excluded.

**Treatment**

If the hernia is giving rise to symptoms, operation should be undertaken. Operation. An adequate vertical or transverse incision us made over the swelling, exposing the linea alba. The protruding extraperitoneal fat is cleared from the hernial orifice by gauze dissection. If the pedicle passing through the linea alba is slender, it is separated on all sides of the opening by blunt dissection. After ligating the pedicle, the small opening in the linea alba is closed by nonabsorbable sutures in adults and with absorbable sutures in children. When a hernial sac is present, it is opened and any contents are reduced, after which the sac neck is transfixed and the sac excised before repairing the linea alba. If smaller protrusions of fat are found above or below the hernia, these should also be dealt with. If the hernia is large (defect greater than 4 cm in diameter), the repair should be reinforced with polypropylene mesh positioned in the retromuscular plane.

**Rare external hernias**

**Interparietal** hernia (syn. interstitial hernia). An interparietal hernia has a hernial sac which passes between the layers of the anterior abdominal wall. The sac may be associated with, or communicate with, the sac of a concomitant inguinal or femoral hernia. Lack of knowledge of this condition is the cause of misdiagnosis and mismanagement.

Other varieties.

- **Preperitoneal** (20 per cent) — usually the sac takes the form of a diverticulum from a femoral or inguinal hernia.
- **Intermuscular** (60 per cent) — the sac passes between the muscular layers of the anterior abdominal wall, usually between the external oblique and internal oblique muscles. The sac is nearly always bilocular and is associated with an inguinal hernia.
- **Inguinosuperficial** (20 per cent) — the sac expands beneath the superficial fascia of the abdominal wall or the thigh. This type is commonly associated with an incompletely descended testis.

**Clinical features.** The patients (mostly male) present with intestinal obstruction, due to obstruction or strangulation of the hernia. In the preperitoneal variety, as no swelling is likely to be apparent, delays in diagnosis occur and consequently the mortality in this variety is high.

**Treatment.** Operation is imperative because of intestinal obstruction.

Spigelian hernia. This is a variety of interparietal hernia occurring at the level of the arcuate line. It is very rare with only 1000 cases reported in the literature. The fundus of the sac, clothed by extraperitoneal fat, may lie beneath the internal oblique muscle where it is virtually impalpable. More often it advances through that muscle and spreads out like a mushroom between the internal and external oblique muscles, and gives rise to a more evident swelling. The patient is often corpulent and usually over 50 years of age, men and women being equally affected. Typically, a soft, reducible mass will be encountered lateral to the rectus muscle and below the umbilicus. Diagnosis is confirmed by computed tomography (CT) or ultrasound scanning, the latter having the advantage of being able to stand the patient upright if no defect is visible in the reclining position. Owing to the rigid fascia surrounding the neck, strangulation may occur.

**Treatment.** Operation. If a defect is palpable, a muscle-splitting approach is used. After isolating the sac, dealing with any contents, and ligating and excising it, the transversus, internal oblique and external oblique muscles are repaired by direct apposition. If no sac is palpable, a paramedian approach is used and the sac sought in the extraperitoneal space. The repair then proceeds as described above.

Lumbar hernia. Most primary lumbar hernias occur through the inferior lumbar triangle of Petit (Fig. 62.19), bounded below by the crest of the ilium, laterally by the external oblique and medially by the latisimus dorsi. Less commonly, the sac comes through the superior lumbar triangle which is bounded by the twelfth rib above, medially by the sacrospinalis and laterally by the posterior border of the internal oblique. Primary lumbar hernias are very rare with only 300 cases reported. More commonly lumbar hernias are secondary to renal operations, when extensive incisional sacs may be present.

Differential diagnosis. A lumbar hernia must be distinguished from

- lipoma;
- a cold abscess pointing to this position;
- phantom hernia due to local muscular paralysis. Lumbar phantom hernia can result from any interference with the nerve supply of the affected muscles (e.g. poliomyelitis).

**Treatment.** A primary lumbar hernia, being small, is easily repaired. As the natural history is for these hernias to increase in size with time, any primary lumbar hernia should be repaired at presentation. Incisional lumbar hernias may be large and the defect is impossible to repair unless fascial flaps are used. The repair can be reinforced with a sheet of polypropylene mesh.

Perineal hernia. This type of hernia is very rare. Varieties include:

- **postoperative hernia through a perineal scar** may occur after excision of the rectum;
- **median sliding perineal hernia** is a complete prolapse of the rectum (Chapter 60);
- **anterolateral perineal hernia** occurs in women and presents as a swelling of the labum majus;
- **posterolateral perineal hernia**, which passes through the levator ani to enter the ischiorectal fossa.

**Treatment.** A combined operation is generally the most satisfactory for the last two types of hernia. The hernia is exposed by an incision directly over it. The sac is opened and its contents are reduced. The sac is cleared from surrounding structures and the wound closed. With the patients in semi-Trendelenburg position, the abdomen is opened and the mouth of the sac is exposed. The sac is inverted, ligated and excised.
and the pelvic floor repaired by muscle apposition and, if indicated, buttressing of the repair with prosthetic mesh.

Obturator hernia. The hernia, which passes through the obturator canal, occurs six times more frequently in women than in men. Most of the patients are over 60 years of age. The swelling is liable to be overlooked because it is covered by the pectineus. It seldom causes a definite swelling in Scarpa’s triangle, but if the limb is flexed, abducted and rotated outwards, sometimes the hernia becomes more apparent. The leg is usually kept in a semiflexed position and movement increases the pain. In more than 50 per cent of cases of strangulated obturator hernia, pain is referred along the obturator nerve by its geniculate branch to the knee. On vaginal or rectal examination the hernia sometimes can be felt as a tender swelling in the region of the obturator foramen.

Cases of obturator hernia which present themselves have usually undergone strangulation, which is frequently of the Richter type.

**Treatment.** Treatment consists of the following:

- perform lower laparotomy (on the side of the lesion, if known). Confirm the diagnosis and then adopt full Trendelenburg’s position;
- the constricting agent is the obturator fascia. Taking every precaution to avoid spilling infected fluid from the hernial sac into the peritoneal cavity, this fascia can be stretched to allow reduction by inserting suitable forceps through the gap in the fascia and opening the blades with care. If incision of the fascia is required, it should be made parallel to the obturator vessels and nerve;
- the contents of the sac are dealt with;
- the broad ligament is stitched over the opening to prevent recurrence.

Gluteal and sciatic hernias. A gluteal hernia passes through the greater sciatic foramen, either above or below the piriformis. A sciatic hernia passes through the lesser sciatic foramen. Differential diagnosis must be made between these conditions and:

- a lipoma or fibrosarcoma beneath the gluteus maximus;
- a tuberculous abscess;
- a gluteal aneurysm.

All doubtful swellings in this situation should be explored by operation.
Umbilicus

Diseases of the umbilicus

- **Inflammation**
  - Infection of the stump of the umbilical cord (omphalitis)
  - Umbilical granuloma
  - Umbilical dermatitis
  - Pilonidal sinus
- **Fistula**
  - Faecal
  - Patent vitellointestinal duct
  - Neoplastic ulceration from the transverse colon
  - Tuberculous peritonitis
- **Urine**
  - Patent urachus
  - Biliary
  - Neoplasms
    - Benign
      - Adenoma (raspberry tumour)
      - Endometrioma
    - Malignant
      - Primary
      - Secondary
        - Stomach
        - Colon, including the rectum
        - Ovary and uterus
        - Breast
- **Hernia**
- **Eversion** (in ascites)

**Inflammation of the umbilicus**

**Infection of the umbilical cord**

By the third or fourth day post delivery the stump of the umbilical cord is found to be carrying staphylococci in over 50 per cent of babies born in maternity hospitals. Less commonly, the stump of the cord harbours streptococci, and epidemics of puerperal sepsis in maternity hospitals have been traced to the umbilical cord of one infant in the nursery thus infected. *Escherichia coli* and *Clostridium tetani* (causing neonatal tetanus) are other possible invaders. The chief prophylaxis is strict asepsis during severance of the cord and the use of 0.1 per cent chlorhexidine, locally, for a few days.

Omphalitis. The incidence of an infected umbilicus is much higher in communities that do not practise aseptic severance of the umbilical cord. When the stump of the umbilical cord becomes inflamed, antibiotic therapy usually localises the inflammation. By employing warm moist dressings, the crusts separate, giving exit to pus. Exuberant granulation tissue requires a touch of silver nitrate. In more serious cases infection is liable to spread along the defunct hypogastric arteries or umbilical vein when, in all probability, one or other of the following complications will supervene.

- **Abscess of the abdominal wall.** If gentle pressure is exerted above or below the navel, and a bead of pus exudes at the navel, a deep abscess associated with one of the defunct umbilical vessels is present. This must be opened. A probe is passed into the sinus to determine its direction and this is followed by a grooved director on to which the skin and overlying tissues are incised in the midline.

- **Extensive ulceration of the abdominal wall.** Extensive ulceration of the abdominal wall due to synergistic infection is treated in the same way as postoperative subcutaneous gangrene (*vide infra*).

- **Septicaemia.** Septicaemia can occur from organisms entering the bloodstream via the umbilical vein. Jaundice is often the first sign. An abscess in the abdominal wall above the umbilicus should be sought. In other respects the treatment of this grave complication follows the usual lines (Chapter 4).

- **Jaundice in the newborn.** Infection reaching the liver via the umbilical vein may cause a stenosing intrahepatic cholangiolitis, appearing some 3—6 weeks after birth.

- **Portal vein thrombosis.** Portal vein thrombosis and subsequent portal hypertension.

- **Peritonitis.** Peritonitis carries a bad prognosis.

- **Umbilical hernia.**

Umbilical granuloma. Chronic infection of the umbilical cicatrix which continues for weeks causes granulation tissue to pout at the umbilicus. There is no certain means of distinguishing this condition from an adenoma. Usually an umbilical granuloma can be treated by one application of silver nitrate followed by dry dressings, but an adenoma soon recurs in spite of these measures.

Dermatitis of and around the umbilicus. This is common at all times of life. Fungal and parasitic infections are more difficult to eradicate from the umbilicus than from the skin of the abdomen. Sometimes the dermatitis is consequent upon a discharge from the umbilicus, as is the case when an umbilical fistula or a sinus is present. In overweight women intertrigo occurs.

A deep, tender swelling in the midline below the umbilicus signifies an abscess present in the extraperitoneal fat and is usually due to an infected urachal remnant. Exploration and proper drainage are necessary.

Pilonidal sinus. Pilonidal sinus (a sinus containing a sheath of hairs) is sometimes encountered. It should be excised.

Umbilical calculus (umbolitli). This is often black in colour, and is composed of desquamated epithelium which becomes inspissated and collects in the deep recess of the umbilicus. The treatment is to dilate the orifice and extract the calculus but, to prevent recurrence, it may be necessary to excise the umbilicus.

Umbilical fistulae

The umbilicus being a central abdominal scar, its understandable that a slow leak from any viscus is liable to track to the surface at this point.
Added to this, very occasionally, the vitellointestinal duct or the urachus remains patent; consequently it has been aptly remarked that the umbilicus is a creek into which many fistulous streams may open.

For instance, an enlarged inflamed gallbladder perforating at its fundus may discharge gallstones through the umbilicus. Again, an unremitting flow of pus from a fistula at the umbilicus of a middle-aged women led to the discovery of a length of gauze overlooked during a hysterectomy 5 years previously.

The vitellointestinal duct. The vitellointestinal duct occasionally persists and gives rise to one of the following conditions.

- It remains patent (Fig. 62.20a). The resulting umbilical fistula discharges mucus and, rarely, faeces. Often a small portion only of the duct near the umbilicus remains obliterated. This gives rise to a sinus that discharges mucus. The epithelial lining of the sinus often becomes everted to form an adenoma.

- Sometimes both the umbilical and the intestinal ends of the duct close, but the mucous membrane of the intervening portion remains and an intra-abdominal cyst develops (Fig. 62.20b).

- With its lumen obliterated or unobliterated, the vitellointestinal duct provides an intraperitoneal band (Fig. 62.20c) which is a potential danger, for intestinal obstruction is liable to occur. The obstruction results from a coil of small intestine passing under or over or becoming twisted around the band.

- Such a band may contract and pull a Meckel’s diverticulum into a congenital umbilical hernia (Fig. 62.20d).

- A vitellointestinal cord connected to a Meckel’s diverticulum, but not attached to the umbilicus, becomes adherent to, or knotted around, another loop of small intestine and so causes intestinal obstruction.

- Sometimes a band extending from the umbilicus is attached to the mesentery near its junction with a distal part of the ileum. In this case the band is probably an obliterated vitelline artery and is not necessarily associated with a Meckel’s diverticulum.

**Treatment.** A patent vitellointestinal duct should be excised together with a Meckel’s diverticulum, if one is present, preferably when the child is about 6 months old. When a vitellointestinal band gives rise to acute intestinal obstruction, after removing the obstruction by dividing the band, it is expedient, where possible, to excise the band and bury the cut ends.

Patent urachus. A patent urachus seldom reveals itself until maturity or even old age. This is because the contractions of the bladder commence at the apex of the organ and pass towards the base. A patent urachus, because it opens into the apex of the bladder, is closed temporarily during micturition and so the potential urinary stream to the bladder is cut off. Therefore the fistula remains unobtrusive until a time when the organ is overfull, usually due to some form of obstruction.

**Treatment.** Treatment is directed to removing the obstruction to the lower urinary tract. If, after this has been remedied, the leak continues or a cyst develops in connection with the urachus, umblectomy and excision of the urachus down to its insertion into the apex of the bladder, with closure of the latter, is indicated.

Neoplasms of the umbilicus

**Umbilical adenoma or raspberry tumour** is commonly seen in infants (Fig. 62.21), but only occasionally later in life. It is due to a partially (occasionally a completely) unobliterated vitellointestinal duct. Mucosa prolapsing through the umbilicus gives rise to a raspberry-like tumour, which is moist and tends to bleed.

**Treatment.** If the tumour is pedunculated, a ligature is tied around it and, in a few days, the polypus drops off. Should the tumour reappear after this procedure, umblectomy is indicated. Sometimes a patent vitellointestinal duct, or more often a vitellointestinal band, will be found associated with a Meckel’s diverticulum. The Meckel’s diverticulum and the attached cord or duct should be excised at the same time as the umbilicus. Histologically, the tumour at the umbilicus consists of columnar epithelium rich in goblet cells.

Endometrioma. Endometrioma occurs in women between the ages of 20 and 45 years. On histological examination it is found to consist of endometrial glands occupying the same plane in the dermis as the sudoriferous glands and opening on to the surface in the same way. The umbilicus becomes painful and bleeds at each menstruation, when the small fleshy tumour between the folds of the umbilicus becomes more apparent. Occasionally an umbilical endometrioma is accompanied by endometriomas in the uterus or ovary. When, as is usually the case, the tumour is solitary, umblectomy will cure the condition.

**Secondary carcinoma.** Secondary carcinoma at the umbilicus (or Sister Joseph’s nodule) (Fig. 62.22) is not very uncommon, but it is always a late manifestation of the disease. The primary neoplasm is often situated in the stomach, colon or ovary, but a metastasis from the breast, probably transmitted along the lymphatics of the round ligament of the liver, is sometimes located here.
The abdominal wall

Burst abdomen (syn. abdominal dehiscence) and incisional hernia (syn. ventral hernia)

In 1—2 per cent of cases, mostly between the 6th and 8th day after operation, an abdominal wound bursts open and viscera are extruded. The disruption of the wound tends to occur a few days beforehand when the sutures apposing the deep layers (peritoneum, posterior rectus sheath) tear through or even become untied. An incisional hernia usually starts as a symptomless partial disruption of the deeper layers during the immediate or early postoperative period, the event passing unnoticed if the skin wound remains intact after the skin sutures have been removed.

Factors relating to the incidence of burst abdomen and incisional hernia.

Technique of wound closure.

- **Choice of suture material** — catgut leads to a higher incidence of bursts than the use of nonabsorbable monofilament polypropylene, polyamide or wire, and should never be used;
- **method of closure** — interrupted suturing has a low incidence. Through and through suturing is good for the obstructed case. A one-layer closure has a low incidence, but it is higher than that following a two-layered closure. Interrupted ‘far and near’ sutures are a recommended technique for single-layer mass closures. When continuous suturing of layers (one or two) is performed a particular fault is the use of a short length of material, pulled tightly, for in an anaesthetised relaxed patient the incision is shortened thereby, and made taut so that the material will act as if it were a cheese wire cutter when the patient is conscious and coughing. The golden rule is to insert a length of suture at least four times the length of the incision but less than five times the length of the incision. This ensures that the layers are gently apposed;
- **drainage** directly through a wound leads to a higher incidence of ‘bursts’ than employing drainage through a separate (stab) incision.

Factors relating to incisions. Midline and vertical incisions have a tendency to burst which is higher than those which are transverse. Since the widespread use of nonabsorbable suture materials even midline vertical incisions have a very low incidence of disruption.

Reasons for operation. Infected case; deep wound infection has a notorious reputation for causing burst abdomen and/or late incisional hernias. Operations on the pancreas, with leakage of enzymes, and on obstructed cases are other reasons for disruption.

Coughing; vomiting; distension. At the completion of an operation any violent coughing set off by the removal of an endotracheal tube and suction of the laryngopharynx strains the sutures; likewise cough, vomiting and distension (e.g. due to ileus) in the early postoperative period. Over-vigorous postoperative ventilation in sedated patients can lead to wound disruption.

General condition of the patient. Obesity, jaundice, malignant disease, hypoproteinaemia and anaemia are all factors conducive to disruption of a laparotomy wound (Chapter 1); abdominal wounds in pregnancy are notorious for a high risk of disruption; steroids delay wound healing.

Burst abdomen (syn. abdominal dehiscence)

Clinical features

A serosanguinous (pink) discharge from the wound is a forerunner of disruption in fully 50 per cent of cases. It is the most pathognomonic sign of impending wound disruption and its signifies that intraperitoneal contents are lying extraperitoneally. Patients often volunteer the information that they ‘felt something give way’. If skin sutures have been removed, omentum or coils of intestine may be forced through the wound and will be found lying on the skin. Pain and shock are often absent. It is important to note that there may be symptoms and signs of intestinal obstruction.

Treatment

An emergency operation is required to replace the bowel, relieve any obstruction and to resuture the wound. While awaiting operation, reassure the patient and cover the wound with a sterile towel. The stomach should be emptied using a nasogastric tube and intravenous fluid therapy commenced.

operation. Each protruding coil of intestine is washed gently with saline solution and returned to the abdominal cavity. Then protruding greater omentum is treated similarly and spread over the intestine. The abdominal wall having been cleaned, all layers are approximated by through and through sutures of monofilament nylon, each passed through a soft rubber or plastic tuber collar. The abdominal wall may be supported by strips of adhesive plaster encircling the anterior two-thirds of the circumference of the trunk. Antibiotic therapy should be started.

Contrary to what might be thought, peritonitis rarely supervenes and, although the skin wound may become infected, healing is satisfactory. A second dehiscence rarely occurs. There is biochemical evidence that healing after disruption produces a stronger wound. This is due to the improvement in collagen metabolism under these circumstances. An incisional hernia is often a later sequel (see below).

Incisional hernia (syn. ventral hernia; postoperative hernia)

Aetiology

Incisional hernia occurs most often in obese individuals, and a persistent postoperative cough and postoperative abdominal distension are its precursors. There is a high incidence of incisional hernia following operations for peritonitis because, as a rule, the wound becomes infected. The placing of a drainage tube through a separate stab incision, as opposed to bringing such a tube through the laparotomy wound, reduces the frequency (see also the section ‘General features common to all hernias’).

An incisional hernia usually starts as a symptomless partial disruption of the deeper layers of a laparotomy wound during the immediate or very early postoperative period. Often the event passes unnoticed if the skin wound remains intact after the stitches have been removed (or because subcuticular stitches have been used which remain in place). A serosanguinous discharge is often the signal of dehiscence, and resuture of the deeper layers of the incision obviates the more difficult repair of an established and much larger hernia later on.

Clinical features

There are great variations in the degree of herniation. The hernia may occur through a small portion of the scar, often the lower end. More
frequently, there is a diffuse bulging of the whole length of the incision. A postoperative hemia, especially one through a lower abdominal scar, usually increases steadily in size and more and more of its contents become irreducible. Sometimes the skin overlying it is so thin and atrophic that normal peristalsis can be seen in the underlying intestine. Attacks of partial intestinal obstruction are common and strangulation is liable to occur at the neck of a small sac or in a locusus of a large one. Nevertheless, most cases of incisional hernia are asymptomatic and broad-necked, and do not need treatment.

**Treatment**

Palliative. An abdominal belt is sometimes satisfactory, especially in cases of a hernia through an upper abdominal incision.

Operation. Many procedures have been advocated, which is testimony to the fact that the repairs may be difficult to accomplish, but it is now clear that one technique is superior to all of the others.

**Preoperative measures**

In order to obtain a lasting repair, very special preparation is required. If the patient is obese, weight reduction by dieting should precede the operation. To attempt to return the contents of a very large hemia to the main abdominal cavity if they have not been there for several years is to court danger, particularly if weight reduction has not been effected. In these circumstances, not only is there a risk of failure of the hemioplasty, but there is a greatly increased risk of paralytic ileus from visceral compression and of pulmonary complications from elevation of the diaphragm. The repair of these large hernias is highly specialised surgery and should only be performed in centres with considerable experience in dealing with them. For example, one technique employed to enlarge the abdominal cavity is that of prolonged pneumo-peritoneum in which the intra-abdominal pressure is raised to 15—18 cmH₂O for up to several weeks preoperatively. The technique requires careful monitoring and patient counselling to be effective but, if employed correctly, can enable a primary repair to be successful.

Operation. Three techniques have been described: simple and complex apposition and plastic fibre mesh or net closures.

**Simple apposition.** The hernial sac is dissected. It is then formally, if not already inadvertently, opened and the contents are reduced. Adherent omentum and bowel have to be freed by dissection before the mouth of the sac can be defined. The layers are repaired usually with nonabsorbable sutures: first the peritoneum, then the fascial (aponeurotic) layers. The lateral edges of the fascia are freed from the overlying muscles for some distance and this fascial layer is approximated with interrupted sutures at the upper and lower ends of the wound. The muscles and the remaining fascial layer are approximated. Tension-relaxing incisions may be required and should be placed well laterally.

**Complex apposition.** These consist of various types of layered closures (Mayo, ‘Keef’, da Silva) and should be considered obsolete and of historical interest only.

**Plastic fibre mesh or net closures.** These techniques are now the method of choice for all but the smallest defects (< 4 cm). The sac is dealt with as above. The layers of the fascia are dissected out and, if above the umbilicus, the posterior rectus sheath edges apposed. A sheet of polypropylene mesh is then inserted between the posterior rectus sheath and the muscle fibres, and anchored in place. If below the umbilicus, the mesh is placed in the preperitoneal space. The anterior rectus sheath is then apposed as above. If the defect is too large to close by apposition of the rectus sheath, the defect in the abdominal wall can be bridged by sewing the mesh to the fascia on either side of the defect, ensuring at least a 4-cm overlap of the fascial edges.

Careful haemostasis and meticulous asepsis are essential during these operations. Postoperative collections of serum can be removed by drainage, using plastic tubing led, via skin punctures lateral to the wound, into closed suction drainage bottles (e.g. Redivac).

Postoperative treatment. Gastric decompression and intravenous fluids are employed, and nothing by mouth allowed until the bowels have functioned. Early ambulation and gentle physical exercise are to be encouraged. The patient should not resume strenuous exercise for several weeks.

Results of treatment. Most series report recurrence of the hernia in between 30 and 50 per cent of cases except where mesh inlay techniques have been employed in specialist centres, where recurrence rates may be as low as 10 per cent.

**Divarication of the recti abdominis**

Divarication of the recti abdominis is seen principally in elderly multiparous patients. When the patient strains, a gap can be seen between the recti abdominis through which the abdominal contents bulge. When the abdomen is relaxed, the fingers can be introduced between the recti.

Treatment. An abdominal belt is all that is required. There is no risk of strangulated intestinal contents. A similar condition is seen in babies, only the divarication exists above the umbilicus. No treatment is necessary; as the child grows a spontaneous cure results.

**Tearing of the inferior epigastric artery**

*Tearing of the inferior epigastric artery* occurs in three dissimilar types of individual, namely elderly women, often thin and feeble; athletic, muscular men, usually below middle age; and pregnant women, mainly multiparas late in pregnancy. The site of the haematoma is usually at the level of the arcuate line, where the posterior rectus sheath is lacking.

Clinical features. The possibility of tearing of the epigastric vessels should always be considered when, following a bout of coughing or a sudden blow to the abdominal wall, an exquisitely tender lump appears in relation to the rectus abdominis. Occasionally, a haematoma occurs within the muscles lateral to the rectus sheath. Unless there is bruising of the overlying skin, the diagnosis may be difficult.

**Differential diagnosis.** The conditions for which the haematoma is frequently mistaken are, in the female, a twisted ovarian cyst, and in both sexes, when the lump is on the right side, an appendix abscess. The sign most likely to be of value in differentiating a haematoma of the abdominal wall from these conditions, namely tending the abdominal musculature, is often unsatisfactory because of the pain it causes. Again, the differential diagnosis between the haematoma and a strangulated Spigelian hernia may be difficult. The absence of vomiting suggests a haematoma and the presence of resonance over the swelling favours a Spigelian hernia, while a plain radiograph of the abdomen sometimes gives positive evidence of the latter.

**As a complication of pregnancy.** Rupture of the inferior epigastric artery occurs occasionally during pregnancy. Surprisingly to relate, the haemorrhage into this closed space from this comparatively small artery has proved fatal.

Treatment. With rest, a comparatively small haematoma may resolve, but sometimes renewed haemorrhage causes the haematoma to
rupture into the peritoneal cavity. Therefore it is safer to operate early, evacuate the clot and ligate the artery.

Infections

**Cellulitis** can occur in any of the planes of the abdominal wall.

- **Superficial cellulitis** is usually discovered when an abdominal wound is inspected following pyrexia. The earliest sign is when the stitches become embedded in the oedematous skin.

  Later there is a bluish extending for a variable distance from the incision or the stitch holes. On palpation with the gloved hand usually one area is found to be more indurated and tender than the remainder. A stitch should be removed from the immediate vicinity, and if pus or serous escapes it should be sent for bacteriological examination; treatment should then be commenced with a broad-spectrum antibiotic.

- **Deep cellulitis** is characterised by brawny oedema towards one or both flanks, and not infrequently of the scrotum or vulva as well. Antibiotic therapy is the mainstay of treatment. When tenderness persists, an anatomical incision dividing the muscles carefully, layer by layer, until pus or purulent fluid is encountered is often advisable.

Progressive postoperative bacterial synergistic gangrene. This is, fortunately, a rare complication after laparotomy, usually for a perforated viscus (notably perforated appendicitis). It has also occurred after gallbladder operations, colectomy for ulcerative colitis and even after drainage of an empyema thoracis. The condition is due to the synergistic action of microaerophilic nonhaemolytic streptococci and, usually, a staphylococcus. The skin in the immediate vicinity of the wound exhibits signs of cellulitis. Within a few hours, a central purplish zone with an outer brilliant red zone can be distinguished and the whole region is extremely tender. The condition advances with various degrees of rapidity (Fig. 62.23). The gangrenous skin liquefies exposing underlying granulation tissue. If the condition persists, overwhelming septicaemia and associated multiorgan failure supervene.

**Treatment.** Identification of the organisms and a report on their sensitivity to antibiotics is essential. Metronidazole should be given together with a powerful broad-spectrum antibiotic. Without vigorous and effective treatment the gangrene spreads to the flanks and the patient may die of toxæmia. If the infection has become established, surgical debridement of all the necrotic and infected tissue should be performed. Hyperbaric oxygen, if available, can be life-saving. Cellulitis due to bacteroides may give no bacterial growth by conventional techniques and may be missed.

**Amoebic cellulitis.** The possibility of this potentially lethal complication of amoebic colitis, liver abscess or empyema being present should always be considered (see Chapter 52). Confirmation may be difficult and an immunofluorescence test necessary.

Subcutaneous gas-forming infection. This is described in Chapter 7 (under ‘Gas gangrene’).

Neoplasms of the abdominal wall

A desmoid tumour is a tumour arising in the musculoaponeurotic structures of the abdominal wall, especially below the level of the umbilicus. It is a completely encapsulated fibroma and is so hard that it creaks when it is cut. Some cases recur repeatedly in spite of apparently adequate excision.

**Aetiology.** Eighty per cent of cases occur in women, many of whom have borne children, and the neoplasm occurs occasionally in scars of old hernial or other abdominal operation wounds. Consequently, trauma, for example the stretching of the muscle fibres during pregnancy or possibly a small haematoma of the abdominal wall, appears to be an aetiological factor. They can occur in cases of familial polyposis coli (Gardner’s syndrome).

**Pathology.** The tumour is composed of fibrous tissue containing multinucleated plasmodial masses resembling foreign-body giant cells. Usually of very slow growth, it tends to infiltrate muscle in the immediate neighbourhood. Eventually it undergoes a myxomatous change; it then increases in size more rapidly. Metastasis does not occur. Unlike fibroma elsewhere, no sarcomatous change occurs.

**Treatment.** Unless the tumour is excised widely, with a surrounding margin of at least 2.5 cm of healthy tissue, recurrence commonly takes place. After removal of a large tumour, repair of the defect in the abdominal wall by nylon mesh is required. These tumours are moderately radiosensitive. (Intrapertoneal desmoids ate best left alone when possible.)

**Fibrosarcoma** of the abdominal wall is rare. It is resistant to radiotherapy and only in some cases can a wide excision, with nylon mesh repair, offer hope of a cure.

**Adenocarcinoma of the colon** or of other viscera may invade the abdominal wall. In such cases, the resection of this extension, along with the primary growth, may require special repair of the resulting defect.

Secondary implantation in the wound may follow any abdominal operation for carcinoma, and bladder cancer is notorious for this propensity.

Urinary symptoms

Haematuria

The presence of blood in the urine (haematuria) is always abnormal and may be the only indication of pathology in the urinary tract (Fig. 63.1). Tiny amounts of blood that are insufficient to stain the urine (microscopic haematuria) may be detected by dipstick testing as part of a routine health check. A substantial haemorrhage into the urinary tract will give the urine a red or brownish tinge (macroscopic haematuria) and the patient may pass blood clots. False positive stick tests and the discoloured urine caused by beetroot and certain drugs (e.g. dindevan, pynidium and furadantin) can be distinguished from haematuria by the absence of red blood cells on urinary microscopy.

Haematuria may be intermittent or persistent. Blood appearing at the beginning of the urinary stream indicates a lower urinary tract cause, while uniform staining throughout the stream points to a cause higher up. Terminal haematuria is typical of severe bladder irritation by stone or by infection. If the patient experiences pain with haematuria, the characteristics of the pain may help to identify the source of the bleeding. Commonly, there is no pain.

None of these variations in the presentation of haematuria is sufficient in itself to diagnose the cause of bleeding, and all patients with haematuria need investigation even if they are taking anticoagulant drugs. In a significant proportion, all tests will be negative: the chance of finding a urological cause in patients under 40 years of age who are found to have microscopic haematuria is particularly small. However, bleeding into the urinary tract may be caused by an occult nephropathy so it is important to check for hypertension in these patients.

Pain

Renal pain

Inflammation and acute obstruction to the flow of urine from the renal pelvis are liable to cause pain that is typically felt as a deep-seated, sickening ache in the loin. It is probably the result of stretching the capsule of the kidney. However, calculi in the kidney can also be painful in the absence of infection, although they may be too small or peripherally placed to cause obstruction. Slow-growing masses such as tumours or cysts are not usually painful unless they are very large. When the cause is inflammatory, there may be local deep tenderness and occasionally spasm of the psoas muscle.

Ureteric colic

This is an acute pain felt in the loin and radiating to the ipsilateral iliac fossa and genitalia. The patient often rolls around in agony as waves of excruciating sharp pain are imposed upon a continuing background of discomfort. Contrast this with the patient suffering from peritoneal pain who lies still to avoid exacerbating the pain by movement.

Ureteric colic is caused by the passage of a foreign body, usually a stone. The site of the pain can be a guide to the progress of the stone: the more the pain radiates into the groin, the more distal the stone. Local tenderness is much less than would be expected from the severity of the pain.

Bladder pain

Bladder pain is felt as a suprapubic discomfort made worse by bladder filling. In men, a sharp pain misleadingly referred to the tip of the penis may be the result of irritation of the trigone of the bladder. Severe inflammation of the bladder can cause an extreme wrenching discomfort at the end of micturition. This symptom of bladder stone was recognised by the old lithotomists who called it strangury.

Prostatic and seminal vesicle pain

This is felt as a penetrating ache in the perineum and rectum. There may be associated discomfort in the groin. The patient is characteristically exasperated and depressed by pain that has a particularly relentless nature. Pelvic pain is often blamed on ‘chronic prostatitis’ but it occurs in both men and women and is notoriously difficult to treat successfully.

Urethral pain

Urethral pain is a scalding or burning felt in the vulva or penis especially during voiding.

Altered bladder function

The normal bladder has two distinct phases of function. During the filling phase the bladder acts as a reservoir to collect urine until it is emptied in the voiding phase. Inappropriate contraction of the bladder detrusor muscle during filling (instability) is perceived as a sensation of urgency to pass urine. The patient may have frequency of micturition and a tendency to urge incontinence. Sleep may be disturbed by nocturia. Instability may be idiopathic in both sexes or part of the bladder response to outflow obstruction, notably in men with enlargement of the prostate. When detrusor instability has a demonstrable neurological cause, it’s known as hyperreflexia.

Symptoms of impaired emptying are most commonly the result of bladder outflow obstruction, but detrusor failure or atony presents a similar picture. The patient has difficulty initiating voiding (hesitancy) and the stream is variable or slow. Abdominal straining improves the weak flow. When the act of micturition is completed there may be a feeling that urine remains in the bladder so the patient tries again (pis-en-deux). With time, the bladder becomes chronically overfilled and is unable to act as an effective reservoir. Urine spills out, typically at night when sleep halts constant trips to the lavatory (chronic retention with overflow).
Investigation of the urinary tract

With the exception of renal and scrotal masses or tenderness, a palpable bladder or an abnormal prostate on digital rectal examination, urological conditions are most likely to be diagnosed from the history or by investigations.

Urine

Dipsticks impregnated with chemicals which change colour in the presence of blood, protein or nitrates (Multistix; Labstix) are a convenient way to screen urine for the presence of abnormalities. When the urine is macroscopically clear and negative on dipstick testing the chances of finding an abnormality on microscopy and culture of a midstream clean-catch specimen are small. Indeed, some bacteriological laboratories decline further examination of the urine in these circumstances on the grounds that its cost-effective. The presence of protein and nitrates (which are a product of the activity of organisms in the urine) indicates the likelihood of infection. The significance of microscopic haematuria is discussed above. Some dipsticks also give an indication of the pH and specific gravity of the urine.

Microscopy is essential to confirm the presence of white and red blood cells in the urine, and bacteria may also be visible under light microscopy. The presence of protein casts suggests disease affecting the renal parenchyma, as does red cell dysmorphia seen on phase contrast microscopy. Schistosoma ova have a typical appearance (Fig. 63.2), and vegetable or meat fibres may be present if there is a fistula connecting the bowel with the urinary tract.

Cytological examination of the urinary sediment is sensitive and specific for poorly differentiated transitional cell tumours anywhere in the urinary tract. However, false negatives are common in the 50 per cent of these cancers that are well differentiated. A new chemical rest (BTA-Bard©) detects a bladder tumour antigen in the urine, and its findings can complement cytological examination of the urine.

Bacteriological culture of a clean catch midstream specimen of the urine is the standard means of identifying urinary pathogens. The presence of organisms at a level of 10^5/ml is deemed to indicate the presence of infection rather than contamination of the urine by bacteria. If there are puscells in the urine but there is no growth on the routine culture media (sterile pyuria) its worth testing for more fastidious organisms. The centrifuged sediment of multiple early morning urine specimens must be cultured on Lowenstein—Jensen medium to detect urinary tract tuberculosis. Chlamydia is another common urinary pathogen that will not be detected on routine culture.

Biochemical examination for electrolytes, glucose, bilirubin, haemoglobin and myoglobin is essential to detect abnormal amounts of these substances in urine. Analysis of a 24-hour specimen of urine will quantify the rate of loss, and is especially useful in the investigation of calculus disease due to abnormal excretion of calcium, oxalate, uric acid and other products of metabolism.

Tests of renal function

More than 70 per cent of the kidney function must be lost before renal failure becomes evident: there is a large functional reserve. It follows that renal damage must be extensive before changes occur in blood constituents whose level is controlled by renal excretion. Such damage is of three main types: reduction of renal plasma flow, destruction of glomeruli or impairment of tubular function. In severe hypertension or renal artery stenosis, the plasma flow is impaired. In glomerulonephritis or acute cortical necrosis, there is a loss of glomeruli, while in pyelonephritis tubular function is most severely affected. In obstructive nephropathy, back-pressure on the renal parenchyma causes all three types of damage.

Levels of blood urea and serum creatinine can be affected by various factors but in practice, when taken together, they serve as a useful clinical guide to overall renal function. A creatinine clearance will give an approximate value for glomerular filtration rate but is prone to error. A more accurate assessment of glomerular function can be obtained from an estimate of the clearance of chromium-51-labelled ethylenediaminetetraacetic acid. Surgeons will usually call on their nephrological colleagues for more detailed investigation of tubular function and renal blood flow

The specific gravity of the urine is fixed at a low level when the kidney loses the power to concentrate because of renal tubular dysfunction. Estimation of urinary loss of sodium, B2-microglobulin or the tubular enzyme N-acetyl-B-D-glucosamine (NAG) will further define the nature of functional impairment.

Radiology—contrast studies

A plain abdominal X-ray showing the kidneys, ureters and bladder (the KUB) can disclose a wealth of useful information. With the film properly orientated (with the liver on the right and gastric air-bubble on the left unless there is situs inversus!) a glance at the spine and bony structures may reveal the presence of scoliosis, spina bifida, degenerative disease of the spine, metastases, fractures and arthritis. All of these may have a relevance to the urological diagnosis. The soft-tissue shadows of the kidneys, outlined to a greater or lesser extent by their more radiolucent fatty coverings, overlie the upper attachments of the psosas muscles. A full bladder often presents a hazy outline arising from the pelvis.

Most urinary calculi absorb X-rays and should be sought in the region of the renal shadows and along the course of each ureter. This normally follows the tips of the transverse processes of the vertebrae, crosses the sacroiliac joints and heads for the ischial spine before hooking medially towards the bladder base. Stones with a low calcium content and those overlying bony structure may be difficult to see on the plain film. Pelvic phleboliths are very common and can look like lower ureteric calculi. Uric acid stones are the most common radiolucent calculi.

Intravenous urogram (urography; IVU) (Fig. 63.3)

Excretion renography has been a mainstay of urological investigation since the introduction of intravenous contrast media in the 1930s. These are organic chemicals to which iodine atoms are attached to absorb X-rays. When injected, usually into a vein in the antecubital fossa, the substance is filtered from the blood by the glomeruli and does not undergo tubular absorption. As a result, it rapidly passes through the renal parenchyma into the urine which it renders radio-opaque.

Although the IVU gives excellent images of the urinary tract, its use should be restricted because in a few patients the iodine in the contrast medium may provoke a potentially life-threatening anaphylactic reaction. Patients with a history of allergy, atopy and eczema are particularly vulnerable, but severe reactions may occur without warning. Less invasive and dangerous imaging techniques are clearly to be preferred where they give comparable diagnostic information.

Preparation

It is usual to give a laxative to clear faeces that might otherwise obscure details of urinary tract anatomy. Modest fluid restriction is permissible
but dehydration is dangerous because it may precipitate acute renal failure.

**Technique**

The patient is observed carefully while the first few drops of contrast medium (Urografin or Niopam 370) are injected. The earliest films, taken within minutes of the injection, show the renal parenchyma opacified by contrast medium — the nephrogram phase. A delayed nephrogram on one side indicates unilateral functional impairment. Distortion of the renal outline or failure of part of the kidney to function suggests a space occupying lesion.

After a few minutes, the contrast is excreted into the collecting system opacifying the calyces and the renal pelvis. Later films show the ureters and, at the end of the study, the patient is asked to pass urine and a final film is taken to show detail of the bladder area. It is important to bear in mind that the static images of the IVU provide only snapshots of dynamic events in the urinary tract. The appearance of a normal ureter changes as peristaltic waves of contraction pass along it.

An IVU is particularly valuable to demonstrate tumours and calculi within the urinary tract which are sometimes difficult to see on ultrasonography. It may also be useful to show details of abnormal anatomy which are difficult to interpret on an ultrasonogram.

As ultrasonography and other forms of scanning have become more sophisticated, the indications for the urogram are fewer. Obstruction to the upper urinary tract interferes with transport of contrast medium into the urine which will show up as a non-functioning kidney on the standard urogram films. In these circumstances, a further radiograph taken many hours after injection of the contrast medium may show hazy opacification of a dilated system. Distortion of the calyces or the renal outline can equally be caused by a tumour or by harmless simple cysts. In each of these cases, more information can be obtained from ultrasonography or computerised tomography (CT).

**Retrograde ureteropyelography (syn. retrograde ureterogram)**

A fine ureteric catheter can be passed into the ureteric orifice through a cystoscope (Fig. 63.4). Contrast medium injected through the catheter will demonstrate the anatomy of the upper urinary tract. The procedure is particularly useful if there is doubt about an intraluminal lesion (Fig. 63.5) or if renal function is deficient (before surgery for pelviureteric junction obstruction, for instance). When a transitional tumour is found it can be sampled by aspiration of urine from the upper tract or by brush biopsy. Retrograde ureteropyelography is possible under topical urethral anaesthesia using the flexible cystoscope.

**Antegrade pyelography**

Percutaneous puncture of a dilated renal collecting system is a reasonably simple procedure for the experienced interventional radiologist. The most common indication is the placement of a nephrostomy tube to drain an obstructed infected kidney or to provide access for percutaneous nephrolithotomy. Antegrade pyelography — where contrast medium is introduced through the nephrostomy — can be helpful when retrograde studies are prevented by obstruction at the extreme lower end of the ureter.

**Digital subtraction arteriography (DSA)**

Refinements in radiological imaging have now almost eliminated the need for translumbar aortography. Satisfactory imaging of the renal vessels can even be achieved by digital subtraction angiography after intravenous injection of contrast medium. More precise information can be obtained by intra-arterial injection through a fine catheter inserted into the femoral artery using the Selenginger technique. Arteriography is now rarely used to demonstrate tumour vasculature in a hypernephroma (Fig. 63.6), but a flush venogram is useful when CT suggests tumour invasion of the renal vein and vena cava.

**Cystography**

Cystography is now most commonly a component of video-urodynamic assessment (see Chapter 65). Its role in assessing ureteric reflux in children has been largely superseded by radionuclide scanning and dynamic ultrasonography.

**Urethrography**

Ascending urethrography is valuable to demonstrate the extent of a urethral stricture (Fig. 63.7) and the presence of false passages and diverticula associated with it. A urethrogram can be used to assess the extent of urethral trauma, but there is a serious danger that contrast medium may pass into the circulation. Lipiodol carries the danger of fat embolus and should never be used, and death has followed the use of barium emulsion. Umbradil viscous V is a radio-opaque water-soluble gel that contains the local anaesthetic lignocaine. It can be injected gently and safely using Knutsson's apparatus even if the urethrum is breached.

**Venography**

Because extension of a renal carcinoma from the renal vein into the vena cava can usually be demonstrated by ultrasound or venography is now infrequently used for this purpose.

**Ultrasonography**

High-resolution ultrasonography is perhaps the imaging technique most widely used in urology. The size of the kidney, the thickness of its cortex, and the presence and degree of hydro-nephrosis can be measured with great accuracy. Intra renal masses can be diagnosed as smooth walled and fluid filled (simple cysts) or solid and complex (possible tumours). The volume of urine in the bladder before and after micturition can be calculated, and even tiny filling defects within it detected. Scrotal contents can be displayed in great detail. Only the lower urethra resists effective investigation by transabdominal ultrasonography because of its small calibre and its proximity to the large bones of the pelvis and spine.

**Transrectal ultrasonography**

This has become a routine component of the investigation of suspected carcinoma of the prostate. Most commonly, suspicion has arisen because the patient has a raised prostate specific antigen or there is an abnormality of the texture or outline of the prostate on digital rectal examination. The features of carcinoma or benign enlargement of the prostate, while not absolutely specific, are sufficiently well recognised to allow an experienced ultrasonographer to identify promising sites for transrectal fine-needle biopsy.

**Computerised tomography**
CT is particularly useful to assess structures in the retroperitoneum (Fig. 63.8). In renal carcinoma it will show:

- the size and site of the tumour and the degree of invasion of adjacent tissue;
- the presence of enlarged lymph nodes at the renal hilum;
- invasion of the renal vein and vena cava.

CT is of crucial importance in the initial staging and follow-up of men with testicular cancer in whom the presence of retroperitoneal lymph node masses is a feature of advanced disease. It has also been used to stage bladder and prostate cancer, but its value is less clear cut in these diseases.

**Magnetic resonance imaging**

In the investigation of renal, bladder and prostatic disease, magnetic resonance imaging is not clearly superior to good-quality CT. Positron emission tomography may prove to be more valuable in staging urological malignancies.

**Radioisotope scanning**

Radioisotope scanning is used in particular to obtain information about function in individual renal units. Diethyltriaminepentaacetic acid (DTPA) behaves in the kidney like inulin: it is filtered by the glomeruli and not absorbed by the tubules. Using a gamma camera, DTPA labelled with technetium-99m can be followed during its transit through individual kidneys to give dynamic representation of renal function. A $^{99m}$Tc-DTPA scan is particularly useful to prove that collecting system dilatation is due to obstruction. In obstruction, radioactivity will remain in the kidney even if urine flow is stimulated by administration of a diuretic. Other substances (DMSA, MAG-3 and Hippuran) labelled with suitable radioactive isotopes have similarly been used to investigate renal function (Fig. 63.9).

Isotope bone scanning is fundamental to staging kidney and prostate cancers which typically metastasise to the skeleton.

**Endoscopy**

Effective visual inspection of the lower urinary tract has been possible since 1877 when Nitze invented his cystoscope. A second leap forward in urological endoscopy came with the introduction by Hopkins of the rod lens telescope and fibre-optic illumination. This permitted the development of a family of endoscopes which allow the urologist to visualise the upper and lower urinary tract for diagnosis and therapy. Finally, in the early 1980s, the small calibre flexible fibrescopic cystoscope was introduced. This allows simple diagnostic cystourethroscopy, bladder biopsy and retrograde ureterography to be performed under topical urethral anaesthesia with minimal discomfort to the patient.
Anuria

Anuria is defined as the complete absence of urine production. Oliguria is present when less than 300 ml of urine is excreted in a day.

The maintenance of renal function and urine production depends upon perfusion of the kidneys with oxygenated blood. Reduced renal blood flow or hypoxia impairs renal function. When both are present, the danger of acute renal failure is even greater.

Renal failure is traditionally divided into:
- pre renal;
- renal;
- post renal (obstructive).

Pre renal

Pre renal cause of acute renal failure include:
- hypovolaemia;
- blood loss;
- sepsis;
- cardiogenic shock;
- anaesthesia;
- hypoxia.

Hypovolaemia

This may result from inadequate fluid intake or from excessive loss of body water. Dehydration, prolonged vomiting, diarrhoea and other abnormal gastrointestinal fluid losses, burns and excessive sweating are all common causes of hypovolaemia.

Blood loss

This is usually caused by trauma or surgery, but acute blood loss from the gastrointestinal tract or associated with childbirth may be sufficient to cause hypovolaemic renal impairment.

Sepsis

Gram-negative septicaemia from a urinary tract source is a particularly potent cause of bacteraemic shock. Sepsis from the biliary tract and overwhelming infection from other sites, especially in the immunocompromised individual, are also associated with acute renal failure.

Cardiogenic shock

Acute dysrhythmia secondary to myocardial infarction, cardiac tamponade and pulmonary embolus may all result in the reduced cardiac output of often poorly oxygenated blood.

Anaesthesia

Hypotension is a hazard of epidural and spinal anaesthesia.

Hypoxia

Prolonged hypoxia from any cause may occasionally be responsible.

Renal

Renal causes of acute renal failure include:
- drugs;
- poisons;
- contrast media;
- eclampsia;
- myoglobinuria;
- incompatible blood transfusion;
- disseminated intravascular coagulation.

It is uncommon for patients with established glomerulonephritis to develop acute oliguria; however, such patients are more prone to rapid deterioration of remaining renal function should any renal insult occur.

Drugs

Aminoglycosides, cephalosporins and diuretics can be nephrotoxic particularly if used in combination. They are quite commonly used inpatients whose renal function is already compromised by sepsis or circulatory abnormalities. Prolonged use of nonsteroidal anti-inflammatory drugs (NSAIDs) can cause a chronic interstitial nephritis and papillary necrosis; they also reduce renal plasma flow and therefore have nephrotoxic properties. Angiotensin-converting enzyme inhibitors used for the control of hypertension can cause a rapid reduction in the glomerular filtration rate; this is particularly liable to occur in patients who have a reduced renal blood flow.

Poisons

Some of these are nephrotoxic.

Contrast media

Even modern contrast media may cause renal failure when injected into a dehydrated patient with compromised renal function.
**Eclampsia**

The early recognition of pre-eclampsia is vital to avoid the nephrotoxic consequences of toxaemia and uncontrolled hypertension.

**Myoglobinuria**

The presence of myoglobin in the urine is associated with the ‘crush’ syndrome after major trauma. Less severe injuries can also cause the syndrome, especially if a compartment syndrome is unrecognised or pressure areas break down.

**Incompatible blood transfusion**

This may lead to renal failure with myoglobinuria.

**Disseminated intravascular coagulation**

Disseminated intravascular coagulation usually follows major sepsis or massive blood transfusion and may occur postpartum.

**Obstructive**

Obstructive causes of acute renal failure include:

- calculi;
- pelvic malignancy;
- surgery;
- retroperitoneal fibrosis;
- bilharzia;
- crystaluria.

**Calculi**

Renal calculus disease is probably the most common cause of acute obstruction leading to anuria. The patient is likely to have unilateral renal colic against a background of nonfunction of the contralateral kidney, often due to previous surgery or pre-existing obstruction by calculus.

**Pelvic malignancy**

Carcinomas arising from the bladder, prostate, cervix, ovary or rectum can all lead to obstruction of one or both ureters. A history of haematuria and vaginal or rectal bleeding sign-post the diagnosis. A large pelvic mass is commonly palpable on bimanual examination.

**Surgery**

The ureters are vulnerable to damage during pelvic and retroperitoneal surgery but injury should be avoided if proper care is taken. It is unusual, but not impossible, to damage both ureters.

**Retroperitoneal fibrosis**

For details of retroperitoneal fibrosis see Chapter 64 on ‘The kidneys and the ureters’.

**Bilharzia**

Schistosomiasis may lead to ureteric fibrosis and stenosis, and may be responsible for the development of squamous cell carcinoma of the bladder.

**Crystaluria**

Crystaluria causing urinary tract obstruction used to be associated with sulphonamide medications. This is now rare. However, uric acid crystaluria can develop in patients receiving chemotherapy for leukaemia or lymphoma unless they are given prophylactic treatment with allopurinol.

**Clinical aspects**

Answers to the following questions should indicate the probable cause of reduced urine output.

- Is urine being produced? Catheterisation of the bladder is mandatory if a voided sample cannot be obtained. If urine is available check the specific gravity, look for the presence of casts (implying a renal cause), test for myoglobinuria and send some for culture and microscopy.

- Is there an obvious pre renal cause? This can usually be answered by clinical examination, assessment of the patient’s vital signs, examination of the fluid balance chart and measurement of the arterial oxygen concentration.

- Is there ureteric obstruction? Hydronephrosis may not be marked in acute obstruction, but ultrasonography will usually show some degree of ureteric dilatation. A plain abdominal radiograph should be checked for calculi.

- What drugs have been given recently? If a drug is thought to be responsible for renal impairment it should obviously be withdrawn unless its use is vital.

- Is this a progression to chronic renal failure? The presence of shrunken kidneys on ultrasound, normochromic anaemia and hypertension suggest progression to a chronic state even if a previous history of renal failure is not available.

**Management and treatment**
Renal failure caused by acute tubular necrosis may progress through three recognisable phases:

• oliguria;

• the diuretic phase;

• recovery.

The initial management is aimed at prompt restoration of circulating volume deficit and correction of tissue hypoxia. Most patients will require a level of care available only in a specialised unit. As a minimum, monitoring with a pulse oximeter and central venous pressure measurement will supple-ment basic observations. For patients with hypovolaemia or sepsis, inotropic support with dopamine may improve cardiac efficiency and increase renal blood flow. If urine production is not promptly restored, frusemide can be given but this is not always successful and the drug is itself associated with nephrotoxicity. Mannitol may be used as a plasma expander and osmotic diuretic, but care must be taken not to overload the circulation. The aim is to achieve the best possible blood pressure with a central venous pressure of 7—9 cmH₂O.

One-hundred per cent oxygen may be needed to maintain the oxygen tension (PO₂).

If these measures fail, acute tubular necrosis has supervened. Excess fluid loads must be avoided and fluid input restricted to match the reduced output plus insensible losses (500—800 ml per 24 hours depending on ambient conditions). Abnormal losses due to vomiting, nasogastric aspiration, diarrhoea or fistulae will be monitored and replaced.

A hyperkalaemic acidosis is the characteristic metabolic abnormality of the oliguric phase of renal failure. Correction of the metabolic acidosis with intravenous bicarbonate is tempting but not always advisable. Rising serum potassium is life threatening and requires effective intervention. A calcium resonium enema is the simplest remedy: The ion-exchange resin can also be administered orally but is unpalatable. Cautious use of intravenous dextrose and insulin should be considered if ion exchange fails. The help of a renal physician is highly desirable.

The diuretic phase traditionally occurs between the 8th and 10th day but may be delayed as long as 6 weeks. Glomerular filtration recommences but tubular function takes longer to recover. A 100% loss of sodium and potas-sium can be expected, and fluid and electrolyte requirements must be carefully judged. In most patients, the diuretic phase is followed by the recovery phase but some never recover and will need renal replacement therapy if they are to survive.

Factors that influence the outcome of acute renal failure include the need for artificial ventilation, the need for inotropic support and the presence of jaundice. There is a significant mortality.

Nutritional support

Many of these patients are unable to eat. If enteral feeding is impossible, parenteral nutrition must be administered with extreme care to avoid circulatory overload.

Infection

These patients are at increased risk of generalised infection. Swabs taken from the nose and throat, sputum specimens and urine, if available, should be sent for culture. If antibiotics are required, they should be non nephrotoxic.

General nursing care

Meticulous recording of fluid balance is obviously central to successful management of these patients. Patients who are seriously ill or comatose need regular turning and care to pressure areas if they are to avoid pressure sores. Physiotherapy to the chest and extremities will aid recovery.

Renal support

Renal replacement is needed for those patients in whom the oliguric or anuric phase is associated with significant uraemic symptoms (vomiting, muscular twitching, itching and altered states of consciousness) or uncontrollable hyperkalaemia.

Peritoneal dialysis. Provided that the patient has not had recent abdominal surgery, penitoneal dialysis can be performed by insertion of a fenestrated catheter under local anaesthetic. This is placed just inferior to the umbilicus in the midline. Sterile dialysis fluid is then run into the penitoneal cavity where it equilibrates with the extracellular fluid using the peritoneum as a dialysis membrane. After a variable time, the fluid is drained into a closed drainage system. The process is repeated in cycles. Occasionally, when anuria is prolonged, a Tenckhoff cuffed catheter needs to be inserted, as used in chronic ambulatory penitoneal dialysis. The disadvantages of acute peritoneal dialysis are the potential for introducing infection into the peritoneum and the rather slow rate of correcting metabolic imbalance, particularly hyperkalaemia.

Haemodialysis. A few sessions of haemo dialysis may be life saving. A double-lumen catheter is placed over a guidewire into one of the great veins (jugular, subclavian or femoral). Between sessions of dialysis, the lines are kept patent by filling them with heparin solution. Haemodialysis can result in a rapid correction of metabolic abnormalities but also tends to result in considerable fluctuations of the overall fluid balance. The other disadvantage is that haemopurification is necessary, and this may be undesirable after a recent surgical procedure.

Haemofiltration. This, like haemodialysis, requires the use of an extracorporeal machine but causes much less haemodynamic upset. This may be of critical importance for the acutely ill patient.

Obstructive renal failure

When the patient is too ill for surgery to remove the cause of obstruction to the upper urinary tract, the treatment of obstructive renal impairment is drainage either externally using a nephrostomy or internally using an indwelling stent.

Percutaneous nephrostomy. Under ultrasonographic guidance and local anaesthetic, a fine-bore hollow needle is introduced via the flank through the parenchyma and into the expanded collecting system of the obstructed kidney. Once it penetrates the system, contrast medium can be injected through the needle to define its exact position. A wire passed through the lumen of the needle is used to guide the insertion of a series of dilators which enlarge the track until it will accept a suitably sized nephrostomy tube (Fig. 63.10). This will drain urine and pus, provided that the latter is not too viscous. The tube is anchored firmly in place to allow continued drainage as renal function recovers.
**Insertion of a J-stent.** The ureter can be drained into the bladder by the insertion of a pigtail- or J-stent (see Fig. 63.10). The procedure begins with a retrograde ureterogram under fluoroscopic control to provide an image of ureter. This will often give an indication of the cause of the obstruction. A guidewire is introduced through the ureteric orifice and guided up the ureter into the renal pelvis. The stent is rail-roaded over the guidewire until its distal end also lies within the renal pelvis above the obstruction. When the guidewire is removed, the ends of the stent curl to form a J-shape or a pigtail to secure the device against migration. Stents can be placed under topical urethral anaesthesia using the flexible cystoscope and may be safely left in position for several months. They are a foreign body in the urinary tract and are prone to infection and encrustation if neglected. It is vital to keep careful records to account for all stents inserted.

If the J-stent cannot be inserted cystoscopically, it may be placed from above through a nephrostomy.

**Open surgery.** This is a rarity when the minimally invasive methods described above are available. Retrograde insertion of a nephrostomy through an incision in the renal pelvis is the preferred method because it can be surprisingly difficult to locate even dilated calyces by blind puncture of the renal parenchyma.
Further reading

Embryology

A bud from the lower end of the mesonephric (Wolffian) duct grows backwards behind the peritoneum to the sacral region. The stalk of the bud forms the ureter and its dilated upper extremity the renal pelvis. From 6 weeks to 8 months, the primitive pelvis bifurcates repeatedly to form first the calyces and, after several subsequent divisions, the collecting ducts.

The renal parenchyma is derived from the metanephros which is the last in a series of embryonic renal masses: the primitive pronephros is supplanted by the mesonephros which is in turn succeeded by the metanephros. The continuity of glomerular apparatus and nephric tubules formed within the metanephros is established through connection with the collecting ducts. Between weeks 5 and 8 of embryonic development, each kidney ascends the posterior abdominal wall to reach its normal position in the loin. At the same time, it rotates so that its hilum faces medially instead of forwards as it did previously.

In humans the lobulation of the foetal kidney is usually lost as the lobules become bonded together by the growth of new cortex and the renal capsule. In some mammals, e.g. oxen and bears, foetal lobulation is retained.

Surgical anatomy

The parenchyma of each kidney usually drains into seven calyces, three in the upper and two each in the middle and lower calyces (Fig. 64.1). Each of the three segments represents an anatomical and physiologically distinct unit with its own blood supply.

Congenital abnormalities of the kidney (Table 64.1)

Absence of one kidney

Congenital aplasia of one kidney is usually discovered incidentally on intravenous urography, computerised tomography (CT) scan or renal Ultrasonography. If the mesonephric duct has failed to bud, the ureter will be absent and on cystoscopy no ureteric orifice is visible on that side. Alternatively, the ureter and renal pelvis are present but the kidney is absent or almost so. In either case the solitary contralateral kidney is likely to be hypertrophied. An absent or grossly atrophic kidney is found in about 1:1400 individuals.

Renal ectopia

In approximately 1:1000 people the kidney does not ascend. Ectopic kidneys are usually found near the pelvic brim and, for reasons which are not understood, they are usually left sided. The contralateral kidney is generally present and in its normal position. Renal ectopia may present diagnostic problems when acute disease develops in the kidney and there is always a danger that an unwary surgeon may be tempted to remove it as an unexplained pelvic mass.

Horseshoe kidney

If the most medial subdivisions of the mesonephric bud meet and fuse in the midline, the normal ascent of the kidneys is impeded by structures arising in the midline. The result is a pair of ectopic kidneys that are usually fused at their lower poles with the junction in front of the fourth lumbar vertebra. Horseshoe kidney is found in 1:1000 necropsies and is more common in men. Fusion of the upper poles is uncommon.

Clinical features

Horseshoe kidneys are liable to become diseased, possibly because the ureters are angulated as they pass over the fused isthmus (Fig. 64.2). This may lead to urinary stasis with consequent infection and nephrolithiasis. More commonly, there is a true pelviureteric junction obstruction as an associated abnormality, with the same consequences. Presentation as a fixed mass below the umbilicus is uncommon and horseshoe kidney is usually a radiological diagnosis. The most frequent appearance on the urogram shows the lower pole calyces on both sides being directed towards the midline. More rarely, all or most of the calyces are reversed (Fig. 64.3). The ureters characteristically have vase-like curves. Although horseshoe kidney is not a contraindication to pregnancy, urinary complications are more frequent.

Division of the isthmus between the kidneys is usually only indicated in the course of surgery for abdominal aortic aneurysm. Although the tissue is likely to be less vascular than normal renal parenchyma, care must be taken to avoid the vascular supply of the horseshoe which is typically eccentric, springing unpredictably from adjacent major vessels.

Unilateral fusion

Unilateral fusion (syn. crossed dystopia) is rare but the urogram appearance is striking. Both kidneys are in one loin and are usually fused. The ureter of the lower kidney crosses the midline to enter the bladder on the contralateral side. Both renal pelves can lie one above each other medial to the renal parenchyma (unilateral long kidney) or the pelvis of the crossed kidney faces laterally (unilateral S-shaped kidney (Fig. 64.4)).

Congenital cystic kidneys (syn. polycystic kidneys)

Polycystic kidneys are hereditary and can be transmitted by either parent as an autosomal dominant trait. This is important in genetic counselling because the risk of an offspring inheriting the condition can be as high as one in two depending upon the penetrance of the gene. The disease is not usually detectable on standard imaging until the second and third decades of life and does not usually manifest itself clinically before the age of 30 years.

Pathology

The kidneys become enormously enlarged, the cysts giving the appearance of a collection of bubbles below the renal capsule. On histological section the renal parenchyma is riddled with cysts of varying size, containing clear fluid, thick brown material or coagulated blood. In 18 per cent of cases there is a congenital cystic liver disease. The pancreas and lungs are occasionally affected as well. The aetiology of all renal cysts is uncertain although theories abound.

Clinical features in the adult

The condition is slightly more common in women than men. There are six clinical features:

- irregular upper quadrant abdominal mass;
- loin pain;
Renal enlargement. The bilateral knobby enlargement can hardly be mistaken when discovered in the course of a routine examination. Less florid examples may be revealed at laparotomy or abdominal imaging for some other condition. Unilateral renal swelling, in which one kidney contains larger cysts than the other, may be confused clinically with a cystic renal tumour.

Pain, felt as dull loin ache, is thought to be caused by the weight of the organ dragging upon its pedicle or by stretching of the renal capsule by the cysts. Haemorrhage into a cyst may cause more severe pain, as may the passage of a calculus from the diseased kidney.

Haematuria. Rupture of a cyst into the renal pelvis may cause haematuria which is typically moderate, lasts for a few days and recurs at intervals. Profuse haematuria is uncommon.

Infection. Pyelonephritis is common in patients with congenital cystic kidney, presumably because of urinary stasis.

Hypertension is present in up to 75 per cent of patients over the age of 20 years with polycystic kidneys. Why some escape this complication is not clear; the high blood pressure could possibly result from a separate genetic factor linked to the gene for congenital cystic kidneys.

Uraemia. Patients with congenital cystic kidneys pass large volumes of urine of low specific gravity (1.010 or less) which contains a trace of albumin but no casts or cells. Chronic renal failure develops as functioning renal tissue is replaced progressively by cysts. The patient complains of anorexia, headache and vague abdominal discomfort. As the symptoms are nonspecific the diagnosis may be missed until drowsiness and vomiting result from the biochemical derangement. Severe anaemia is common. Signs of end stage renal failure often begin suddenly during middle life and the patient is unlikely to survive without renal replacement by dialysis or renal transplantation.

Imaging

Ultrasound and CT will show multiple cysts in both kidneys, and sometimes cysts in the liver and other organs. The presence of blood and debris in the cysts may mimic the heterogeneity of a cystic adenocarcinoma. By contrast, simple (acquired) cysts are usually solitary and have smooth thin walls and homogeneous contents (Fig. 64.5). Doubt about the diagnosis can be resolved by cytological examination of cyst fluid obtained by fine needle aspiration.

Polycystic kidneys have a typical appearance on excretory urography: the renal shadows are enlarged in all directions; the renal pelvis is compressed and elongated; and the calyces are stretched over the cysts and are often narrow (like spiders' legs) or bell-like (Fig. 64.6).

Treatment

Renal failure. As kidney failure develops, a low protein diet will help to postpone the need for renal replacement. Infection, anaemia and disturbances of calcium metabolism need appropriate treatment, usually by a nephrologist.

Surgical treatment to uncap the cysts (Rovsing's operation) is rarely indicated because few surgeons now accept that this can preserve renal function by relieving pressure on the parenchyma. If cysts are to be decapped in the hope of reducing pain, the operation can be done laparoscopically.

Infantile polycystic disease

Infantile polycystic disease is an unrelated and much rarer condition. The kidneys are large and may obstruct birth. Many cases are stillborn and most of the others die from renal failure early in life. The condition is inherited as an autosomal recessive.

Unilateral multicystic disease

Unilateral multicystic disease is much more common. It presents as a nonfunctioning mass in the flank. Exploration and removal is the treatment of choice. In the differential diagnosis, Wilms' tumour (see below), neuroblastoma and congenital hydronephrosis are all rarer conditions.

Solitary renal cyst (syn. simple cyst of the kidney) (Fig. 64.5)

The term 'solitary' cyst serves to distinguish the condition from congenital cystic disease of the kidneys, but more than one cyst is often present in one or both kidneys. Simple cysts are most frequently discovered incidentally on imaging of the upper abdomen: they rarely give symptoms. A palpable mass, pain from haemorrhage into the cyst and infection are relatively uncommon presentations. Occasionally a cyst in the hilum of the kidney (a parapelvic cyst) presses on the pelviureteric junction and causes obstructive symptoms.

When discovered as a filling defect on excretion urography the true nature of a solitary cyst will be apparent by its characteristic appearance on ultrasonad or CT. Percutaneous cyst puncture will yield fluid for cytological examination but this is rarely necessary with sophisticated modern imaging.

Differential diagnosis

In sheep-rearing districts, hydatid cyst of the kidney is common. On the right side if hydatid disease is suspected the swelling is liable to be mistaken for hydatid cyst of the liver. Occasionally, the patient complains of passing 'grape skins' (ruptured daughter cysts) in the urine. Removal of the cyst must follow the principles used in excision of hydatid cyst of the liver, i.e. the scolecides must be killed by injection of a scolicide-like formalin solution before the cyst is handled. If the cyst is large nephrectomy may be the safest course.

Aberrant renal vessels

Two or more renal arteries are most common on the left. The main importance of the abnormality is as a source of potential error during operations in the retroperitoneum, especially those on the kidney. The renal arteries are functional end arteries so division of an aberrant lower pole artery will lead to infarction of the section of parenchyma that it supplies. Renal veins, by contrast, have extensive collaterals and an aberrant vein can be divided with impunity. Aberrant vessels probably do not cause hydronephrosis, although a hydronephrotic renal pelvis
may bulge between renal vessels, making them particularly noticeable (Fig. 64.7).
Congenital abnormalities of the renal pelvis and ureter

Duplication of a renal pelvis

Duplication of a renal pelvis (Fig. 64.8) is the most common congenital abnormality of the upper renal tract and is found in about 4 per cent of patients. It is usually unilateral and is slightly more common on the left. The upper renal pelvis is relatively small and drains the upper group of calyces; the larger lower renal pelvis drains the middle and lower groups of calyces.

Duplication of a ureter

Duplication of a ureter is found in about 3 per cent of excretion urograms. The ureters often join before they reach the bladder, usually in the lower third of their course (Fig. 64.9) and have a common ureteric orifice. Less commonly the ureters open independently into the bladder, in which case the ureter from the upper pelvis opens distal and medial to its fellow (Fig. 64.10).

Clinical features

Duplication of the renal pelvis or ureter is often a chance finding on renal imaging but infection, calculus formation and pelviureteric junction obstruction are more common than in normal kidneys. One of the moieties may be dysplastic and nonfunctioning. Where the two ureters open separately, the lower orifice is liable to be abnormal in function or position. Failure of the normal valvular mechanism at the ureterovesical junction may lead to urinary reflux and, if there is associated infection, damage to the parenchyma of the upper moiety. An ectopic second ureteric opening is a rarity but it may cause puzzling symptoms.

In the female an ectopic ureter opens either into the urethra below the sphincter (Fig. 64.11) or into the vagina. The diagnosis can often be made from the history alone and is confirmed by excretion orography. A girl or woman who has dribbled urine for as long as she can remember, despite the fact that she has a desire to void and indeed voids normally, probably has an ectopic ureteric orifice. The orifice is often difficult to see because it is guarded by a valve: it may help to give an intravenous injection of a dye such as indigocarmine to colour the urine leaking from it.

In the male patient the aberrant opening is above the external urethral sphincter so the patient is continent. The ureteric orifice at the apex of the trigone, the posterior urethra, in a seminal vesicle or in an ejaculatory duct is likely to be functionally abnormal and infection is the most common complication.

Treatment

Asymptomatic duplication of the kidney is a harmless variant and does not require treatment. If one moiety is severely diseased or atrophic, partial nephrectomy is usually simple and effective. An ectopic ureter in the female frequently drains hydronephrotic and chronically infected renal tissue, which is best excised. Rarely, the incontinence can be cured and renal function preserved by implanting the ectopic ureter into the bladder or by joining it to its fellow.

Congenital megaureter

Congenital megaureter is a curious and uncommon condition which may be bilateral and is often associated with other congenital anomalies. A functional obstruction at the lower end of the ureter leads to progressive dilatation and a tendency to infection. The ureteric orifice appears normal and a ureteric catheter passes easily. Reflux is not a feature of the untreated condition but is almost inevitable if the ureteric orifice is opened endoscopically to make it drain. Definitive surgical treatment involves refashioning the lower end of the affected ureter so that a tubular reimplantation into the bladder can be done to prevent reflux.

Postcaval ureter

The right ureter passes behind the inferior vena cava instead of lying to the right of it. If this causes obstructive symptoms, the ureter can be divided and rejoined in front of the cava using a long oblique anastomosis without tension. Unusually, the retrocaval portion of the ureter is fibrotic and must be excised.

Ureterocele

Ureterocele is a cystic enlargement of the intramural portion of the ureter thought to result from congenital atresia of the ureteric orifice. Although present from childhood, the condition is often unrecognised until adult life. The ‘adder head’ on excretory orography (Fig. 64.12) is typical. Usually the cyst wall is composed of urothelium only and the diagnosis is confirmed by the cystoscopic appearance of a translucent cyst enlarging and collapsing as urine flows in from the upper ureter (Fig. 64.13). Treatment should be avoided unless there are symptoms arising from infection and/or stone formation. Ureterocele is most common in women; occasionally the cyst may cause obstruction to the bladder outflow by prolapsing into the internal urethral opening.

Endoscopic diathermy incision is usually all that is required for treatment of a symptomatic ureterocele, although a micturating cystogram is advisable to detect postoperative urinary reflux. In advanced unilateral cases with hydronephrosis or pyonephrosis, nephrectomy may be appropriate.
Injuries to the kidney

In civilian life injuries to the kidney result most often from either blows or falls on the loin or crushing injury to the abdomen, typically in a road traffic accident. Haematuria after trivial injury to the kidney should suggest the possibility of a pre-existing abnormality, e.g. calculus, hydronephrosis or tuberculosis.

The degree of injury varies considerably from a small subcapsular haematoma to a complete tear involving the whole thickness of the kidney (Fig. 64.14). The kidney may be partially or wholly avulsed from its vascular pedicle; one pole may be completely detached.

Closed renal injury is almost always extraperitoneal. The exception is seen occasionally in young children who have very little extraperitoneal fat. The peritoneum, which is closely applied to the kidney, can tear with the renal capsule allowing blood and urine to leak into the peritoneum.

Clinical features

Superficial soft tissue bruising may testify to the severity of the blow but is often absent. There is likely to be local pain and tenderness.

Haematuria

Haematuria is the cardinal sign of a damaged kidney, but it may not appear until some hours after the injury. Profuse bleeding may be accompanied by clot colic.

Severe delayed haematuria

Sudden profuse haematuria can occur between the third day and the third week after the accident in a patient who appears to be progressing favourably. It is due to a clot becoming dislodged.

Meteorism

Abdominal distension 24—48 hours after renal injury is probably due to retroperitoneal haematoma implicating splanchnic nerves.

Management and treatment

Conservative treatment of closed renal trauma is usually successful but appropriate measures must be instituted without delay. The possibility of injury to other organs must be considered at an early stage.

1. Blood should be cross matched and available for trans-fusion if there is evidence of hypovolaemic shock or continuing haemorrhage. Intravenous access should be established.

2. The patient must be confined to bed while there is macro-scopic haematuria and physical activity must be curtailed for at least 1 week after the urine clears.

3. Morphine should be given as an analgesic and sedative.

4. Hourly pulse and blood pressure charts must be kept.

5. Antibiotics should be given to prevent infection of the haematoma.

6. Each sample of urine passed should be checked for haematuria and the result charted.

7. An intravenous urogram (IVU) should be obtained urgently (a) to assess the damage to the kidney and (b) to show that the other kidney is normal.

Surgical exploration

Surgical exploration is necessary in less that 10 per cent of closed injuries and is indicated if either there are signs of progressive blood loss or there is an expanding mass in the loin. The aim is to stop bleeding while conserving as much renal tissue as possible; and a renal arteriogram performed preoperatively can be helpful in framing a strategy for doing this. There is also a chance that a skilled radiologist will be able to stop the haemorrhage by embolisation if a bleeding vessel can be identified.

The approach to the kidney should be transperitoneal to exclude the possibility of damage to other abdominal organs. The danger is that release of the tamponading effect of the perirenal haematoma will result in massive uncontrollable haemorrhage and this eventuality must be prepared for. When the kidney is irretrievably ruptured or avulsed from its pedicle, nephrectomy is the only course. Small tears can be sutured over a haemostatic sponge or a piece of detached muscle. Large single rents in the kidney are best dealt with by passing a tube nephrostomy through the defect and suturing the renal tissue around it. If the laceration is confined to one pole of the kidney, partial nephrectomy may be practicable.

When a solitary existing kidney is sufficiently damaged to need exploration, it must be repaired. Failing this, the wound is packed firmly with gauze to stop the bleeding in the hope that some renal function may be retained when the ruptured kidney heals.

Multiple injuries

The mortality of cases of ruptured kidney with damage to the liver spleen or hollow intra-abdominal organs is high.

Complications

1. Heavy haematuria may lead to clot obstruction of the bladder outflow and bladder washout through a catheter or a cystoscope may be necessary.

2. Para renal pseudohydronephrosis may occur in the course of a few weeks as a result of a combination of complete cortical tear and ureteric obstruction caused by scarring.

3. Hypertension resulting from renal fibrosis may occur 3 months or more after injury. It is often refractory to medical treatment and
4. Aneurysm of the renal artery (Fig. 64.15) is a rare but striking complication of severe renal trauma. There is pain in the loin and a nontender swelling may be felt if the aneurysm is large. Congestion of the parenchyma leads to intermittent haematuria. Aortography is diagnostic. Rupture of a renal artery aneurysm is liable to be fatal and excision or nephrectomy is urgently indicated.
Injuries to the ureter

Rupture of the ureter

This is an uncommon result of a hyperextension injury of the spine. The diagnosis is rarely made until there is swelling in the loin or iliac fossa associated with a reduction of urine output. An excretion urogram shows extravasation of contrast from the ureter on the injured side.

Injury to one or both ureters during pelvic surgery

This is far more common and occurs most often during vaginal or abdominal hysterectomy. Typically there is a failure to recognise the ureter, which is divided, ligated, crushed or excised. Preliminary catheterisation of the ureters prevents such accidents as the catheters make it easy to see and feel the ureters.

Injury recognised at the time of operation

Ureterovesical continuity should be restored by one of the methods described below unless the patient’s condition is poor when deliberate ligation of the proximal end of the ureter is the best course. If the patient rallies within 2 days, temporary nephrostomy is carried out with a view to repair of the injury later.

Injury not recognised at the time of operation

Unilateral injuries. There are three possibilities.

No symptoms. Secure ligation of a ureter may simply lead to silent atrophy of the kidney that it drains. If the other kidney is functioning, the injury may be unsuspected until the patient undergoes urological imaging some time later.

Loin pain and fever, possibly with pyonephrosis occurs with infection of the obstructed system. Excretory urography shows no function, a state that will be permanent unless urgent steps are taken to relieve the obstruction, usually by inserting a percutaneous nephrostomy.

A urinary fistula develops through the abdominal or vaginal wound. The urogram shows extravasation of contrast with or without obstruction to one or both ureters. Temporary nephrostomies may be inserted and repair postponed until oedema and inflammation have subsided. The traditional delayed repair, however, leaves the patient incontinent and demoralized. Early repair is now regarded as safe provided that the patient is fit and the surgeon has the necessary experience.

Bilateral injury. Ligation of both ureters leads to anuria. Ureteric catheters will not pass and urgent relief of obstruction is mandatory.

Repair of the injured ureter (Tab 62.2)

1. If there is no loss of length and the cut ends of the ureter can be brought together without tension, they should be joined by a spatulated anastomosis over a double pigtail catheter. (A pigtail catheter is a plastic tube with preformed coils at each end. The catheter is inserted over a guide-wire which straightens its ends. When the wire is removed, the coils reform to anchor the ends of the catheter.)

2. If the division is very low down, the bladder wall may be hitched up so that the ureter can be reimplanted into it. Extra length may be obtained by mobilising the kidney.

3. Boari’s operation (Fig. 64.16). A flap of bladder wall is fashioned into a tube to replace the lower ureter.

4. The ureter may be implanted end to side into the contralateral ureter. The disadvantage of a transureteroureterostomy is that it risks converting a unilateral injury into a bilateral one.

5. Occasionally, when conservation of all renal tissue is vital, replacement of the damaged ureter by a segment of ileum is necessary.

6. Nephrectomy may be the best course when the patient’s outlook is poor and the other kidney is normal.
Hydronephrosis

Hydronephrosis is an aseptic dilatation of the kidney due to a partial or complete obstruction to the outflow of urine.

Unilateral hydronephrosis

Unilateral hydronephrosis (Table 64.3) is caused by some form of ureteric obstruction, with the ureter above the obstruction being dilated.

Bilateral hydronephrosis

Bilateral hydronephrosis is usually the result of urethral obstruction, but it may be caused by one of the lesions described above occurring on both sides.

When due to lower urinary obstruction, the cause may be:

1. Congenital:
   (a) congenital stricture of the external urethral meatus or, rarely, phimosis;
   (b) congenital valves of the posterior male urethra or congenital contracture of the bladder neck.

2. Acquired:
   (a) benign prostatic enlargement or carcinoma of the prostate; postoperative bladder neck scarring;
   (b) inflammatory or traumatic urethral stricture, phimosis.

Urethral obstruction tends to lead to hypertrophy of the bladder detrusor muscle which can lead to obstruction to the ureters in the intramural part of their course.

Pathology

In a kidney with an extrarenal pelvis, the dilatation first affects the pelvis alone (pelvic hydronephrosis). If the obstruction is not relieved, the calyces become increasingly dilated and the renal parenchyma is progressively destroyed by pressure atrophy. In a kidney with a predominantly intrarenal pelvis, destruction of the parenchyma occurs more rapidly. A kidney destroyed by long-standing hydronephrosis is a thin-walled lobulated sac containing pale uriniferous fluid of low specific gravity.

Clinical features

Unilateral hydronephrosis

The female:male ratio of unilateral hydronephrosis (most commonly caused by idiopathic pelviureteric junction obstruction or calculus) is 2:1; the right side is more commonly affected.

Presenting features include the following.

1. Insidious onset of mild pain or dull aching in the loin. There is often a sensation of dragging heaviness which is made worse by excessive fluid intake. An enlarged kidney may be palpable if the cause is pelviureteric junction obstruction.

2. Attacks of acute renal colic may occur with no palpable swelling.

3. Intermittent hydronephrosis. After an attack of acute renal pain a swelling in the loin is found. Some hours later, following the passage of a large volume of urine, the pain is relieved and the swelling disappears (Dietl’s crisis).

Bilateral hydronephrosis

From lower urinary obstruction. There is little to call attention to the hydronephrosis except, perhaps, a dull loin ache. Symptoms of bladder outflow obstruction predominate. The kidneys are unlikely to be palpable because renal failure intervenes before the kidneys become sufficiently large.

From bilateral upper urinary tract obstruction.

This is rare compared with unilateral lesions although idiopathic retro-peritoneal fibrosis commonly affects both ureters. Although both systems are obstructed, symptoms may be referred to one side only.

From pregnancy. Dilatation of the ureters and renal pelves occurs early in pregnancy and becomes more marked until the 20th week. The condition results from the effects of high levels of circulating progesterone on the ureteric smooth muscle and it may be considered as part of normal pregnancy. The ureters return to their normal size within 12 weeks of delivery. The main importance of the condition is an increased liability to infection and the possibility that abdominal pain during pregnancy may be erroneously ascribed to ureteric obstruction.

Imaging

Ultrasound scanning (Fig. 64.17) is the least invasive means of detecting hydronephrosis and has been used to diagnose pelviureteric junction obstruction in utero.

Excretion urography is helpful if there is still significant function in the obstructed kidney. The extrarenal pelvis is dilated and the minor calyces lose their normal cupping and become ‘clubbed’. In very advanced cases, the thin rim of poorly functioning renal parenchyma may give a faint nephrogram around the dilated calyces — a ‘soap-bubble’ appearance. If the level of obstruction is in doubt it can help to take follow up films up to 24 hours after the contrast has been injected. The radio-opaque medium slowly diffuses to fill the obstructed system down to the block.

Isotope renography is the most helpful test to establish that dilatation of the renal collecting system is due to obstruction. A substance
usually diethylenetriaminepenta acetic acid (DTPA) or MAG-3] which is filtered by the glomeruli and not absorbed is injected intravenously. The DTPA is labelled with technetium \textsuperscript{99m}, a gamma-ray emitter, so that the passage (of \textsuperscript{99m}Tc labelled DTPA) through the kidneys can be tracked using a gamma camera. \textsuperscript{99m}Tc-DTPA is quickly cleared from a normal kidney but if the ureter is obstructed the marker is trapped in the renal pelvis and will not be washed out even if the flow of urine is increased by administering frusemide (Fig. 64.18).

Very occasionally, doubt still persists and a Whitaker test is indicated. A percutaneous puncture of the kidney is made through the loin and fluid is infused at a constant rate with monitoring of intrapelvic pressure. An abnormal rise in pressure confirms obstruction. Retrograde pyelography (Fig. 64.19) is rarely indicated but will confirm the site of obstruction immediately before corrective surgery.

**Treatment**

The indications for operation are bouts of renal pain, increasing hydronephrosis, evidence of parenchymal damage and infection. Conservation of renal tissue is the aim; nephrectomy should be considered only when the renal parenchyma has been largely destroyed. Mild cases should be followed by serial ultrasound scans and operated upon if dilatation is increasing.

**Pyeloplasty**

The Anderson—Hynes operation (Fig. 64.20) is appropriate in cases of pelviureteric junction obstruction where a reasonable thickness of functioning parenchyma remains. The affected kidney is displayed and the upper third of the ureter and the renal pelvis carefully mobilised. A renal vein overlying the distended pelvis can be divided but an artery in this situation should be preserved to avoid infarction of the territory that it supplies. The anastomosis is made in front of such an artery using absorbable stitches to avoid calculus formation on the suture line. It is usual to protect the anastomosis with a nephrostomy tube or a ureteric stent.

**Endoscopic pyelolysis**

Disruption of the pelviureteric junction by a specially designed balloon passed up the ureter and distended under radiographic control has been used to treat idiopathic pelviureteric junction obstruction. The long-term benefit of this and other minimal access techniques still has to be proved.
Renal calculi

Aetiology
The subject is complex and the following represents a brief summary of current opinion.

**Dietetic.** Deficiency of vitamin A causes desquamation of epithelium. The cells form a nidus around which stone is deposited. From a study of economic conditions in places where stones are common, it is evident that the inhabitants do suffer dietary imbalance. It is uncertain whether this mechanism is of importance other than in the formation of bladder calculi.

**Altered urinary solutes and colloids.** Dehydration leads to an increased concentration of urinary solutes and tends to cause them to precipitate. It has been postulated that reduction of urinary colloids which absorb solutes or mucoproteins which chelate calcium will also result in a tendency for stone components to come out of solution.

Decreased urinary citrate. The presence of citrate in urine, 300—900 mg/24 hours (1.6—4.7 mmol/24 hours) as citric acid, tends to keep otherwise relatively insoluble calcium phosphate and citrate in solution. The urinary excretion of citrate is under hormonal control and decreases during menstruation.

**Renal infection.** Infection favours the formation of renal calculi. Both clinical and experimental stone formation are common when urine is infected with urea splitting streptococci, staphylococci and especially *Proteus* sp. The predominant bacteria found in the nuclei of urinary stones are staphylococci and *Escherichia coli*.

**Inadequate urinary drainage and urinary stasis.** Stones are liable when urine does not pass freely.

**Prolonged immobilisation from any cause, e.g. paraplegia,** is liable to result in skeletal decalcification and an increase in urinary calcium favouring the formation of calcium phosphate calculi.

**Hyperparathyroidism** leading to hypercalcaemia and hypercalciuria is found in 5 per cent or less of those who present with radio-opaque calculi. In cases of recurrent or multiple stones this cause should be eliminated by appropriate investigations (see Chapter 45). Hyperparathyroidism results in a great increase in the elimination of calcium in the urine. These patients ‘pass their skeletons in their urine’. A parathyroid adenoma should be removed before definitive treatment for the urinary calculi.

**Randall’s plaque and microliths.** Randall suggested that the initial lesion in some cases of kidney stone was an erosion at the tip of a renal papilla. Deposition of calcium on this erosion produced a lesion which has been called Randall’s plaque. It has further been shown that minute concretions (microliths) regularly occur in the renal parenchyma and Carr postulated that these particles are carried by lymphatics to the subendothelial region where they may accumulate. Ulceration of the epithelium exposes the potential calculus to the urine with the result that a stone forms. The importance of Randall’s plaques and Carr’s microliths in most patients with stones is a matter for debate.

**Types of renal calculus**

**Oxalate calculus** (calcium oxalate) (Fig. 64.21). Oxalate stones are irregular in shape and covered with sharp projections which tend to cause bleeding. The surface of the calculus is discoloured by the pigments of altered blood. A calcium oxalate monohydrate stone is very hard and absorbs X-rays well; it is easy to see radiologically.

**Phosphate calculus** [usually calcium phosphate, although sometimes combined with ammonium magnesium phosphate (struvite)] is smooth and dirty white (Fig. 64.22). The stone tends to grow in alkaline urine especially when proteus organisms are present which split urea to ammonium. As a result, the calculus may enlarge to fill all or most of the renal collecting system forming a stag horn calculus (Fig. 64.22). Even a very large stag horn may be clinically silent for years until it signals its presence by causing intractable urinary infection or haematuria. Because they are large, phosphate calculi are usually easy to see on X-ray films.

**Uric acid and urate calculi** are hard, smooth and often multiple. Their colour varies from yellow to reddish brown and they sometimes have an attractive multifaceted appearance. Pure uric acid stones are radio lucent and appear on an excretion urogram as a filling defect, which can be mistaken for a transitional tumour of the upper urinary tract. In practice most uric acid stones contain some calcium so they cast a faint radiological shadow. In children mixed stones of ammonium and sodium urate are sometimes found. They are yellow soft and friable. They are radio lucent unless they are contaminated with calcium salts.

**Cystine calculi** are uncommon. They appear in the urinary tract of patients with a congenital error of metabolism which leads to cystinuria. Cystine crystals are hexagonal, translucent white and appear only in acid urine. Cystine stones are often multiple and may grow to form a cast of the renal pelvis and calyces. They are pink or yellow when first removed but they change colour to a greenish hue when exposed to air. Cystine stones are radio-opaque because of the sulphur that they contain, and they are very hard.

**Xanthine calculi** are extremely rare. They are smooth and round, brick red in colour and show lamellation on cross section.

**Clinical features**
Renal calculi are very common. Fifty per cent of patients present between the ages of 30 and 50 years. The male:female ratio is 4:3.

The symptoms are variable and the diagnosis sometimes remains obscure until the stone is discovered on a radiograph.

**Silent calculus**
Some stones, even large stag-horn calculi, cause no symptoms for long periods during which there is progressive destruction of the renal parenchyma. If the calculi are bilateral, uraemia may be the first indication of their presence; although secondary infection usually gives symptoms first.

**Pain**
Pain is the leading symptom in 75 per cent of people with urinary stone disease.

Fixed renal pain is located posteriorly in the renal angle (Fig. 64.23), anteriorly in the hypochondrium, or in both. It may be worse on movement, particularly on climbing stairs.
**Ureteric colic** is an agonising pain passing from the loin to the groin. Typically it starts suddenly causing the patient to move around trying in vain to find comfort. Strangury, the painful passage of a few drops of urine, may occur if the stone is in the intramural ureter. An attack of colic rarely lasts more than 8 hours. It is not associated with pyrexia, although the pulse rate usually rises as a reflex response to the severe pain.

Ureteric colic is often caused by a stone entering the ureter but it may also occur when a stone becomes lodged in the pelviureteric junction. The severity of the colic is not related to the size of the stone.

**Abdominal examination.** During an attack of ureteric colic there is rigidity of the lateral abdominal muscles but not, as a rule, of the rectus abdominis. Percussion over the kidney produces a stab of pain and there may be tenderness on gentle deep palpation. Hydronephrosis or pyonephrosis leading to a palpable swelling in the loin is rare.

**Haematuria**

Haematuria is sometimes a leading symptom of stone disease and occasionally the only one. As a rule the amount of bleeding is small.

**Pyuria**

Infection is likely in the presence of stones and is particularly dangerous when the kidney is obstructed. As pressure builds in the dilated collecting system, organisms are injected into the circulation and a life-threatening sepsicaemia can quickly develop.

The mechanical effect of stones irritating the urothelium may cause pyuria even in the absence of infection.

**Investigation of suspected urinary stone disease**

**Radiography**

Calculi are easier to see if the bowel is empty and it is helpful to administer a vegetable laxative. The 'scout' film must show the kidney, ureters and bladder (a 'KUB' film). When a renal calculus is branched, there is no doubt about the diagnosis (Fig. 64.24). An opacity that keeps a constant position relative to the urinary tract during respiration is likely to be a calculus within it.

A doubtful opacity can sometimes be shown to be anterior to the vertebral bodies on a lateral radiograph and hence out side the urinary tract (Table 64.4); such is the finding with calcified mesenteric nodes and opacities within the alimentary tract.

**Excretion urography**

Excretion urography is the most useful investigation to establish the presence of a calculus. It also shows where the stone is and gives important information about the function of the other kidney.

**Ultrasound scanning**

Ultrasound scanning is of most value in locating stones for treatment by extracotporeal shock wave treatment (see below).
Surgical treatment of urinary calculi

Conservative management

Calculi which are smaller than 0.5 cm are likely to pass spontaneously unless they are impacted. Any surgical intervention carries the risk of complication and needless intervention should be avoided. Small renal calculi may cause symptoms by obstructing a calyx or acting as a focus for secondary infection. However, most can be safely observed until they pass.

Preoperative treatment

If urinary infection is present, appropriate antibiotic treatment is started and continued during and after surgery as necessary.

Operation for stone

In developed countries, open surgery for renal calculus disease is uncommon. Most stones are treated by specialist urologists using minimal access and minimally invasive techniques. Open operations are still needed when the appropriate expertise is not available or newer techniques have failed to clear the calculus. The following account should be read with this in mind.

Modern methods of stone removal

Kidney stones

Percutaneous nephrolithotomy (Fig. 64.25). This involves the placement of a hollow needle into the renal collecting system through the soft tissue of the loin and the renal parenchyma. A wire inserted through the needle is used to guide the passage of a series of dilators which expand the track into the kidney until it is large enough to take the nephroscope used to look for the stone. Small stones may be grasped under vision and extracted whole. Larger stones must be fragmented by an ultrasound or electrohydraulic probe and removed piecemeal.

The aim of the procedure is to remove all fragments if possible and this may take quite a long time if the calculus is large. When the operation is finished a nephrostomy tube is left to drain the system. This decompresses the kidney and allows repeated access to the system if stone particles remain. Percutaneous nephrolithotripsy is sometimes combined with extracorporeal shock-wave lithotripsy (ESWL) in the treatment of complex (slag-horn) calculi. The surgeon removes the central part of the stone percutaneously and the more peripheral fragments are treated by ESWL.

Complications of percutaneous nephrolithotripsy include (1) haemorrhage from the punctured renal parenchyma — this may be profuse and difficult to control; (2) perforation of the collecting system with extravasation of irrigant (which should be saline); (3) perforation of the colon or pleural cavity during placement of the percutaneous track.

Extracorporeal shock-wave lithotripsy. The management of kidney stones has been revolutionised by the development of lithotriptors. The first of these was made in Germany by the Dornier Company. Many machines of different design are now available.

A urinary calculus is a crystalline structure. If it is bombarded with shock waves of sufficient energy it will disintegrate into fragments. The principle is seen at its simplest in the original Dornier machine where shock waves were generated by an electrical discharge placed at one focus of an ellipsoid mirror. The patient was positioned, under radiographic control, so that the calculus was subjected to the full force of the shock waves where they were concentrated at the second focus of the mirror. As shock waves are poorly transmitted through air, both the patient and the shock-wave generators were immersed in a bath of water.

When ESWL is successful, the stone fragments have to be passed down the ureter. Ureteric colic is common after ESWL and the patient must be given appropriate analgesia, usually in the form of a nonsteroidal anti inflammatory drug such as diclofenac. If the stone is large the bulky fragments may become impacted in the ureter, causing obstruction. To avoid this, a self-retaining stent should be placed in the ureter so that the kidney can drain while the pieces of stone pass. Occasionally impacted fragments have to be removed ureteroscopically (see below).

In addition to pain and fragment impaction, the principal complication of ESWL is infection. Many calculi contain bacteria which are released when the stone is broken. It is wise to give prophylactic antibiotics before ESWL and an obstructed system should be decompressed by the insertion of a ureteric stent or percutaneous nephrostomy before treatment.

The clearance of stone from the kidney will depend upon the consistency of the stone and its site. Most oxalate and phosphate stones fragment well and, if lying in the renal pelvis, will clear within days. The results with harder stones, especially cystine stones, are less satisfactory. When treating calyceal stones, the patients should be warned that the clearance of fragments may take months.

There is currently great interest in the long-term outcome of patients treated by ESWL. Certainly some stones recur, especially if small fragments remain after treatment. Long-term renal damage now seems unlikely.

OpenSurgery for renal calculi (Fig. 64.27)

Operations for kidney stone are usually performed via a loin or lumbar approach. All of the procedures are difficult unless the kidney is fully mobilised and its vascular pedicle controlled. A sling should be placed around the upper ureter to stop stones migrating downwards.

Pyelolithotomy is indicated for stones in the renal pelvis. When the wall of renal pelvis has been dissected free from its surrounding fat, an incision is made in its long axis directly on to the stone. The stone is removed with gallstone forceps, care being taken not to break it because fragments may be difficult to retrieve. Stone fragments in peripheral calyces may be detected by direct palpation or by intraoperative radiography or nephroscopy. If there is no infection, the pelvic incision is closed with interrupted absorbable sutures. If there is gross sepsis, it is wise to place a nephrostomy to drain the system.

Extended pyelolithotomy. The plane between the renal sinus and the wall of the collecting system is developed on the posterior surface of...
the kidney. This avoids major vessels and allows incisions to be made into the calyces so that even large stag-horn stones can be removed intact.

**Nephrolithotomy.** If there is a complex calculus branching into the most peripheral calyces, it may be necessary to make incisions into the renal parenchyma to clear the kidney. Nephrolithotomy may also be necessary when the adhesions resulting from previous surgery make access to the renal pelvis difficult. The renal pedicle must be temporarily cross-clamped to reduce bleeding from the highly vascular renal tissue. Incisions are made just posterior and parallel to the most prominent part of the convex renal border where the territories of the anterior and posterior branches of the renal artery meet (Brödel’s line). Cooling the kidney with ice packs or cooling coils extends the time that the kidney can remain ischaemic without permanent damage. All the incisions must be carefully closed with haemostatic sutures and the patient observed after the operation for signs of reactionary haemorrhage.

Partial nephrectomy is sometimes preferable when the stone is present in the lowermost calyx and there is associated infective damage to the adjacent parenchyma.

**Nephrectomy** is indicated when the kidney has been destroyed by obstruction and infection associated with stone disease. This is particularly the case when there is xanthogranulomatous pyelonephritis. This stone-related inflammatory mass must be removed with particular care because it is liable to be attached to adjacent structures such as the colon.

**Treatment of bilateral renal stones.** Usually the kidney with better function is treated first, the operation on the contralateral side being deferred for 2—3 months. Exceptions are if either one kidney is more painful, suggesting an obstruction, or there is pyonephrosis in one kidney — this must be drained by percutaneous nephrostomy.

In cases of silent bilateral stag-horn calculi in the elderly and infirm, it may be best not to operate. The patient should be encouraged to maintain a high fluid intake.

**Prevention of recurrence**

Frère Jacques, that famous lithotomist of the Middle Ages, used to say, ‘I have removed the stone, but God will cure the patient’. When a renal stone has been removed, steps must be taken to prevent recurrence.

Ideally all stone formers should be investigated to exclude metabolic factors. In practice the pick-up rate in patients with a single small stone is very small. The urine of all patients with stones should be screened for infection. The following investigations are appropriate in bilateral and recurrent stone formers:

- Serum calcium, measured fasting on three occasions to exclude hyperparathyroidism;
- Serum uric acid;
- Urinary urate, calcium and phosphate in a 24-hour collection. The urine should also be screened for cystine;
- Analysis of any stone passed.

**Dietary advice** is not usually helpful in avoiding stone recurrence in people who have a normal balanced diet. Those who consume excessive amounts of milk products (calcium stones), rhubarb, strawberries, plums, spinach and asparagus (calcium oxalate stones) should be advised to be more moderate.

Patients with hyperuricaemia should avoid red meats, offal and fish, which are rich in purines and should have treatment with allopurinol. Eggs, meat and fish are high in sulphur-containing proteins and should be restricted in those with cystinuria.

The most effective dietary advice is that originally offered to stone sufferers by Hippocrates. They should **drink plenty** to keep their urine dilute. Fluid intake should be increased appropriately to take account of increased losses.

**Drug treatment** has not been shown to be effective other than in those few patients who are shown to have idiopathic hypercalciuria. Bendrofluazide 5mg and a calcium restricted diet reduces urinary calcium.
Ureteric calculus

A stone in the ureter nearly always has its birth in the kidney. Most are single small stones which pass spontaneously.

Clinical features

The presence of a stone passing down the ureter often causes intermittent attacks of ureteric colic.

Ureteric colic

A stone in the upper ureter produces symptoms identical with those of a stone blocking the pelviureteric junction. As the stone progresses to the lower ureter, the waves of agonising pain are typically referred more to the groin, external genitalia and the anterior surface of the thigh. In a man, the testis may be retracted by spasm of the cremaster and tenderness may persist for some days after the colic has ceased. When the stone is in the intramural ureter, the pain is referred to the tip of the penis. In both sexes there may be strangury.

Impaction

Most stones pass spontaneously from the ureter but there are five sites of anatomical narrowing where the stone may be arrested (Fig. 64.28). When the stone becomes impacted the attacks of colic give way to a more consistent dull pain, often felt in the iliac fossa. The pain is increased by exercise and lessened by rest. Distension of the renal pelvis due to obstruction may cause pain and discomfort in the loin. As time goes by the stone may become imbedded as the adjacent ureteric wall becomes eroded and oedematous due to pressure ischaemia. Perforation of the ureter and extravasation of urine is a rare complication.

Severe renal pain persisting for 1 or 2 days and then subsiding suggests that the ureter is completely obstructed by the stone. If urography (IVU) or ultrasonography suggests that obstruction persists after 1—2 weeks, the calculus should be removed because prolonged distension of the kidney will lead eventually to atrophy of the renal parenchyma.

Haematuria

Almost every attack of ureteric colic is associated with microscopic haematuria which lasts for a day or so. More profuse bleeding is uncommon and should raise the suspicion that the colic is due to passage of a clot.

Abdominal examination

There is tenderness and some rigidity over some part of the course of the ureter. The principal difficulty on the right side is to distinguish symptoms and signs of ureteric colic from those of acute appendicitis or acute cholecystitis. The pre-sence of haematuria does not rule out appendicitis, because an inflamed appendix lying near the ureter can give rise to a local ureteritis which will result in some red cells in the urine. In practice, the patient with acute renal colic is usually in greater pain and less systemically ill.

Imaging

Most urinary calculi are radiodense and visible on a plain abdominal radiograph. The stone may not be seen along the line of the ureter if it is very small or if it is obscured by contents of the gut or the shadows of nearby bones. An intravenous urogram performed while the patient has pain can confirm the diagnosis. During and for some time after an attack of renal colic there will probably be little or no excretion on the affected side. Occasionally, there is an extravasation of contrast from the dilated system. Late radiographs, taken up to 36 hours after the injection of contrast, may show dilatation of the ureter down to an obstructing calculus. A radiolucent uric acid stone may be demonstrated as a filling defect in the contrast.

Analgesic abusers occasionally simulate symptoms to obtain drugs and the urogram is useful in excluding renal colic. If the urogram is normal during an attack, the patient does not have renal colic.

Cystoscopy is not indicated routinely but may reveal oedema and petechiae of the urothelium around the ureteric orifice when the stone is in the lower ureter. The stone may be visible in the orifice as it makes its passage into the bladder.

Retrograde ureterography is usually performed as an immediate preliminary to an endoscopic operation to remove a calculus but it may be of use if doubt remains after the intravenous urogram.

Treatment

Pain

Nonsteroidal anti-inflammatory drugs such as diclofenac and indomethacin have replaced opiates as the first line of treatment for renal colic. The value of smooth muscle relaxants such as propantheline (Pro-Banthine) is debatable.

Removal of the stone (Table 64.5)

Expectant treatment is appropriate for small stones that are likely to pass naturally. This may take many months and, as long as the patient is not disabled by recurrent attacks of colic, the progress of the stone can be followed by radiographs repeated every 6—8 weeks.

Endoscopic stone removal. Dormia basket. The use of wire baskets under image intensifier control has been replaced by ureteroscopic techniques, but may be useful when the necessary instruments and expertise are not available. There is a significant danger of ureteric injury, and basketry under radiographic control should only be used for small stones that are within 5 or 6 cm of the ureteric orifice (Fig. 64.29).

Ureteric meatotomy. Stones often lodge in the intramural part of the ureter. Careful endoscopic incision using a diathermy knife can enlarge the opening and free the stone. The procedure may lead to urinary reflux but it is rare for this to cause problems.

Ureteroscopic stone removal. A ureteroscope is a long endoscope which can be passed transurethrally across the bladder into the ureter (Fig. 64.30). The ureteroscope is used to remove stones which are impacted in the ureter. Stones that cannot be caught in baskets or endoscopic forceps under direct vision are fragmented using an electrohydraulic, percussive or laser lithotriptor.

Push bang. A stone that is lying in the middle or upper part of the ureter can often be flushed back into the kidney using a ureteric catheter.
The repositioned calculus is ‘secured’ in the kidney by a J-stent. The patient can then be referred for ESWL.

**Lithotripsy in situ.** Provided the stone is in a part of the ureter that can be identified by the imaging system of the lithotriptor, it can be fragmented *in situ*. This form of treatment is not appropriate if there is complete obstruction or if the stone has been impacted for a long time.

**Open surgery**

Ureterolithotomy. A radiograph should be taken to confirm the position of the stone immediately before surgery.

The incision must be appropriate for the position of the stone. Calculi in the upper third of the ureter are approached through a loin or upper quadrant transverse incision as used for a stone in the renal pelvis. Access to midureteric stones is through a muscle-cutting iliac fossa incision; lower ureteric stones are best reached through a Pfannenstiel incision.

For stones close to the bladder exposure is improved by ligating and dividing the superior vesicle vascular pedicle. The ureter is exposed in the retroperitoneum and slings are applied above and below the calculus to stop it from migrating from the operative field. The ureter is incised longitudinally, directly on to the stone, which is freed from adhesions by blunt dissection, and removed with stone forceps. Soft catheters are passed upwards and downwards to ensure that the ureter is clear. The ureterotomy is closed with interrupted absorbable sutures and a drain left in place for a day or so to drain urine leakage.

**Idiopathic retroperitoneal fibrosis**

This is a rare condition in which one or both ureters become bound up in a progressive fibrosis of the retroperitoneal tissues. The cause is unknown although some cases may be drug related. A similar clinical picture occurs in patients with leaking aortic aneurysm and infiltrating retroperitoneal malignancy.

The patient complains of backache which is unremitting for several months. The onset of anuria and renal failure prompts investigation of the renal tract which reveals hydronephrosis. The excretion urogram typically shows displacement of the obstructed ureters towards the midline and the appearances on CT are diagnostic. The sedimentation rate is markedly raised.

**Treatment.** It may be possible to insert ureteric stents as a temporary measure while renal function recovers. If not, percutaneous nephrostomies will allow the obstructed kidneys to drain. Some patients need renal replacement by dialysis. Some advocate that these patients should be treated conservatively with high-dose steroids. Surgical treatment involves careful dissection of the ureters from their entrapment (ureterolysis). Wrapping omentum around the freed ureters make recurrent obstruction less likely.
Kidney infections *(Table 64.6)*

**Aetiology**

Renal infections arise in the following ways.

- **Haematogenous infection** from a primary site in the tonsils or carious teeth, or from cutaneous infections, particularly boils or a carbuncle. Renal tuberculosis occurs by blood-borne spread from lymph nodes in the neck, chest or abdomen.

- **Ascending infection** in the urinary tract is the most common route, and it is most likely to occur when there is vesicoureteric reflux. Urinary stasis and the presence of calculi are common contributory factors.

**Bacteriology.** *Escherichia coli* and other Gram-negative organisms are commonly responsible. When *Streptococcus faecalis* is present it is usually accompanied by other organisms. In *E. coli* and streptococcal infections the urine is acid. *Proteus* spp. and staphylococci split urea, forming ammonia which makes the urine alkaline and promotes the formation of calculi.
Acute pyelonephritis

Acute pyelonephritis is more common in females, especially during childhood, at puberty, soon after marriage (as a complication of ‘honeymoon cystitis’), during pregnancy and during menopause. It occurs more on the right and is frequently bilateral.

Clinical features

There may be prodromal symptoms of headache, lassitude and nausea but the onset of pain is usually sudden, often with a rigor and vomiting. There is acute pain in the flank and hypochondrium. In a few cases the pain resembles renal colic. The temperature rises to 38.8 or 39.5°C and is remitting. The symptoms of cystitis set in soon after the onset with urgency, frequency and scalding dysuria. On examination, there is tenderness in the hypochondrium and in the loin. Rarely in cases of severe bilateral pyelonephritis, especially when there is an associated obstruction, the damage to renal function may be sufficient to cause uraemia.

Bacteriological examination of the urine

A midstream urine should be collected into a sterile container; the urine is centrifuged and the sediment examined microscopically. In early acute pyelonephritis there are usually a few pus cells and many bacteria. The macroscopic appearance of the urine may be misleadingly clear, until the infection becomes established when the urine is cloudy and full of pus. Culture and sensitivity testing of the causative organisms allows a rational choice of antibiotic, but parenteral treatment with a broad-spectrum antibiotic should be started before the results are available.

Severe cases

There are repeated rigors and the temperature rises to 40°C or more, often without a corresponding rise in pulse rate. There is vomiting, sweating and thirst; the patient feels awful. The blood culture is usually positive, especially if the specimen has been taken during a rigor.

Differential diagnosis

When the symptoms and signs are typical the diagnosis is straightforward. In other circumstances it may be difficult to be sure that the patient does not have pneumonia, acute appendicitis or acute cholecystitis. The urgent need is to distinguish acute pyelonephritis from appendicitis, and the site of pain and the presence of marked peritonism are usually helpful in identifying the latter. A plain abdominal radio-graph may show the outline of a swollen kidney and, if the infection is severe, a skilled ultrasonographer may be able to detect the typical appearances of pyelonephritis.

Pyelonephritis of pregnancy

Pyelonephritis of pregnancy usually occurs between the fourth and sixth month of gestation in women who have a past history of recurrent urinary infection. In about 10 per cent of cases the disease runs a severe and protracted course and occasionally leads to abortion or premature birth.

Urinary infection in childhood

Urinary infection in childhood is important to recognise because it may endanger the function of the growing kidney. In young children, there may be few symptoms but the child passes cloudy or offensive urine. The possibility of urinary sepsis should always be considered if a child fails to thrive, fails to eat or suffers unexplained pyrexia. Pain or screaming on micturition may occur. The older child may complain of loin pain and may develop urinary frequency and nocturnal incontinence.

Up to 50 per cent of children with urinary infection have an under-lying anatomical abnormality. Once the diagnosis has been confirmed by examination of a clean-catch specimen or by a specimen obtained by suprapubic needle puncture, a full urological investigation is essential.

Vesico-ureteric reflux of urine is detectable in about 35 per cent of children with recurrent urinary infection. In some patients the reflux is caused by high pressure in a neurogenic bladder. It may be intermittent and is often more marked when there is active infection. Renal damage results from the combination of reflux and urinary infection early in life and reflux nephropathy is the most common cause of end stage renal failure in the UK. Once the diagnosis has been confirmed by micturating cystography, the urine should be cleared by means of an appropriate antibiotic. Long-term prophylactic antibiotic treatment has become the favoured treatment for recurrent urinary infections resulting from reflux. Surgical reimplantation of the ureters is reserved for those in whom conservative measures fail. Reimplantation in these patients often fails to cure reflux.

Acute pyelonephritis associated with urinary retention

Acute pyelonephritis is a relatively uncommon complication of chronic urinary retention. Often the organisms are introduced during instrumentation and, in the days of unsterile catheterisation, the condition was known as ‘surgical kidneys’. Patients who have significant post-micturition urinary residue should be given prophylactic antibiotics to cover transurethral procedures.

Treatment of acute pyelonephritis

The treatment of acute pyelonephritis should be prompt, appropriate and prolonged. A full investigation to exclude underlying abnormalities in the urinary tract should be undertaken as soon as the attack is controlled.

The patient will usually feel like lying in bed. While awaiting the bacteriological report and the results of sensitivity tests, an antimicrobial with a wide range of activity, such as amoxycillin or gentamicin, should be administered, parenterally if necessary. If the urine is acid, as it is in the common coliform infections, alkalisation of the urine by potassiumcitrate may help by inhibiting the growth of these organisms and relieving dysuria. When pain is severe a morphine-like analgesic drug may be necessary if nonsteroidal anti-inflammatory agents are not effective. The patient should be encouraged to drink copiously; if this is not possible because of nausea and vomiting, an intravenous infusion should be set up.

Most urinary infections acquired outside hospital are sensitive to relatively cheap agents such as trimethoprim and amoxycillin. Hospital-acquired infections are much more likely to be resistant and more expensive second-line antibiotics may be needed. Gentamicin and carbenicillin are suitable for combating infections with more resistant strains of Pseudomonas pyocyanea, Proteus sp. and Klebsiella sp. Ciprofloxacin is particularly useful against Pseudomonas sp. in patients who do not have septicaemia. Despite the efficacy of modern antibiotic drugs, recurrent infection is likely if there is an untreated underlying abnormality of the urinary tract such as a stone,
vesicoureteric reflux or retention of urine.
Chronic pyelonephritis

Chronic pyelonephritis is so often associated with vesico ureteric reflux that some feel that it is better named ‘reflux nephropathy’. It is an important cause of renal damage and death from end-stage renal failure.

Pathology

There is interstitial inflammation and scarring of the renal parenchyma with a patchy distribution. The renal tubules bear the brunt of the destruction they are atrophic and dilated. The glomeruli retain their normal structure until the final stages of the disease.

Clinical features

The condition is almost three times as common in women as it is in men. Two-thirds of affected females are under 40 years of age, whereas 60 per cent of the males are over 40.

It is possible, but unusual, for chronic pyelonephritis to remain clinically silent until the symptoms of advanced renal insufficiency appear. Lumbar pain, dull and nonspecific in character, is present in 60 per cent of cases. Increased urinary frequency and dysuria are common.

Hypertension is present in 40 per cent of cases and may be of the accelerated (‘malignant’) type. It develops slowly and is most in evidence in long-standing disease.

Constitutional symptoms of lassitude, malaise, anorexia, nausea and headache constitute the main complaint in 30 per cent of cases. The true cause of these nonspecific symptoms may elude diagnosis for years.

Pyrexia. Attacks of low-grade fever often prompt the urinary tract investigations which bring the condition to light.

Anaemia. Normochromic anaemia due to unsuspected renal impairment is an occasional presenting feature.

Investigations

As the glomeruli are relatively preserved, proteinuria is less marked than in glomerulonephritis (<3 g daily). Casts are not usually present but white cells are plentiful.

Bacteriological examination of the urine commonly reveals the presence of *E. coli, S. faecalis, Proteus* sp. or *Pseudomonas* sp.

Treatment

Treatment may be difficult and is aimed at eradicating predisposing contributory factors such as obstruction or stones and treating the infection with appropriate antibiotics, often as repeated courses of treatment. Unfortunately, once the parenchyma has been scarred it becomes vulnerable to blood-borne organisms and reinfection is likely, sometimes with a different and resistant organism. Consequently, antibiotics confer only temporary benefit and progressive renal damage is common.

Surgical treatment is only indicated when the disease is confined to one kidney. This is unusual but in such cases nephrectomy or partial nephrectomy may stop the symptoms of infection and make hypertension easier to control. Some patients with end-stage renal failure require renal transplantation.

Hypertension and a unilateral renal lesion

Ischaemia of the renal parenchyma leads to the release of pressor agents which cause arterial hypertension. Where a renal lesion is discovered during the investigation of hypertension, nephrectomy may not bring the pressure to normal but it may make the hypertension more amenable to drug treatment.
Pyonephrosis

The kidney is converted into a multilocular sac containing pus or purulent urine. Pyonephrosis can result from infection of a hydronephrosis, follow acute pyelonephritis or, most commonly, arise as a complication of renal calculus disease. Pyonephrosis is usually unilateral.

Clinical features

The classical triad of symptoms is anaemia, fever and a swelling in the loin. When the condition arises as an infected hydronephrosis, the swelling may be very large and the pyrexia very high and associated with rigors. Symptoms of cystitis may be prominent.

Investigations

The plain radiograph may show a calculus and an ultrasonogram will demonstrate dilatation of the renal pelvis and calyces. The intravenous urogram will show poor function and the features of hydronephrosis on the affected side.

Treatment

Pyonephrosis is a surgical emergency because the patient is threatened with permanent renal damage and a potentially lethal septicaemia. Parenteral antibiotics should be given immediately and the kidney drained. If the pus is too thick to be aspirated through a large percutaneous nephrostomy, it may be necessary to consider open nephrostomy. In cases where there is a stone, the stone should be removed. Nephrectomy may be considered when long-standing obstruction is known to have destroyed the kidney, and function on the other side is good.

Renal carbuncle

An abscess may form in the renal parenchyma as the result of blood-borne spread of organisms, especially coliforms or Staphylococcus aureus, from a focus elsewhere in the body. Occasionally the condition results from infection of a haematoma following a blow to the kidney. Renal carbuncle is most commonly seen in diabetic patients, intravenous drug abusers, those debilitated by chronic disease and patients with acquired immunodeficiency.

Pathology. The renal parenchyma contains an encapsulated necrotic mass.

Clinical features. There is an ill-defined tender swelling in the loin, persistent pyrexia and leucocytosis, signs that closely simulate those of perinephric abscess. In early cases there is no pus or bacteria in the urine but they appear after a day or so. Urography shows a space occupying lesion in the kidney which may be confused with a renal adenocarcinoma on ultrasonography and CT (Fig. 64.31).

Treatment. Resolution by antibiotic treatment alone is unusual. Formal open incision of the abscess may be necessary if the pus is too thick to be drained by percutaneous aspiration.
Perinephric abscess

The common causes of perinephric abscess are shown in Fig. 64.32. Other causes are infection of a perirenal haematoma and perinephric discharge of an untreated pyonephrosis or renal carbuncle. A mycobacterial perinephric abscess may arise by extension from a nearby tuberculosis vertebra.

Clinical features

The classical symptoms and signs of perinephric abscess are a high swinging pyrexia, abdominal tenderness and fullness in the loin (Fig. 64.33). Local signs present early if the infection starts in the lower part of the perinephric fat. Infection at the upper pole is masked by the lower ribs and the signs in the loin are much less marked. The white cell count is always markedly raised but there are characteristically no pus cells or organisms in the urine.

Imaging

The psoas shadow is obscured on the plain abdominal radiograph. There may be a reactionary scoliosis — with the concavity toward the abscess — and elevation and immobility of the diaphragm on the affected side. A calculus may be present. Ultrasonography and CT are diagnostic.

Treatment

Open drainage may be necessary if the abscess cannot be aspirated through a large percutaneous needle. A lumbar incision is made under antibiotic cover. This should be large enough to allow the surgeon to open pockets of pus and to explore for an unruptured cortical abscess which may also be present. A specimen of pus is sent for culture and the wound is closed over a tube drain.
Renal tuberculosis

Aetiology and pathology

Tuberculosis of the urinary tract arises from haematogenous infection from a distant focus which is often impossible to identify. The lesions are usually confined to one kidney. A group of tuberculous granulomas in a renal pyramid coalesces and forms an ulcer. Mycobacteria and pus cells are discharged into the urine. Untreated, the lesions enlarge and a tuberculous abscess may form in the parenchyma. The necks of the calyces and the renal pelvis stenosed by fibrosis confine the infection so that there is tuberculous pyonephrosis which is sometimes localised to one pole of the kidney. Extension of pyonephrosis or tuberculous renal abscess leads to perinephric abscess and the kidney is progressively replaced by caseous material (putty kidney) which may be calcified (cement kidney). At any stage the plain radiograph may show areas of calcification (pseudocalcii). Less commonly the kidneys may be bilaterally affected as part of the generalised process of miliary tuberculosis (Fig. 64.3). Renal tuberculosis is often associated with tuberculosis of the bladder and typical tuberculous granulomas may be visible in the bladder wall. In the male, tuberculous epididymo-orchitis may occur without apparent infection of the bladder.

Clinical features

Renal tuberculosis usually occurs between 20 and 40 years of age, and is twice as common in men as in women; also, the right kidney is affected slightly more often than the left.

**Urinary frequency** is often the earliest symptom and may be the only one. The patient complains that, over a period of months, there has been a progressive increase in both day-time and night time frequency.

**‘Sterile’ pyuria.** In early cases the urine is pale and slightly opalescent. Routine urine culture is negative.

**Painful micturition** is a feature as soon as tuberculous cystitis sets in. First there is a suprapubic pain if voiding is delayed; later a burning pain accompanies micturition. When there is secondary infection a superadded agonising pain referred to the tip of the penis or to the vulva is often associated with haematuria and strangury.

**Renal pain** is often minimal but there may be a dull ache in the loin.

**Haematuria**

In 5 per cent of cases the first symptom is haematuria occurring from an ulcer on a renal papilla. The tuberculous lesion may be difficult to detect radiologically and mycobacteria may not be cultured from the urine until the onset of more suggestive symptoms some months later.

A tuberculous kidney is oedematous and friable and is more liable to damage than a normal kidney.

**Constitutional symptoms** are common. Weight loss is usual and a slight evening pyrexia is typical. A high temperature suggests secondary infection or dissemination, i.e. miliary tuberculosis.

**On examination**

It is unusual for a tuberculous kidney to be palpable. The prostate, seminal vesicles, vasa and scrotal contents should be examined for nodules or thickening.

**Investigation**

**Bacteriological**

Bacteriological examination of at least three full specimens of early morning urine should be sent for microscopy and culture before specific chemotherapy is started. Staining of the urine sediment with the Ziehl—Neilsen stain occasionally shows the presence of acid-fast bacilli but proof that these are pathological mycobacteria must await prolonged culture on Lowenstein—Jensen medium. Where the clinical picture is convincing it is permissible to start antituberculous therapy in anticipation of the culture results which will come some 6 weeks later.

**Radiography**

A plain abdominal radiograph may show the calcified lesions described above.

**Intravenous urography**

In the very earliest stages of the disease the normally clear cut outline of a renal papilla may be rendered indistinct by the presence of ulceration. Later there may be evidence of calyceal stenosis (Fig. 64.35) and/or hydroureteric obstruction caused by stricture of the renal pelvis or the ureter draining the affected kidney; this may be more easily demonstrable by retrograde ureterography (Fig. 64.36). A tuberculous abscess appears as a space-occupying lesion which causes adjacent calyces to splay out. The bladder may appear shrunken with its wall irregular or thickened. In late stages there may be dilatation of the contralateral ureter from obstruction where the ureter passes through a thickened and oedematous bladder wall.

**Cystoscopy**

Cystoscopy is not indicated as a routine part of the investigation of urinary tuberculosis but is often performed because there has been haematuria or unexplained bladder symp-toms. There may be little to see in the first stages of the disease but later the bladder urothelium is found to be studded with granulomas which cluster particularly around the ureteric orifices. The tubercles may coalesce to produce a tuberculous ulcer. As the bladder wall fibroses the bladder capacity decreases. Contraction of the fibrosed ureteric lugs at the ureteric orifice which is displaced upwards, its mouth wide open (the so-called ‘golf-hole’ ureteric orifice).

**Chest radiograph**

A chest radiograph is indicated to exclude an active lung lesion.
**Treatment**

Antituberculous chemotherapy is best managed by a physician with experience of the most modern drug regimens and their potential adverse effects. The surgeon must ensure that the state of the urinary tract is reviewed during the first few weeks of therapy because *stricturing of the renal pelvis and ureter may continue after treatment has started.*

Prognosis in renal tuberculosis is good and there should be no recrudescence of the disease if the patient completes the course of chemotherapy.

**Operative treatment**

Operative treatment should be as conservative as possible. The aim is to remove large foci of infection, which are difficult to treat with drugs, and to correct the obstruction caused by fibrosis. The optimum time for surgery is between 6 and 12 weeks of the start of antituberculous chemotherapy.

The surgeon needs a repertoire of procedures to deal with various potential effects of urinary tuberculosis. An obstructed lower pole calyx may be drained into the upper ureter. A strictured renal pelvis needs a pyeloplasty. Ureteric stenosis and shortening may require a Boari operation or a bowel interposition, depending on the level and extent of the fibrosis. If the kidney has no function it is best to perform a nephroureterectomy (Fig. 64.37). A bladder which is so contracted that it can no longer function as a reservoir for urine may need to be replaced with a neobladder fashioned from a loop of bowel in a *substitution cystoplasty.*
Neoplasms of the kidney (Table 64.7)

Benign neoplasms

Adenoma. Pea-like cortical adenomas are occasionally discovered at post mortem examination or incidentally during radiological imaging. They are asymptomatic and by definition benign.

Angioma may cause profuse haematuria, often in young adults. The source of the bleeding may be difficult to diagnose without renal angiography.

Angiomyolipoma is an unusual tumour of the kidney which is often but not always associated with tuberous sclerosis. Its high fat content gives it a typical appearance on CT. Malignant elements are present in about a quarter of them and may lead to metastasis.

Malignant neoplasms

Benign tumours of the kidney are rare and it is a good rule that all neoplasms of the kidney which are recognised clinically should be treated as malignant. They are uncommon between the ages of 7 and 40.

Renal neoplasms in children

Wilms' tumour (syn. nephroblastoma)

This is a mixed tumour containing epithelial and connective tissue elements arising from embryonic nephrogenic tissue. The tumours are usually discovered during the first 4 years of life. They are normally in one or other pole of one kidney, but bilateral tumours occasionally pose a difficult clinical problem.

Pathology. The cut surface of the tumour is grayish or pinkish white. A rapidly growing tumour is likely to be soft and friable in consistency (Fig. 64.38).

Microscopically the tumour is composed of epithelial and connective tissue cells, occasionally with islands of bone, cartilage and muscle fibre. Some of the elements in this cellular mixture may be less sensitive to radiotherapy than others.

Clinical features.

Abdominal tumour. An abdominal tumour appears which grows rapidly while the general well being of the child deteriorates. The mass may be enormous compared with the tiny patient.

Pyrexia, which is a feature in half of these patients, disappears when the tumour is removed.

Haematuria denotes extension of the tumour into the renal pelvis and the prognosis is not so good.

Imaging by ultrasonography, urography or CT confirms a solid space occupying lesion in the kidney.

Metastasis occurs early, mainly by the bloodstream to the lungs. Liver and bone metastases are rare; and brain metastases even more so. Lymphatic spread is uncommon.

The presence of bone secondaries favours a diagnosis of nephroblastoma, another renal tumour of childhood which is treated in the same way as Wilms' tumour.

Treatment. These children do best when treated in specialist units. Nephrectomy should be performed as soon as possible and followed by radiotherapy with or without chemotherapy. Partial nephrectomy may be possible in patients with bilateral disease.

Prognosis. Under 1 year of age 80 per cent survive for 5years, but the prognosis is less good in older children. Recurrences usually occur within a year, so a child surviving for 18 months or more is probably cured.

Renal neoplasm in adults

Hypernephroma (syn. Grawitz’s tumour)

This is an adenocarcinoma and is the most common neoplasm (75 per cent) of the kidney. It arises from renal tubular cells. Whether carcinoma arises in pre-existing adenomas is a matter for dispute.

Pathology. Moderate sized tumours are spherical and often occupy the poles of a single kidney, most commonly the upper pole. Tumours in the hilum are less common. The cut surface of the tumour is usually yellowish or dull white, semitransparent, with areas of haemorrhage (Fig. 64.39). The tumour is often divided into lobules by fibrous septa, some of which are cystic. Larger tumours are irregular in shape with central haemorrhage and necrosis.

Microscopical structure. The most common pattern is of solid areas of polyhedral or cubical clear cells with deeply stained small rounded nuclei and abundant cytoplasm containing lipids, cholesterol and glycogen. The cells are occasionally arranged as papillary cysts or tubules. Less commonly the cells are granular (dark), and both clear and dark cells may be represented in the same tumour. In all cases the stroma is scanty but rich in large blood vessels.

Spread. The tumour is prone to grow into the renal vein. Pieces of growth are swept into the circulation and end up in the lungs where they grow to form cannonball secondary deposits (Fig. 64.40). Metastasis to bone also occurs and a secondary deposit in a long bone may remain the only sign of distant spread for a year or more. Highly vascular metastases may pulsate. If the tumour extends beyond the renal capsule it is liable to metastasise via the lymph nodes in the hilum of the kidney to the para-aortic nodes and beyond.

Clinical features. Hypernephroma is twice as common in men as in women. Haematuria is usually the presenting symptom, sometimes with clot colic. There may be a dragging discomfort in the loin or the patient may detect a mass. In men, a rapidly developing varicocele is a rare but
impressive sign, occurring most often on the left side because the left gonadal vein is obstructed where it joins the left renal vein.

**Atypical presentations.**

1. In 25 per cent of cases there are no local symptoms. The patient presents with symptoms due to secondary deposits such as a painful enlargement of a long bone (Fig. 64.41), a pathological fracture, persistent cough or haemoptysis.

2. Occasionally persistent pyrexia (37.8—38.9°C) is the only symptom. There is no evidence of infection. Persistence of the pyrexia after nephrectomy suggests the presence of metastases.

3. A small number of patients presents with constitutional symptoms and is found to be extremely anaemic.

4. Polycythaemia occurs in 4 per cent of cases as a result of the production of erythropoietin by tumour cells. The erythrocyte sedimentation rate is always raised above the 1—2 mm found in idiopathic polycythaemia vera. The blood count returns to normal after nephrectomy unless there are metastases. Other hormones, such as renin and calcitonin, may be produced by the tumour. Hyper-calcæmia is common.

5. Nephrotic syndrome has been reported as a rare presentation of hypernephroma.

**Investigation.** *Intravenous urography* is still an important component of the investigation of haematuria. The plain radiograph may show abnormal calcification in the tumour and distortion of the renal outline which will be confirmed on the nephrogram film. The calyces may be stretched and distorted. It is important to know whether the contralateral kidney is working (Fig. 64.42).

**Ultrasound and CT.** Once a mass has been demonstrated in the kidney a scan is needed to decide whether it is solid or cystic. Modern high-definition ultrasound will give this information. CT with enhancement will demonstrate the extent of the lesion more clearly and will show whether there is hilar lymphadenopathy or renal vein involvement (Fig. 64.43).

**Renal angiography** is used less since CT became available. Enthusiasm for preoperative embolisation of hypernephromas has waned. Occasionally a flush inferior cavagram is helpful to show the extent of caval involvement by tumour growing in from the renal vein.

**A chest radiograph** is essential to detect lung secondaries. An isotope bone scan will reveal deposits in the skeleton.

**Treatment.** If the tumour is confined to the kidney treatment is nephrectomy with removal of the perinephric fat.

**Nephrectomy** can be performed through a loin or a transverse or oblique upper abdominal incision. The transabdominal approach has the advantage that the renal pedicle and the inferior vena cava can be widely exposed.

The vascular pedicle should be ligated before the kidney is mobilised because handling the tumour may cause malignant cells to be released into the circulation. The first step in the procedure is to clean the renal artery and ligate it in continuity. This may be more difficult from an anterior approach because the vessel lies behind the vein. However, once the artery is occluded the tumour loses most of its profuse blood supply and massive bleeding during mobilisation becomes less likely. The renal vein should be gently palpated to be sure that it does not have tumour in its lumen. If it is empty, it can be divided between ligatures. The renal artery is then divided and the kidney mobilised within its fascial and fatty coverings. Troublesome bleeding can still occur when aberrant vessels feeding the tumour are divided, and these must be carefully ligated or coagulated. The ureter is then traced downwards as far as is safe and divided between ligatures.

If the renal vein or the inferior vena cava is invaded the surgeon must obtain control of the cava above and below as a first priority. If there is extension into the thorax, the cardiac team may be needed to put the patient on cardiac bypass so that tumour can be removed from the right side of the heart if necessary.

Adenocarcinoma of the kidney does not respond well to radiotherapy or conventional chemotherapy. There have been early promising results from clinical trials of the cytokine interleukin-2 in this condition.

**Prognosis.** Removal of even the largest neoplasm may cure the patient. In operable cases 70 per cent of patients are well after 3 years and 60 per cent after 5 years. Macroscopic involvement of the renal vein or its tributaries, tumour invasion beyond the capsule and lymph node involvement all worsen the prognosis. These resemble those of the bladder but are much less common. They tend to invade the renal parenchyma and have a tendency to distant spread. There is a strong tendency for the tumours to be multifocal. Seeding down the lumen of the urinary tract may give rise to multiple ureteric tumours, but the condition is thought to arise from a field change which renders the whole urothelium liable to metaplasia. Whether the carcinogen is chemical or viral is uncertain in most cases.

**Clinical features.** Haematuria is the most common symptom and usually causes the patient to seek help before the tumour mass becomes palpable.

**Urine cytology.** Examination of the urine for the presence of malignant cells may indicate whether the tumour is well or poorly differentiated. There is some evidence that those with poorly differentiated tumours do better if they have a short course of radiotherapy before surgery. It is therefore useful to obtain cells from the tumour by sampling using a brush or catheter passed up the ureter under radiological control.

**Intravenous urography** usually demonstrates the tumour (Fig. 64.45). Retrograde pyelography may be helpful if the urogram is indistinct.

**Treatment.** Conventional surgical treatment is by nephroureterectomy. The ureter must be disconnected with a cuff of bladder wall. If this is done by open surgery a second incision is needed to remove the kidney. Alternatively, the ureteric orifice can be widely resected with a resectoscope and the ureter delivered by a somewhat perilous blunt dissection from the upper abdominal wound used to remove the kidney. Thispluck operation is not for the inexperienced. Some urologists argue that well-differentiated upper urinary tract transitional tumours should be treated conservatively like superficial bladder tumours. However, percutaneous resection of these cancers is controversial and steps must be taken to avoid the growth of tumour seeded in the percutaneous track.

**Squamous cell carcinoma of the renal pelvis**

This is rare and often associated with chronic inflammation and leucoplaakia resulting from stone. The tumours are radiosensitive but metastasise at an early stage and the prognosis is poor.

**Transitional cell tumours of the ureter**
These are rare. They behave like tumours of the renal pelvis. Treatment is by nephroureterectomy.

About one half of patients with tumours of the upper urinary tract will have tumours in the bladder at some stage. Follow-up by cystoscopy with regular urography is therefore necessary to detect recurrent tumours.

**Balkan nephropathy.** Transitional cell tumours of the upper urinary tract have a very high incidence in certain areas of the former Yugoslavia. They also have a high incidence of a form of primary nephropathy. The causative agent has not been identified with certainty but there seems to be an association with the consumption of grain products stored in a damp environment. Tumours which develop against a background of Balkan nephropathy should be treated by conservative surgery in view of the impaired overall renal function.

**Nephrectomy for benign disease**

Nephrectomy is now rarely performed for benign disease but may be necessary if the kidney is atrophic or dysplastic or the cause of accelerated hypertension. Nonfunctioning kidneys resulting from longstanding obstruction or stone disease are a potential site for infection and even malignancy. Because they do not excrete they cannot be properly seen on an excretion urogram and it is often wisest to perform a **simple nephrectomy.** In a simple nephrectomy the kidney is dissected free though the convenient plane between the capsule and its fatty coverings. If this plane is obscured by the scarring of previous surgery a **subcapsular nephrectomy** may be safer. **Laparoscopic nephrectomy** is sometimes possible for small kidneys destroyed by benign disease but the technique requires special skills and the costs and benefits are under evaluation.

Surgical anatomy and physiology

Surgical anatomy

• Lined by transitional epithelium which covers a connective tissue known as the lamina propria

• The fibres of the detrusor smooth muscle are intermingled and not arranged in distinct layers

• When the detrusor hypertrophies from bladder outlet obstruction, neurological bladder dysfunction or detrusor instability, the fasciculi of the inner layer, covered by urothelium, stand out to give rise to the endoscopic and radiological appearance of trabeculation

• Lining the trigone is a separate, thin layer of smooth muscle to which the epithelium is closely adherent and which extends as a sheath around the lower ureters and also passes into the proximal urethra

• Around the male bladder neck is the smooth muscle internal sphincter which fulfills a sexual function, it is innervated by alpha-adrenergic fibres and prevents retrograde ejaculation

• The distal sphincter is a horseshoe-shaped mass of striated muscle which lies anterior and distal to the prostate or proximal two-thirds of the female urethra

• The distal sphincter is a somatic, striated muscle, quite distinct from the pelvic floor and is supplied by S2—S4 fibres via the pudendal nerve and also by somatic fibres passing directly through the inferior hypogastric plexus

Fascial and ligamentous supports of the bladder

Several parts of the surrounding pelvic fascia are of surgical importance. Posteriorly, there are condensations of the endopelvic fascia which are continuous with the lateral ligaments of the rectum; these pass forward medial to the ureter to join with the fascia surrounding the prostate: these sheets of fascia need to be divided during radical cystectomy. The anterior puboprostatic ligaments are well defined, are condensations of the anterior part of the endopelvic fascia and are of great surgical importance. Each stretches from the front of the prostate to the lower part of the peristome of the pubis. They lie lateral to the dorsal vein complex of the penis and in their deep parts are closely adherent to large veins. When they are divided it is important to stay laterally and very close to the peristome of the pubis.

The urachus and obliterated hypogastric arteries, together with the folds of peritoneum overlying these structures, are called the false (median and lateral umbilical) ligaments of the bladder. Condensations of fascia around the blood vessels passing to the bladder are known as the superior and inferior vascular pedicles.

Arteries

The superior and inferior vesical arteries are derived from the anterior trunk of the internal iliac artery. Branches from the obturator and inferior gluteal arteries (and in the female from the uterine and vaginal arteries) also help to supply the bladder.

Veins

The veins form a plexus on the lateral and inferior surfaces of the bladder; in the male the prostatic plexus is large and continuous with the vesical plexus, which drains into the internal iliac vein.

Lymphatics

These accompany the veins, and drain into the lymph nodes along the internal iliac vessels and thence to the obturator and external iliac chains. Some lymphatics pass to nodes which are situated posterior to the internal iliac artery lying directly on the sacral fascia.

Physiology (Fig. 65.1)

The nerves concerned in micturition are as follows.

The parasympathetic input

This innervation is the most important component and is derived from the anterior primary divisions of the second, third and fourth sacral segments (mainly S2 and S3). These fibres pass through the pelvic splanchnic nerves to the inferior hypogastric plexus, from which they are distributed to the bladder. The pelvic plexus is easily damaged during excisions of the rectum, following which disturbances of micturition and sexual function may occur.

The sympathetic input

These nerves arise in the 11th thoracic to the second lumbar segments. These fibres pass via the presacral hypogastric nerve and the sympathetic chains to the inferior hypogastric plexus, which is situated lateral to the rectum, and thence to the bladder.

Somatic innervation

A somatic innervation also passes to the distal sphincter mechanism via the pudendal nerves and also via fibres which pass through the inferior hypogastric plexus without synapsing to the distal sphincter.

The sympathetic nerves convey afferent painful stimuli following overdistension of the fundus. Other afferents arise from the mucosa where they respond to touch, temperature and pain, and also from the muscle of the detrusor and lamina propria where they convey stretch information. These afferents pass via the inferior hypogastric plexus to the posterior roots of S2—S4. Efferent fibres pass via the pelvic para-sympathetics. Normal micturition is co-ordinated in the pons in the midbrain where detrusor contraction is timed with inhibition of the distal sphincter mechanism. Interruption of this pathway with preservation of the function of the sacral cord is therefore likely to result in a contractile detrusor but with a tonically active distal sphincter mechanism which does not relax during voiding (detrusor-sphincter dyssynergia).
**Ectopia vesicae (syn. exstrophy of the bladder)**

This is thought to be caused by the incomplete development of the infra-umbilical part of the anterior abdominal wall, associated with incomplete development of the anterior wall of the bladder owing to delayed rupture of the cloacal membrane.

**Clinical features of ectopia vesicae**

- One in 50,000 births (four male: one female)
- Characteristic appearance (Fig. 65.2) because of the pressure of the viscera behind it
- Edges of abdominal wall can be felt
- Umbilicus is absent

*In the male* the completely epispadiac penis is broader and shorter than normal, and bilateral inguinal herniae may be present; the prostate and seminal vesicles are rudimentary, whereas the testes are normal and have usually descended.

*In the female* the clitoris is bifid and the labia minora are separated anteriorly, exposing the vaginal orifice. In both sexes, there is separation of the pubic bones (Fig. 65.3), which are connected by a strong ligament. This bony defect causes no disability and subsequent delivery is normal. The linea alba is also broad. In the rare, incomplete form of penile epispadias or female epispadias, the pubes are united and the external genitalia are almost normal, although in the female the clitoris is bifid (Fig. 65.4).

**Treatment**

*Iliac osteotomy, closure of the bladder and closure of abdominal wall*

In the first year of life, the bladder is closed following osteotomy of both iliac bones just lateral to the sacroiliac joints. Later reconstruction of the bladder neck and sphincters is required. In some patients, the reconstructed bladder remains small and requires augmentation.

Another option is urinary diversion which may be necessary if continence is poor following bladder reconstruction. This can be done by means of a ureterosigmoid anastomosis or the formation of an ileal conduit, colonic conduit or continenturinary diversion. Long-term complications are frequent after ureterosigmoidostomy. These include: (1) stricture at the site of anastomosis with bilateral hydronephrosis and infection; (2) hyperchloraemic acidosis; and (3) there is an increased risk (20-fold) of tumour formation (adenomas aid adeno-carcinoma) at the site of the ureterocolic anastomosis.
Rupture of the bladder

This may be intraperitoneal (20 per cent) or extraperitoneal (80 per cent) (Figs 65.5 and 65.6). Intraperitoneal rupture may be secondary to a blow, kick or fall on a fully distended bladder and it is more common in the male than in the female, and usually follows a bout of beer drinking. More rarely, it is due to surgical damage. Extraperitoneal rupture is usually caused by a fractured pelvis or is secondary to major trauma or surgical damage.

Intraperitoneal rupture

• Sudden, agonising pain in the hypogastrium, often accompanied by syncope
• The shock later subsides and the abdomen commences to distend
• No desire to micturate
• Varying degrees of abdominal rigidity and abdominal distension are present on examination
• No suprapubic dullness, but there is tenderness
• There may be shifting dullness
• If the urine is sterile, symptoms and signs of peritonitis are delayed

Extraperitoneal rupture

In many cases of pelvic trauma, this is difficult to distinguish from rupture of the membranous urethra. This injury is dealt with in Chapter 66 on ‘The prostate and seminal vesicles’.

Confirming a suspected diagnosis of intraperitoneal rupture

• Plain X-ray in the erect position may show the ground-glass appearance of fluid in the lower abdomen
• Intravenous urography (IVU) may confirm a leak from the bladder
• A peritoneal ‘tap’ may be of value if facilities for radiological examination are not available
• If doubt still exists and if there is no sign of fracture then retrograde cystography can be performed safely. With careful asepsis a small [14 French gauge (FG)] catheter is passed. Usually some blood-stained urine will drain. A solution made from 60 ml of 35 per cent Hypaque® or Conray® with 120 ml of sterile isotonic saline is injected into the bladder and radiographs are taken (Fig. 65.7)

Treatment of intraperitoneal rupture

The mainstay is to provide adequate drainage of the bladder. The standard treatment is to perform a lower midline laparotomy, urine is removed by suction, after which the patient is placed in Trendelenberg’s position. The edges of the rent, which are usually situated in the posterior part of the dome of the bladder, are trimmed and sutured with two layers of interrupted catgut stitches, and the operation completed by placement of a suprapubic and urethral catheter. The peritoneum should be irrigated with copious amounts of warm saline. Very rarely, the bladder will rupture through an unsuspected tumour and it is perhaps wise in atypical cases to take a biopsy before suturing the defect.

Wounding of the bladder during operation

Operations in which the bladder is liable to be injured are: (1) inguinal or femoral hemirotomy; (2) hysterectomy by either the abdominal or vaginal route; and (3) excision of the rectum. In the latter two operations, the bladder should be catheterised prior to operation to minimise the risks of this accident. If the injury is recognised at the time, the bladder must be repaired in two layers and urethral catheter drainage maintained for 7 days. If it is not recognised, the treatment is similar to that of rupture of the bladder.

When accidental perforation of the bladder occurs during endoscopic resection of a bladder tumour, or the prostatic capsule is perforated during transurethral prostatectomy, the perforation is usually extraperitoneal. When the accident is recognised at the time, drainage of the bladder with a large urethral catheter and the administration of antibiotics usually suffice. If, however, a mass of extravasated fluid is palpable per abdomen it is best to place a small drain into the extra-peritoneal perivesical space through a small stab incision. A laparotomy will usually be required if an intraperitoneal perforation is caused by transurethral resection of a large bladder tumour on the dome of the bladder.
Retention of urine

Retention of urine is either acute or chronic, the latter leading ultimately to retention-with-overflow (see Chapter 66 on ‘The prostate and seminal vesicles’).

Acute retention

The most frequent causes of acute retention

- In the male:
  - Bladder outlet obstruction
  - Urethral stricture
  - Postoperative
- In the female:
  - Retroverted gravid uterus
  - Multiple sclerosis
- In the male child:
  - Meatal ulcer with scabbing
- Other causes:
  - Spinal anaesthesia
  - Acute urethritis or prostatitis
  - Blood clot in the bladder
  - Urethral calculus
  - Rupture of the urethra
  - Phimosis
  - Neurogenic (injury or disease of the spinal cord)
  - Smooth muscle cell dysfunction associated with ageing
  - Faecal impaction
  - Anal pain (haemorrhoidectomy)
  - Intensive postoperative analgesic treatment
  - Certain drugs

Clinical features

Clinical features of acute retention urine

- No urine passed for several hours
- The bladder may be visible and is tender to palpation (Fig. 65.8) and dull to percussion
- Rarely, a prolapsed lumbar disc causing a cauda equina lesion will be the cause — exclude this by checking the reflexes in the lower limb and perianal sensation

Treatment

In most patients, the correct treatment is to pass a fine urethral catheter (14 FG — French gauge is defined as the circumference in millimetres) and to arrange further urological management. Occasionally, a patient with postoperative retention may pass urine if he or she is sedated and placed in a warm bath. If the patient gives a good history of bladder outflow obstruction there seems little point in attempting conservative measures and a catheter should be passed; this should be carried out using full aseptic technique. Following a thorough wash of the hands and arms, sterile gloves should be donned. The external genitalia are gently cleaned using soapy antiseptic solution (Savlon®). A tube of local anaesthetic (Lidothesin®) is then carefully inserted down the urethra (Figs. 65.9, 65.10, 65.11 and 65.12) warning the patient that this will create a stinging sensation, but if the jelly is injected slowly through the plastic nozzle it should cause no pain. The jelly should be massaged well posteriorly in the urethra in an attempt to anaesthetise the sphincter and prostatic urethra, and it is of advantage to place a penile clamp for 10 minutes. A small (12—14 FG) Foley self-retaining catheter should then gently be passed down the urethra while the penis is held taut. In a female patient, the labia should be parted using the middle and index finger of the left hand, which should not be moved once the cleaning process has been performed to prevent contamination. Providing a stricture is not the cause of the retention, the catheter should normally pass freely into the bladder. Once urine begins to drain down the catheter it is wise to pass a few more centimetres of catheter into the bladder before the self-retaining balloon is inflated to avoid inflation of the balloon in the prostatic urethra. Force should not be necessary. Occasionally, a large obstructing middle lobe of the prostate may prevent a simple catheter entering the bladder; in this instance a coudé catheter should pass without difficulty. The bladder is then allowed to drain and the catheter attached to a closed drainage system. In the male, if the catheter will not pass into the bladder, it is usually due to poor technique, lack of anaesthesia, traumatisation of the urethra or because there is a urethral stricture. The usual reason is that the local anaesthetic has not been left long enough.

If, after a reasonable attempt with catheters, the bladder has not been entered, the following plan should be pursued according to circumstances.

Suprapubic puncture. Suprapubic puncture with commer-cially available catheters such as Cystofix® or a ‘Bonnano’ catheter is straightforward provided that the bladder is palpable. If such devices are not available a lumbar puncture needle or an Abbocath® is a useful method of relieving acute retention when catheterisation has failed. However, if the bladder is allowed to refill after it has been punctured, leakage into the prevesical space may follow

The best plan is to place a suprapubic catheter after anaesthetising the skin, the fascia and the retro pubic space with 0.5 per cent lignocaine. Correct placement of the needle can be confirmed by aspiration of the bladder. A large-bore needle is then placed, down which a fine catheter is passed (Cystofix) and secured in position by suturing. The other option is to place a plastic suprapubic trochar and cannula which has a removable plastic strip on the side so that a standard 12 FG Foley catheter can be passed down it, the balloon inflated, the strip pulled off and the plastic cannula pulled away from the catheter (Addacath).

If these devices are not available, a catheter can be placed in the bladder under direct vision through a small incision under local anaesthetic, although this has nothing to recommend it if percutaneous devices are available.

Urethral instrumentation. In a patient with a known urethral stricture, an experienced urologist may elect to dilate the stricture or the patient may be taken to theatre, a urethroscopy carried out, the stricture divided using a urethrotome under direct vision and a urethral catheter placed
Whenever the bladder is catheterised for urinary retention it is important to record the volume drained and to examine the patient’s abdomen a few minutes after the procedure to exclude some other intra-abdominal pathology. Conditions such as rupture of an aortic aneurism, ureteric colic or inflamed colonic diverticula can cause confusion as they present with a low urine output (mistaken as retention) and abdominal pain.

**Chronic retention**

**Chronic retention**

- Chronic retention differs from acute retention in that the distension of the bladder is almost painless.
- These patients are at risk of upper tract dilatation because of the high intravesical tension due to the large residual urine and the high resting bladder pressure.
- Men with chronic retention owing to bladder outlet obstruction require urgent referral for prostatectomy.
- Those with a serum creatinine level greater than 200 micro-mol/litre are at risk of developing a postobstructive diuresis following catheterisation and may need careful monitoring with replacement of inappropriate urine losses by intravenous saline; they are also at risk of haematuria as the previously distended urinary tract suddenly shrinks. Slow decompression by means of intermittent spigotting of the catheter does not prevent haematoma.

**Retention with overflow**

In this condition the patient has no control of his or her urine, small amounts passing involuntarily from time to time from a distended bladder. It may follow a neglected acute retention or chronic retention.

Retention with overflow is referred to also under ‘incontinence’ and ‘prostatic enlargement’. The general principles which govern the treatment of this condition are similar to those of acute retention.

**Indwelling catheters and closed systems of catheter drainage**

The incidence of ascending infection following catheterisation is decreased by connecting the catheter (urethral, suprapubic or perineal) to sterile tubing connected to a sterile collecting bag and employing irrigations only if clot retention occurs (Fig. 65.13). When a catheter has been in situ for 5 days or more some degree of urethritis and bacteriuria is likely. Changing a catheter in the presence of active urethritis entails a risk of severe infection spreading from the anterior to the posterior urethra and thence to other parts of the urogenital system — not to mention the risk of bacteraemia, sepsicaemia and abscess formation elsewhere. In such patients, the change of catheter should be covered by appropriate prophylactic antibiotics.

**Special forms of retention of urine**

**Postoperative retention of urine**

Retention of urine can occur after any operation, but is common after operations on the anal canal and perineal region. After operations on the pelvic viscera, retention of urine is so common (sometimes owing to damage to the pelvic autonomic plexus or to nonspecific causes) that it is usual to forestall it by inserting a catheter before or at the conclusion of the operation.

When the patient is an elderly male, prostatic obstruction, hitherto latent, should be suspected. Many patients cannot urinate while lying or sitting in bed. In a heavily sedated patient, urinary retention may be missed and patients may suffer from severe over-distension of the bladder which can result in long-term impairment of voiding function. This is particularly common after hip replacement in elderly patients as there may be reluctance to catheterize them.

**Treatment.** First of all, reassure the patient and provide privacy. If the male patient, while supported, is permitted to sit on the edge of his bed he is often able to empty his bladder. The sound of running water is often helpful. When circumstances permit, a warm bath is often helpful. If after a reasonable trial patients cannot pass urine they must be catheterised temporarily.

**Acute retention due to drugs**

A number of drugs is prone to induce or precipitate retention of urine. Antihistamine drugs, antihypertensive drugs, anticholinergics and tricyclic antidepressants may be responsible for producing acute retention of urine.

**Management of the neuropathic bladder**

Immediately after a spinal cord injury, spinal shock occurs (see Chapter 33 on ‘The spine’), which may last for days, weeks or even months, and in this state the detrusor is paralysed, the bladder distends and overflow incontinence will occur. This will lead to damage to the detrusor muscle, infection and ultimately renal failure. Management is as follows.

1. The bladder must be kept empty either by intermittent catheterisation with an aseptic technique performed two or three times daily, or by the use of an indwelling urethral catheter on continuous drainage and making sure that the patient has a high urinary output (3 litres/day) to combat infection. Currently, the use of intermittent catheterisation is preferred as soon as the patient can be moved when the spinal injury is stable.

2. The upper level of the neurological lesion must be assessed by the level of sensory and motor loss. Ischaemic necrosis of the cord may extend a variable distance below the upper level of cord injury. Where sensory loss below the upper level of cord injury is total, recovery is unlikely. Incomplete lesions, in contrast, may recovery somatic and bladder function.

3. Demonstration of intact bulbocavernosus and anal reflexes indicates that the sacral cord and nerves are intact. In such circumstances reflex bladder contractions are likely to develop, although they may be insufficient to empty the bladder completely. If these reflexes are absent and there is persistent total loss of perineal sensation it means that either the sacral cord or cauda equina is damaged. In such circumstances an acontractile bladder is likely to develop. In cauda equina lesions there may be sensory, motor or mixed loss.

4. Full urodynamic assessment of bladder function should be undertaken when the injury is stable (see below). A urodynamic study allows
accurate assessment of detrusor and sphincter activity, and the sensation. Various aspects of bladder function can be checked including adequacy of bladder emptying, bladder capacity, pressure during filling and continence related to the extent and level of neurological damage. Many types of bladder dysfunction can occur.

The results of these studies should enable decisions to be made as to the further management of the bladder, the prime aim being to prevent upper tract damage by promoting good bladder emptying and to avoid infection. The following situations represent only the typical pattern of bladder function.

Lesions above cord segment T10

The common situation is an upper motor neuron bladder with all reflexes intact but isolated from higher control and inhibition. Such patients are at risk of autonomic dysreflexia.

Emptying. The bladder is usually contractile, but because co-ordinated inhibition of the distal sphincter mechanism does not occur (detrusor-sphincter dyssynergia), the contractions are often high pressure and ineffective in producing complete bladder emptying. The bladder neck is normally open in these patients. If left untreated, the upper tracts suffer at the hands of the chronically full bladder and raised intravesical pressure. Hydronephrosis and renal failure may result.

Capacity. This is usually decreased after some years with the development of trabeculation and a typical ‘fir-tree’ appearance of the bladder. The bladder pressure is often increased and demonstrates marked phasic increases as the bladder tries to contract and empty against the spastic sphincter mechanism.

Control. The patients are incontinent during the high-pressure phasic contractions because the sphincter resistance suddenly diminishes, allowing urinary leakage.

The treatment of these patients depends on urodynamic assessment. Constant vigilance is required, a watch being kept for hydroureter. This may be done by serial intravenous urography (IVU) or ultrasound scanning. Regular follow-up urodynamic investigations are necessary. The patient with complete bladder emptying and reasonable capacity with normal upper tracts may be managed by means of condom drainage. The patient with incomplete bladder emptying and good capacity may be managed by means of clean intermittent catheterisation (CISC). Patients with poor emptying, low capacity and upper tract dilatation require additional treatment. This may range from endoscopic sphincterotomy and condom drainage in the male, which will allow complete bladder emptying at low pressure, to complete bladder reconstruction with bladder substitution using intestinal segments and the fitment of artificial urinary sphincters, depending on the mobility and motivation of the patient and available services.

Lesions involving the sympathetic outflow, T11 T12, L1, L2

These patients are usually similar to the above group, but may have increased outflow resistance. alpha-Adrenergic blockers may help.

Damage to the sacral centre S2, 3, 4 and cauda equina lesions

This is essentially a lower motor neuron bladder.

Emptying. The detrusor is acontractile because there is injury to the parasympathetic innervation. Abdominal straining and pressure on the bladder through the abdominal wall can produce reasonable emptying in some patients. Nowadays, the mainstay of management is the use of clean intermittent self-catheterisation popularised by Lapides (CISC), which involves the patient passing themselves a clean, but not sterile, catheter 2 or 3 hourly to ensure adequate bladder emptying. Some patients may have a sensation of filling through the hypogastric nerves if T11 and T12 are intact.

Capacity. The bladder capacity may be good, but these patients may have high resting bladder pressures and high tonic increases during bladder filling, which means that if bladder emptying is incomplete there is a risk to the upper urinary tract. The bladder neck is usually open and the distal sphincter mechanisms may be paralysed, but the fixed urethral resistance prevents good bladder emptying by means of straining. Vesico-ureteric reflux is common and upper tract damage is frequent in neglected cases.

Control. Patients who can achieve satisfactory bladder emptying by means of CISC usually have reasonable continence.

Persistent retention of urine following excision of the rectum or radical hysterectomy

10 to 15 per cent of patients undergoing radical rectal excision for cancer sustain damage to the inferior hypogastric plexus leading to incontinence in the male and neurogenic bladder dysfunction. This type of bladder dysfunction is similar to the cauda equina lesion, but the pressures during filling tend to be greater, leading to more incontinence and a greater risk to the upper tracts. Postoperative retention in other patients is simply caused by bladder outlet obstruction. The best plan is to catheterise the patient with a 14 Fr silicone catheter, to allow a period for postoperative recovery, and then carry out a urodynamic investigation which will distinguish these two conditions. One requires treatment by means of prolonged CISC, while the other will respond well to transurethral prostatectomy.
Incontinence of urine

Normal urinary continence is dependent on several factors. These include normal mobility and normal brain function allowing a perception of when it is socially acceptable to void, normal bladder sensation, normal voluntary detrusor contraction producing good bladder emptying, a normally competent sphincter mechanism which relaxes appropriately during a voluntary detrusor contraction allowing good bladder emptying and good bladder capacity with normally low pressures during filling. This is clearly a fine balance and several factors can cause incontinence.

In the diagnosis of urinary incontinence, a careful history and physical examination may help, but it will be necessary to carry out urodynamic testing in most patients if surgical intervention is proposed. The urine should be cultured to exclude infection and the serum creatinine should be measured. It may be appropriate to have anatomical visualisation of the urinary tract by means of IVU if one suspects a ureteric fistula, although ultrasound examination will often provide adequate details.

Urodynamic testing

The key to the practical management of lower urinary tract dysfunction lies with urodynamic investigation. The principle is artificially to simulate bladder filling and emptying whilst obtaining pressure measurements (Fig. 65.14).

The patient attends with a full bladder and is allowed to void in private to measure maximum urinary flow rate. After voiding, the residual urine is measured by means of ultrasound to assess the completeness of bladder emptying. Urodynamic testing involves the aseptic passage of a small pair of catheters or a twin-lumen catheter into the bladder; this allows the bladder to be filled with saline or contrast medium at a rate of 50 ml/minute whilst a continuous recording of the intravesical pressure is made via a transducer. To obtain true detrusor pressure, a second pressure channel is required to assess intra-abdominal pressure which is usually measured by means of a small intrarectal or intravaginal balloon. The bladder is filled until the patient states that their bladder is full. Screening by means of radiographic imaging may be carried out to assess bladder neck closure, and urinary leakage during voiding or during bouts of phasic detrusor pressure (detrusor instability). The patient is then asked to void at the end of bladder filling after the filling catheter has been removed.

Usefulness of urodynamic testing

- Distinguishing genuine stress incontinence (due to sphincter weakness) from detrusor instability in women (Fig. 65.15)
- Classification of neurogenic bladder dysfunction
- Distinguishing bladder outflow obstruction from idiopathic detrusor instability in men
- Investigation of incontinence

The normal bladder will accept approximately 400—550 ml when filled with saline at room temperature at filling rates of 50 ml/minute. The pressure increase in the bladder should be less than 15 cmH2O. In addition, phasic pressure increases should not be seen. The normal voiding pressure should not exceed 60 cmH2O in men and about 40 cmH2O in women, with a flow rate of between 20 and 25 ml/second.

Common abnormalities identified during urodynamic testing in incontinence

- Phasic increases giving rise to sensations of urgency of micturition and urge incontinence (detrusor instability; Fig. 65.16). This abnormality is found in patients with several types of neurogenic bladder dysfunction such as multiple sclerosis (MS), Parkinson’s disease, or following a stroke or certain types of spinal injury when it is known as detrusor hyperreflexia. In addition, about 50 per cent of men with bladder outflow obstruction have detrusor instability, and in about half of these men the instability resolves after prostatectomy. Idiopathic detrusor instability is common and must be distinguished from genuine stress incontinence in women before performing bladder neck suspension procedures.

- Genuine stress incontinence is defined as urinary leakage occurring during increased bladder pressure when this is solely due to increased abdominal pressure and not due to increased true detrusor pressure (Fig. 65.15). It is caused by sphincter weakness.

- Chronic urinary retention with overflow incontinence. This is recognised by a large residual volume of urine (Fig. 65.17) and is usually associated with high pressures during bladder filling.

- Bladder outflow obstruction, which is associated with increased voiding pressures often being in excess of 90 cmH2O (Fig. 65.18), coupled with low urinary flow rates.

- Neurogenic bladder dysfunction.

Causes of incontinence

There are various ways of classifying causes of incontinence. A good functional method is as follows.

- **Problems of social control** — patients with Alzheimer’s disease, Parkinson’s disease or multi-infarct dementia often have urinary incontinence owing to a combination of uninhibited detrusor hyperreflexia and impaired social perception.

- **Storage problems** — patients with a small capacity owing to fibrosis from tuberculosis or interstitial cystitis can develop incontinence. Patients with a small functional capacity owing to severe idiopathic detrusor instability, neurogenic bladder dysfunction or urinary infection also can develop incontinence.

- **Severe impairment of emptying** — patients with chronic retention or some types of neurogenic bladder dysfunction often have small functional bladder capacities with detrusor overactivity causing incontinence, despite having large residual volumes of urine.

- **Weak sphincter** — patients with genuine stress incontinence owing to previous prolonged labour or with damage to the distal sphincter mechanism secondary to prostatectomy or with neurogenic bladder dysfunction often have impaired sphincter function which leads to stress incontinence. Congenital causes such as epispadias also result in sphincter weakness.

- **Fistulae** — leakage from fistulae or upper tract duplication with an ectopic ureter.

The common causes may be classified into male, female or mixed sex groups.
Male

Chronic urinary retention with overflow. This is a common cause of incontinence and may be due to benign prostatic hypertrophy, carcinoma of the prostate, urethral stricture and, in younger men, hypertrophy of the bladder neck. The key to the diagnosis lies with the history of prolonged hesitancy and a poor urinary stream with both daytime and nocturnal ‘dribbling incontinence’ coupled with the finding of a distended bladder. Examination may reveal that the bladder is visibly distended, the transverse suprapubic crease is lost and the painless distension of the bladder may be palpated or percussed. It may easily be diagnosed by means of ultrasound measurement of residual urine volume. The treatment is discussed in Chapter 66.

Postprostatectomy. Postprostatectomy incontinence may result from injury to the external sphincter mechanism which may be caused by clumsy surgery — urodynamic evaluation will demonstrate genuine sphincter weakness. The other cause of incontinence is idiopathic detrusor instability, although such patients often have significant irritative symptoms prior to prostatectomy and should be identified and investigated by means of urodynamic studies prior to prostatectomy.

Female

Stress incontinence. The commonest cause of leakage of urine in women is genuine stress incontinence (GSI), although in some parts of the world vesicourethral fistulae owing to neglected labour are very common. GSI occurs sec-ondary to weakness of the distal sphincter mechanism associated with laxity of the pelvic floor. It is usually found in multiparous women with a history of difficult labour often accompanied by the use of forceps. It can be found in normal young women who indulge in competitive trampolining and also in patients with epispadias. The classical symptoms are complaints of urinary loss during coughing, laughing, sneezing or sudden change of posture. The symptoms may change with the menstrual cycle. The volume of urine loss can be measured during an exercise test which is performed by putting the patient through a standard set of tests with 300 ml of fluid in the bladder; in GSI the fluid losses usually range from 10 to 50 ml. Urinary frequency and urgency are, however, often found in such patients as they try to avoid incontinence by frequent voiding.

Idiopathic detrusor instability can closely mimic GSI and indeed can coexist with it. It is important to make a correct preoperative diagnosis by urodynamic measurements, as the outcome of surgery is significantly worse in women with idiopathic detrusor instability.

Minor degrees of stress urinary incontinence often can be controlled by means of teaching the patient a series of pelvic floor exercises. However, if this fails then surgery is indicated. The best standard operation is the Butch colposuspension.

This operation is carried out with the patient in the Lloyd-Davies position through a Pfannenstiel incision. The vaginal fascia is identified by sweeping the bladder off the vagina and three sutures are placed on each side between the vaginal fascia and the iliopectine ligament. A suprapubic catheter is placed. The operation corrects minor degrees of cystocele. Voiding difficulties are frequent, but usually temporary. It is best to warn women with large bladder capacities and low voiding pressures that this complication may occur and that they may require to carry out CISC for a period. The operation is very successful in the treatment of GSI with 90 per cent 1-year good results, which are maintained in about 80 per cent at 5 years. Endoscopic needle bladder neck suspension can now be carried out, but is less successful than open operation.

Common to both sexes

Idiopathic detrusor instability (DI). This condition is very common. Phasic increases in bladder pressure may occur during filling in otherwise normal patients (idiopathic) or it may be found in several conditions including neurogenic bladder dysfunction (then known as detrusor hyperreflexia) and bladder outflow obstruction. Idiopathic detrusor instability may be symptomless, but usually results in symptoms of frequency, urgency, urge incontinence, nocturia or nocturnal incontinence (enuresis) depending on the severity of the instability. It must be distinguished from GSI and from bladder outflow obstruction as colposuspension or prostatectomy have poor results in patients with severe idiopathic DI. Most urologists will want to exclude infection, tuberculosis or carcinoma in situ by urine culture, cytological examination, cystoscopy and confirmation of the diagnosis by means of urodynamic investigation. The mainstay of treatment is the use of various anticholinergic medication (propantheline, oxybutinine, tolterodine, and amitryptiline). Severe symptoms resistant to conventional conservative treatment resulting in major impairment of quality of life may need more aggressive treatment such as enterocystoplasty.

Ageing. In both sexes ageing can result in smooth muscle cell dysfunction that can cause combinations of small functional capacities, detrusor instability, impaired bladder emptying and symptoms of lower urinary tract dysfunction.

Congenital. Ectopic vesicae and severe epispadias. The abnormal entry of an ectopic ureter distal to the sphincter complex or into the vagina in a female should theoretically result in total urinary incontinence. This is discussed in Chapter 62.

Trauma. Trauma, whether from pelvic surgery or asso-ciated with pelvic fracture, may result in disruption of the nerve supply to the bladder or urethra or in fistula formation.

Infection. Simple lower urinary tract infection may be sufficient, particularly in a woman, to induce urinary incon-tinence. A history of frequency, burning and a fever should prompt the diagnosis. The bladder may be tender whether palpated suprapubically or per vaginum. Symptoms will usually settle with a course of antibiotics, but in the case of recurrent infection further investigation of the urinary tract will clearly be indicated.

Neoplasia. Locally advanced cancers in the pelvis, partic-ularly carcinoma of the cervix in a woman and prostate in a man, may result in direct invasion of the sphincter mechanism causing incontinence; occasionally, fistula formation may occur in women.

Other causes

Neurogenic incontinence

This has been dealt with in the previous section. The common causes include:

• myelodysplasia;
• multiple sclerosis;
• spinal cord injuries;
• cerebral dysfunction [cerebrovascular accident (CVA), dementia);
• Parkinson’s disease (paralysis agitans).

These conditions lead to a combination of neurogenic vesical dysfunction often associated with loss of mobility. Careful investigation of the whole urinary tract is always required, and the treatment needs to strike a fine balance between preventing hydronephrosis from abnormally high bladder pressures yet at the same time maintaining continence.

The mainstay of management is accurate urodynamic assessment to assess bladder emptying, incontinence and the risks to the upper tract. The upper tracts should be assessed with regular ultrasound scanning, and assessment of the patient’s mobility, intelligence and motivation is vital. The important factors to assess urodynamically are:

- bladder emptying;
- bladder capacity and bladder pressure during filling;
- continence.

The standard way of dealing with impaired bladder emptying is the use of CISC. Occasionally, in an elderly immobile patient an indwelling urethral or suprapubic catheter or an ileal conduit external urinary diversion may be justified, or the performance of an endoscopic sphincterotomy followed by the use of a condom appliance should be considered.

Patients with a small functional bladder capacity (< 150 ml), a high-pressure increase during filling (> 25 cmH2O) and a large residual volume of urine are at high risk of developing upper tract dilatation, and in the past would have undergone endoscopic sphincterotomy. However, there have been major changes in the management of mobile, well-motivated patients with impaired bladder emptying or with high-risk bladders. Such treatment will often involve major bladder reconstruction with replacement of the high-pressure bladder with a low-pressure substitute made of a detubularised bowel segment, often accompanied by surgery to the bladder outflow using artificial urinary sphincters or a colposuspension. Such treatment will usually need to be accompanied by the patient carrying out CISC afterwards.

Small bladder capacity

The capacity of the bladder may be considerably diminished in several conditions. This can cause crippling urinary frequency and incontinence. It may follow tuberculosis, radio-therapy or interstitial cystitis. Radiotherapy for pelvic cancer can also cause this problem.

Drug-induced incontinence

The detrusor muscle is basically under postganglionic parasympathetic control and the main neurotransmitter system is cholinergic. Recent studies have established the presence of a number of neurotransmitters including alpha adrenergic fibres in the region of the bladder neck and other neuropeptides, whose function is uncertain as yet, are present throughout the bladder. A number of drugs can induce urinary retention (anticholinergic agents, tricyclic antidepressants, lithium and some antihypertensives). Overflow incontinence may ensue. Drugs giving extrapyramidal side-effects may induce urinary frequency and incontinence, for example phenothiazine.

Constant dribbling of urine coupled with normal micturition

This occurs when there is a ureteric fistula or an ectopic ureter associated with a duplex system opening into the urethra beyond the urethral sphincter in females, or into the vagina. The history is diagnostic, and intravenous pyelography or ultrasound scanning may reveal the upper pole segment which is often poorly functioning. These segments are very liable to infection. Treatment is by excision of the aberrant ureter and portion of kidney which needs it. A ureteric fistula can be difficult to diagnose and may require retrograde ureterography and a high degree of suspicion to demonstrate.

Nocturnal enuresis

This is a condition of young children and young adults. The time at which children become dry at night varies, of course, and in some of them it is merely a delayed onset of continence. In others it persists until late adolescence and is classified into primary and secondary nocturnal enuresis.

Primary nocturnal enuresis occurs in patients with nocturnal enuresis alone and with no daytime symptoms. Often, they have been dry for a period and the vast majority of patients will eventually become dry. In the meantime a sympathetic approach to these children is essential. They often respond to a system of rewards using a ‘star’ chart. In addition, the use of DDAVP (vasopressin analogues) can produce increased urinary concentration at night with a decrease in nocturnal incontinence. Other treatments include the use of amitriptyline and alarms which wake the child (or at least the child’s parents) when incontinence occurs.

Patients with secondary nocturnal enuresis have daytime symptoms of urinary frequency, urgency and urge incontinence. Essentially, these patients have idiopathic detrusor instability and should be treated in a similar way (see subsection on ‘Treatments for incontinence’).

Treatments for incontinence

Treatments are listed below. Management is dependent on making a correct working diagnosis. The treatment depends on the cause. The aim is to keep the patient dry, free of odour, to lessen the incidence of skin excoriation, and to protect the kidneys from the effects of infection and back pressure.

Management and treatment

Problems of social functioning. Patients with Alzheimer’s disease, Parkinson’s disease and multi-infarct dementia are difficult to treat. Often these patients will respond to regular toileting. Anticholinergic agents can cause confusion in these patients and often, in severe cases, an indwelling catheter is needed.

Storage problems. Patients with a small capacity owing to fibrosis may require augmentation cystoplasty. Patients with a small functional bladder capacity owing to detrusor over-activity from neurogenic bladder dysfunction or idiopathic detrusor instability should be tried on
anticholinergic medication, but in severe cases, particularly in neuropathic patients at high risk of upper tract dilatation, bladder substitution (near-total supratrigonal cystectomy followed by the need for detubularised ileocaecal segment bladder substitution) or augmentation (enterocystoplasty) may be needed. These procedures should only be carried out after careful assessment in units used to dealing with these problems. Patients with very impaired mobility and MS may require ileal conduit diversion.

**Impaired bladder emptying.** Patients with overflow incontinence owing to bladder outflow obstruction will respond well to prostatectomy, after an initial period of catheterisation to allow bladder and renal function to recover to some extent. Patients with impaired bladder emptying owing to neurogenic bladder dysfunction should be treated in the first place by means of CISC.

**Weak sphincter.** Patients with genuine stress incontinence owing to previous prolonged labour should be treated by means of pelvic floor exercises or colposuspension. Those with post-prostatectomy incontinence or with neurogenic bladder dysfunction may require fitment of an artificial urinary sphincter (Fig. 65.19) if they are well motivated and mobile.

**Leakage from fistulae or upper tract duplication with an ectopic ureter.** This will require the appropriate surgical treatment.

**Appliances in women are usually unsatisfactory. In elderly, immobile or mentally impaired patients, an indwelling catheter drained constantly into a leg urinal is usually a satisfactory solution, although in some instances diversion via an ileal conduit is necessary. In men, a condom urinary appliance may be satisfactory, and can avoid an indwelling catheter.

**More major surgical treatments**

Various types of urinary diversion. This may be required for the treatment of end-stage incontinence that is not otherwise treatable (see later in this chapter).

**Bladder substitution procedures.** The principle behind these operations is the creation of a low-pressure, large capacity reservoir. These can be made using any segment of bowel isolated on its vascular pedicle (Figs 65.20, 65.21, and 65.22). This is then detubularised by dividing its antimesenteric border and suturing this into a plate. This can then be re-configured into a spherical structure. This reservoir can then be anastomosed to the bladder remnant after excision of the fundus above the trigone. If necessary, the ureters can be re-implanted into the bowel segment. This new bladder (Fig. 65.23) will almost certainly need to be emptied by means of intermittent self-catheterisation (CISC).

**‘Clam’ enterocystoplasty.** This procedure was originally described by Bramble for the treatment of nocturnal enuresis. It is now being used more frequently in the treatment of idiopathic detrusor instability. It involves the isolation of a 16-cm segment of ileum on its vascular pedicle. This is divided on its antimesenteric border and sutured into the opened out bladder. The bladder is divided along a circumference from bladder neck at 3 o’clock to 9 o’clock in the coronal plane (Fig. 65.24). This procedure can also be used as an augmentation procedure in patients with neurogenic bladder dysfunction and a reasonable preoperative bladder capacity (approximately 300 ml).

**Fitment of artificial urinary sphincter.** See Fig. 65.19.

Bladder stones

Definition

A primary bladder stone is one that develops in sterile urine; it often originates in a kidney and passes down the ureter to the bladder, where it enlarges.

A secondary bladder stone occurs in the presence of infection, bladder outflow obstruction, impaired bladder emptying or a foreign body such as nonabsorbable sutures, metal staples or catheter fragments.

Incidence

Until the twentieth century, bladder stone was one of the most prevalent disorders among the poor, and the incidence was especially high in childhood and adolescence. Owing to improved diet, especially an increased protein—carbohydrate ratio, primary vesical calculus is rare in Western society—particularly among children.

Composition and cystoscopic appearance

Most vesical calculi are mixed but have one component in excess, and assume the appearance of that variety.

Oxalate calculus is a primary calculus that grows slowly. Usually, it is of moderate size and is solitary. Its surface is uneven (mulberry type); sometimes it bristles with spines (Fig. 65.25). Although calcium oxalate is white, the stone is usually dark brown or black because of the incorporation of blood pigment on to it.

Uric acid and urate calculi are round or oval, fairly smooth, and vary in colour from pale yellow to light brown; they may be single or multiple (Fig. 65.26). They may occur in patients with gout, but are also found in patients with ileostomies or with bladder outflow obstruction.

Cystine calculus occurs only in the presence of cystinuria and is radio-opaque owing to its high sulphur content.

Triple phosphate calculus is composed of ammonium, magnesium and calcium phosphates, and occurs in urine infected with urea-splitting organisms. It tends to grow rapidly. In some instances, it occurs on a nucleus of one of the foregoing types of calculus; much more rarely on a foreign body (Figs 65.27 and 65.28). In others, the nucleus is composed of desquamated epithelium and bacteria. It is dirty white in colour and of chalky consistency.

A bladder stone is usually free to move in the bladder. It gravitates to the lowest part of the bladder which is the outflow when the patient is erect or sitting. In the recumbent position (and at cystoscopy) the stone occupies a position behind the interureteric ridge. Less commonly, the stone is wholly or partially in a diverticulum where it may be hidden from view.

Clinical features

Males are eight times more often affected than females. It may be asymptomatic and found incidentally during cystoscopy before a prostatectomy is carried out.

Symptoms

Frequency is the earliest symptom, although it is often more common during the daytime. There may be a sensation of incomplete bladder emptying.

Pain (Strangury) is most often found in patients with a spiculated oxalate calculus. It usually occurs at the end of micturition and is referred to the tip of the penis or to the labia majora, more rarely to the perineum or suprapubic region. The pain is worsened by movement. In young boys, screaming and pulling at the penis with the hand at the end of micturition are indicative of bladder stone.

Haematuria is characterised by the passage of a few drops of bright red blood at the end of micturition, and is due to the stone abrading the vascular trigone — a fact that also accounts for the pain.

Interruption of the urinary stream is due to the stone blocking the internal meatus and may develop into acute retention of urine which occurs infrequently in adults.

Symptoms of urinary infection. Urinary infection is a common presenting symptom.

Examination

Rectal or vaginal examination is usually normal, occasionally a large calculus is palpable in the female.

Examination of the urine usually reveals microscopic haematuria, pus or crystals typical of the calculus, for example envelope like in the case of an oxalate stone, or hexagonal plates with cystine calculi.

Radiography — in most patients, the stone is visible on a plain X-ray (Fig. 65.29). If the stone is radiolucent, a filling defect may be visualised on IVU. Radiographs of the whole of the urinary tract should be taken to exclude upper tract stone.

Cystoscopy is essential and most stones nowadays can be dealt with endoscopically. Frequently, on introducing the sheath of the cystoscope, a significant ‘click’ will be felt when a free lying stone comes in contact with the instrument.

The whole of the bladder should be inspected: basal or generalised inflammation may be seen. In men with bladder outflow obstruction endoscopic resection of the prostate should be performed at the same time as the stone is dealt with.

Treatment

In most patients, the cause of the underlying stone should be sought and treated. This may include bladder outflow obstruction plus infection and incomplete bladder emptying in patients with neurogenic bladder dysfunction. In most patients, treatment can be delivered endoscopically.
Litholapaxy

Historically, the blind lithotrite ([Fig. 65.30]) was an early type of minimally invasive technique. Other methods include the optical lithotrite and the electrohydraulic probe or ultrasound probe ([Fig. 65.31]). Nevertheless, the blind lithotrite is still a satisfactory instrument in the right hands for the treatment of a large, hard stone. Other devices include the stone punch which is useful to crush small fragments further so that they can be evacuated with an Ellik evacuator.

Contraindications to perurethral litholapaxy are given below.

- **Urethral:**
  - A urethral stricture that cannot be dilated sufficiently
  - When the patient is below 10 years of age
- **Bladder:**
  - A contracted bladder
- **Stone characteristics:**
  - A very large stone

**Technique.** The patient should receive appropriate antibiotics treatment before operation. The major advantage of the blind lithotrite is that, because of its solidity and strength, harder stones can be crushed than is the case with the optical instrument. A cystoscopic lithotrite, stone punch or stone loop enables the stone or stone fragments to be seized under vision. To carry out litholapaxy, the bladder is filled with about 200—300 ml of saline and the instrument is introduced with its obturator in place so that its closed jaws point downwards. After irrigation of the bladder and insertion of the telescope, the stone is seen. The distal blade is hooked over the centre of the stone and grasped. After withdrawing the telescope slightly to prevent damage to the optics, the screw is turned slowly, breaking the stone. Large fragments are crushed into small ones by repeating the manoeuvre. With the jaws closed the lithotrite is rotated so that the jaws point upwards, and after removing the telescope and allowing the saline and stone fragments to escape, the instrument is withdrawn. The use of an Ellik evacuator is necessary to ensure complete removal of all stone fragments.

**Mechanohydraulic lithotripsy**

The lithoclast generates energy by purely mechanical means using a steel ball which is fired in a closed chamber at the proximal end of the endoscopic probe. Also, an energy source is generated between paired or concentric electrodes. With repeated discharges, the stone is broken into small pieces. The probes come in two or three sizes and it is sensible to use the largest (9 F) for bladder calculi. The patient is cystoscoped and the probe placed close to the stone, but away from the end of the telescope, and fired. It is important not to damage the bladder wall by discharging the electrode on the mucosa. A newly developed device

**Evacuation of the fragments.** Fluid (200 ml) is introduced into the bladder. The evacuator, filled with solution, is fitted on to the sheath. The bulb is compressed slowly and then permitted to expand. The returning solution carries with it fragments of stone which sink into the glass receptacle. Alternate compression of the bulb and aspiration is continued until no further fragments fall. The beak of the cannula is turned to the left and to the right, and suction is applied in these situations. After checking that no fragments are left in the bladder, a Foley catheter is introduced and left in situ for 24 hours.

**Suprapubic lithotomy**

The alternative to litholapaxy is removal of the stone through a suprapubic incision, after which the bladder is closed and drained by a urethral catheter.

**Percutaneous suprapubic litholapaxy**

It is possible to insert a needle into the bladder and then pass a guide wire. As in percutaneous nephrolithotomy, Alken metal dilators can be passed over the guidewire to dilate the track, an Amplatz sheath is inserted and a large-bore nephroscope can be inserted. This is the best method to use if it is not possible to carry out litholapaxy per urethram because of a narrow urethra.

**Extracorporeal shock wave lithotripsy (ESWL)**

These devices can be used in the treatment of bladder calculi, but if the stone is large endoscopic litholapaxy is preferable.

**Removal of a retained Foley catheter**

This is not an uncommon problem and is usually caused by the channel which connects the balloon to the side arm becoming blocked, usually at the very distant end. The best way of dealing with this problem is to further inflate the balloon with 20 ml of water and then burst the balloon percutaneously using a spinal needle under ultrasound screening. The instillation of fluid such as ether to dissolve the balloon is not recommended because fragments of balloon may be left behind. However the balloon is burst, it is important to subsequently cystoscope the patient to ensure that any fragments are removed before they can form a foreign body calculus.
Foreign bodies in the bladder

The commonest foreign body is a fragment of catheter balloon (see above). The variety of foreign bodies which have been removed from the bladder is astonishing, for example manicure stocks, hair clasps, hairpins and candle wax. Occasionally, a foreign body enters through the wall of the bladder, for example nonabsorbable sutures used in an extra-vesical pelvic operation. The diagnosis rests on cystoscopy, and in the case of radio-opaque foreign bodies on radiography.

Complications of a foreign body in the bladder

• Lower urinary tract infection

• Perforation of the bladder wall

• Bladder stone

Treatment

A small foreign body can usually be removed per urethram by means of an operating cystoscope. Occasionally, a suprapubic approach using the percutaneous insertion of a cystoscope is needed.
Diverticula of the bladder Definition

The normal intravesical pressure during voiding is about 35—50 cmH2O. Pressures as great as 150 cmH2O may be reached by a hypertrophied bladder endeavouring to force urine past an obstruction. This pressure causes the mucous lining between the inner layer of hypertrophied muscle bundles to protrude, so forming multiple saccules. If one or more, but usually one, saccule is forced through the whole thickness of the bladder wall, it becomes a diverticulum (Fig. 65.32). Congenital diverticula are due to developmental defect.

Aetiology of diverticulum

- **Congenital diverticulum** — This is rare. It may be situated in the mid line anterosuperiorly and represent the unobliterated vesical end of the urachus. It empties with the bladder and is symptomless. Others in the usual situation on the base of the bladder can occur without obstruction, and may require excision because of the risk of chronic infection or stone formation in a young adult.

- **Pulsion diverticulum** — the usual causative obstructive lesion is bladder outflow obstruction.

Pathology

Usually the mouth of the diverticulum is situated above and to the outer side of one ureteric orifice. Exceptionally, it is near the midline behind the interureteric ridge. The size varies from 2 to 5 cm, but may be larger. It is lined by bladder mucosa and the wall is composed of fibrous tissue only (com-pare traction diverticulum). A large diverticulum enlarges in a downward direction and sometimes may obstruct a ureter—probably because of peridiverticular inflammation.

Complications

Most patients who develop a small bladder diverticulum secondary to bladder outflow obstruction develop no symptoms after the prostate is resected. The presence of a diverticulum per se is not an indication for open resection and surgical treatment.

**Recurrent urinary infection**

As the pouch cannot empty itself there remains a stagnant pool of urine within it. Once infected, the infection persists. In long standing cases, peridiverticulitis causes dense adhesions between the diverticulum and surrounding structures. Squamous cell metaplasia and leucoplakia are infrequent complications.

**Bladder stone**

This develops as a result of stagnation and infection. The stone often protrudes into the bladder.

Hydronephrosis and hydroureter

This is extremely rare and is a consequence of peridiverticular inflammation and fibrosis.

**Neoplasm**

Neoplasm arising in a diverticulum is an uncommon complication (< 5 per cent). The prognosis is dependent on the stage of the tumour (see a later section).

Clinical features

An uninfected diverticulum of the bladder usually causes no symptoms. The patient is nearly always male (95 per cent) and over 50 years of age.

There are no pathognomonic symptoms; they are those of lower urinary tract obstruction, recurrent urinary infection and pyelonephritis. Haematuria (due to infection, stone or tumour) is a symptom in about 30 per cent. In a few patients, micturition occurs twice in rapid succession (the second act may follow a change of posture).

Cystoscopy

This is the usual means of discovering the diverticulum. Most often its orifice is seen as a clear-cut hole about 5 mm in diameter, the depths of which are black and un-illuminated (Fig. 65.33). With inadequate distension of the bladder, the mouth of the diverticulum is closed with epithelium thrown into radiating pleats (Fig. 65.34). Full distension of the bladder is needed if searching for a diverticulum.

Intravenous urography

IVU may give information regarding the size of the diverticulum.

Retrograde cystography

In practice, this is only used during a video urodynamic investigation which may have been carried out in the investigation of voiding dysfunction. This test will also give information about the emptying characteristics of the bladder and diverticulum.

Ultrasoundography

A diverticulum may be detected during an ultrasound scan carried out to measure the residual urine after voiding (Fig. 65.35).

Indications for operation

Operation is only necessary for the treatment of complications. Provided the diverticulum is small and the associated outflow obstruction has been dealt with, there is no reason to resect the diverticulum. Even a large diverticulum may not require treatment in the absence of infection or other complications.

Preoperative treatment
When the urine is infected, suitable preoperative antibiotic treatment is given. In the presence of gross sepsis and retention of urine, it is necessary to resort to an indwelling urethral catheter for a period.

**Combined intravesical and extravesical diverticulectomy**

This is the standard operation. Cystoscopy is performed, a ureteric stent is passed up the ureter on the affected side, as damage or devascularisation of the ureter is the most common serious complication. The anterior bladder wall is exposed through a suprapubic incision, the peritoneum is displaced upwards and the side of the bladder bearing the diverticulum is cleared from surrounding structures until the pouch is identified. The bladder is then incised in the mid-line and the diverticulum is packed with a strip of gauze. Usually the neck of the diverticulum can be separated from the ureter and when the pouch is free it is severed from its attachment to the bladder with a diathermy knife. The resulting defect is closed in two layers. A suprapubic catheter is left in place and an extravesical drain is inserted.

An alternative method, if the sac is densely adherent, is to carry the incision in the bladder down to the rim of the diverticular orifice, then to detach the diverticulum, together with its fibrous rim. The incision in the bladder is closed and the diverticulum left in position with a corrugated drain into it for 2—3 days. The track fibroses rapidly after removal of the drain.

If bladder outlet obstruction is part of the picture, prostatectomy should be carried out at the same time as the diverticulectomy.

**Traction diverticulum (syn. hernia of the bladder)**

A portion of the bladder protruding through the inguinal or femoral hernial orifice occurs in 1.5 per cent of such herniae treated by operation(Fig. 65.36).
Urinary fistulae

A urinary fistula is an abnormal communication between any part of the urinary system and the skin or some internal hollow viscus. The persistence of a fistula on the skin implies the presence of distal obstruction or the presence of chronic infection, such as tuberculosis, or a foreign body, such as a stone or nonabsorbable ligature.

Congenital urinary fistula

- Ectopia vesicae;
- from a patent urachus — the presence of a urinary leak from the umbilicus present at birth or commencing soon after suggests this diagnosis. In adult life infection in a urachal cyst may produce a fistula and adenocarcinoma may occur (Figs 65.37 and 65.38).

Treatment is by means of excision of the urachal tract and closure of the bladder once distal obstruction has been excluded;

- in association with imperforate anus (see Chapter 61).

Traumatic urinary fistula

Perforating or penetrating wounds, damage not recognised during surgery, or poor healing and avascular necrosis following a combination of radiotherapy and surgery may lead to fistula formation. Also, clot retention occurring after a transvesical prostatectomy or diverticulectomy may lead to dehiscence of the bladder wound and a temporary fistula, which will heal quickly, provided the bladder is kept empty with an indwelling catheter.

Vesicovaginal fistula

This is a common condition which rapidly leads to loss of morale and serious social disruption in countries where surgical treatment is not readily available.

A etiology

- Obstetrics — the usual cause is protracted or neglected labour;
- Gynaecological — the operations chiefly causing this complica-tion are total hysterectomy and anterior colporrhaphy;
- Radiotherapy — the main cause is radiotherapy used in the treatment of carcinoma of the cervix; to a lesser extent external beam irradiation of the pelvic viscera for other reasons is responsible;
- Direct neoplastic infiltration — exceptionally, carcinoma of the cervix ulcerates through the anterior fornix to impli-cate the bladder.

When a wound of the bladder is recognised and repaired at once, leakage is uncommon, but escape of urine will quickly follow if such damage passes unnoticed. However, most vesicovaginal fistulas are the result of ischaemic necrosis of the bladder wall due to prolonged pressure of the foetal head in obstetric cases. In gynaecological cases, the ischaemia is brought about by grasping the bladder wall in a haemostat, including the bladder wall in a suture, or perhaps even by local oedema or haematoma. Leakage due to necrosis of tissue seldom manifests itself before 7 days after the operation.

An intractable fistula following radium treatment of carcinoma of the cervix uteri may arise from avascular necrosis years after the apparent cure of the original lesion.

Clinical features

There is leakage of urine from the vagina and as a consequence excoriation of the vulva occurs. Digital examination of the vagina may reveal a localised thickening on its anterior wall, or in the vault in the case of posthysterectomy fistula. On inserting a vaginal speculum, urine will be seen escaping from an opening in the anterior vaginal wall. It is usually possible to pass a bent probe from the vagina into the bladder. Cystoscopy may be difficult, owing to the contraction of the bladder from cystitis and the escape of urine from the fistula. However, usually the tip of the probe that has been passed can be seen emerging through an area of granulation tissue.

Differential diagnosis between a ureterovaginal and vesicovaginal fistula can be made if a swab is placed in the vagina and a solution of methylene blue is injected through the urethra; the vaginal swab becomes coloured blue if a vesico-vaginal fistula is present. With the advent of good, portable X-ray image intensifiers, a cystoscopy and bilateral retrograde ureterograms provide a more reliable demonstration of the anatomy. Ureterovaginal fistula is discussed in Chapter 62. An IVU should be performed to exclude a coincidental ureterovaginal fistula. Usually it demonstrates some upper tract dilatation owing to partial obstruction.

Treatment

Just occasionally, conservative management of a vesicovaginal fistula following hysterectomy by urethral bladder drainage is successful. Usually, operative treatment is required and the traditional teaching has been to delay surgery for some months. This has recently been questioned. The low fistula (subtrigonal) is best repaired per vaginam. The fistula is exposed with dissection of the edges which are freshened. The bladder is then closed using absorbable sutures and the vagina subsequently closed with a separate layer. A urethral catheter should be left in situ for at least 10 days. For the higher (supratrigonal) fistula, a transvaginal approach can be extremely difficult. These patients should always be cystoscoped prior to a repair procedure and bilateral ureterograms performed as occasionally one of the ureters is also involved. For the high fistula, a suprapubic approach is the best method in most hands. The Pfannenstiel incision should be re opened, the bladder should be dissected free from the peritoneum and bisected posteriorly in the midline down to the level of the fistula. The bladder is then separated from the vagina and, occasionally, careful dissection from the rectum is also required. The vagina is then closed with a heavy catgut suture and omentum brought down to lie between the closed vagina and the bladder anteriorly. This is lightly sutured in place and the bladder then closed. A urethral and suprapubic catheter should be left in situ for 10—14 days.

For the patient with a ureterovaginal fistula, an extraperitoneal approach to the ureter via the previous Pfannenstiel incision is made. Considerable adhesions will be encountered but the ureter can usually be found above the level of the injury and followed down. Fibrosed or strictured ureter should be discarded and then reimplantation into the bladder is required. Depending on the amount of ureter lost, it may be possible to achieve a simple reimplantation with a psoas hitch procedure. If the gap is too large to be bridged by this manoeuvre, a Boari flap of anterior bladder wall should be cut and brought over to meet the ureter and a reimplant performed. The most important principle of ureteric
reimplantation is that there should be no tension on the anastomosis. Results from these repairs need to be good as a failure will cause despair and further enrage the already litigious patient.

**Fistula from renal pelvis to skin or gut**

Tuberculosis of a kidney may result in caseation and a chronic sinus leading to duodenum, colon or skin in the iliac fossa or lumbar triangle. Similarly, a pyonephrosis may spontaneously discharge into the gut or on to the skin. Cases of duodenal ulcer involving the pelvis of the right kidney and Crohn’s disease involving either renal pelvis or ureter, or cases of xanthogranulomatous pyelonephritis may cause fistulae.

**Fistulae arising as a result of infection**

The commonest cause is diverticulitis of the colon. They may also follow Crohn’s disease, appendix abscess or pelvic sepsis in association with acute salpingitis, or may be the result of surgery and radiotherapy within the pelvis.

The onset may not be dramatic and may well be treated as a simple urinary infection. The diagnosis can be difficult to make, but on cystoscopy a patch of oedema on the left side of the vault is suggestive and bubbles of gas may be seen (Fig. 65.39). A cystogram may reveal the fistula. However, as the track is not always patent the test may be negative. A contrast enema may be helpful not only to demonstrate the fistula, but also to define the cause. The passage of gas *per urethram* in a patient is most suggestive (provided that diabetes resulting in urinary infection with a gas-forming organism is excluded).

**Treatment**

In most patients, a single-stage operation is indicated provided that the surgeon is experienced in colonic surgery. In some cases, a defunctioning colostomy is made above the fistula as the first step and inflammation is allowed to subside over 2—3 months. At laparotomy, the communication is separated, the hole in the bladder being closed and patched with omentum, and the segment of diseased bowel resected; the main feature is to ensure that the left colon, and if necessary the splenic flexure, is fully mobilised to facilitate a tension free, well-vascularised anastomosis. The bladder is drained by a urethral catheter. The colostomy is closed several weeks later provided that a barium enema reveals no leaks.

**Cases due to carcinoma**

By the time a fistula between the bowel and the bladder has developed the tumour is usually locally advanced, but may be operable.

**Urethral fistulae**

These occur as the result of infection above a stricture producing a para urethral abscess which ruptures into the urethra, allowing extravasation to occur suddenly into the scrotum and perineum. Urine and infection extend into the upper 2.5 cm of thigh and lower abdominal wall. Wide-spread cellulitis and tissue necrosis (which may lead to Fournier’s gangrene) may occur unless drainage of urine is achieved by suprapubic cystostomy, and the tissue planes are freely drained by inguinal and scrotal incisions.

**Neoplastic fistulae**

Primary bladder tumours very rarely fungate through the abdominal wall unless an open cystotomy has been performed without further treatment, such as low dose irradiation being performed to cut down the risk of wound implantation. Only palliative treatment is possible in most of such cases. Involvement of the bladder by tumours of cervix, uterus, colon and rectum can produce fistulae, as may lymphosarcoma of the small gut. Carcinoma of the prostate rarely produces a rectal fistula. Treatment in most such cases is difficult and prolonged, and in most only palliative relief can be given. It is rarely in the patient’s interest to carry out urinary diversion, although minimally invasive techniques such as placement of ureteric stents can be helpful in palliating symptoms.
Lower urinary Infection and cystitis

Infection of the bladder gives rise to symptoms of frequency, urgency, suprapubic discomfort, dysuria and cloudy offensive urine. These symptoms are often known as ‘cystitis’. Lower urinary tract infections (UTI) are much more common in women than in men, particularly in the under 50s. Recurrent lower urinary infection occurs in some healthy women after intercourse, without any demonstrable abnormality of the urinary tract. Repeated attacks of UTI in women, or a single attack in a man or a child of either sex, should always be followed by investigation to discover and treat the predisposing cause; sometimes, however, no cause can be found. Asymptomatic bacteriuria is found commonly (in approximately 5—10 per cent of cases), particularly in women, and investigation may fail to demonstrate any underlying cause.

Predisposing causes

• Incomplete emptying of the bladder which may be secondary to bladder outflow obstruction caused by prostatic obstruction, urethral stricture or meatal stenosis, bladder diverticulum, neurogenic bladder dysfunction or decompensation of the detrusor muscle.

• The presence of a calculus, foreign body or neoplasm.

• Incomplete emptying of the upper tract caused by dilatation of the ureters associated with pregnancy or vesico ureteric reflux. In childhood, the mainstay of treatment of vesicoureteric reflux is antibiotic therapy; operation is reserved for those with recurrent infection despite antibiotics or severe upper tract dilatation.

• Oestrogen deficiency which may give rise to lowered local resistance.

• Colonisation of the perineal skin by strains of *Escherichia coli* expressing molecules that facilitate adherence to mucosa.

Avenues of infection

*Ascending infection* from the urethra is the commonest route (see Chapter 66). The organisms originate in the bowel, contaminate the vulva and reach the bladder because of the shortness of the female urethra. The passage of urethral instruments may cause urinary infection in either sex, especially when the bladder contains residual urine. This happens because it carries organisms from the urethra into the bladder (Fig. 65.40).

Other routes are less common. These include: *descending* from the kidney (tuberculosis), *haematogenous spread*, *lymphogenous* and from *adjoining structures* (fallopian tube, vagina or gut).

Bacteriology

*Escherichia coli* is the commonest organism, followed by *Proteus mirabilis, Staphylococcus epidermidis* and *Streptococcus faecalis*. Infection with other organisms or mixed organisms is found in patient with neurogenic bladder dysfunction or those with a long-standing indwelling urethral catheter. These organisms include *Pseudomonas, Klebsiellae, Staphylococcus aureus* and various streptococci. Tuberculous infection is considered below. The presence of pus cells without organism calls for repeated examination for *Mycobacterium tuberculosis* and *Neisseria gonorrhoeae*. Having eliminated these possibilities, the underlying condition may be abacterial cystitis, carcinoma *in situ*, renal papillary necrosis, stones or incomplete treatment of a urinary infection.

Clinical features

Symptoms

The severity of the symptoms varies greatly.

**Frequency.** This occurs during the day and night, it may occur every few minutes and may cause incontinence.

**Pain.** Pain varies from mild to severe. It may be referred to the suprapubic region, the tip of the penis, the labia majora or the perineum.

**Haematuria.** The passage of a few drops of blood-stained urine or blood-stained debris at the end of micturition is a frequent accompaniment. Less often the whole specimen is blood stained.

**Pyuria.** This is usually present.

Examination

On examination there is tenderness over the bladder. Initial and midstream urine specimens should be collected in a male as acute prostatitis may be present (see below) which will lead to threads in the initial specimen. The midstream specimen must be subjected to microscopy and culture, and the sensitivity of any organisms assessed.

Treatment

Treatment should be commenced forthwith, and modified if necessary when the bacteriological report is to hand. The patient is urged to drink. Appropriate first-line antibiotics include trimethoprim, amoxycillin or one of the quinolones. Failure to respond indicates the necessity for further investigation to exclude predisposing factors.

Investigation

Cystoscopy. This is not necessary in the acute phase.

**Other investigations.** These include measurement of urinary flow rates and post-void residual urine. An IVU will usually be carried out together with cystoscopy. Difficult cases may require urodynamic investigation.
Special forms of lower urinary tract infection

Acute abacterial cystitis (acute haemorrhagic cystitis)

The patient presents with symptoms of severe UTI. Pus is present in the urine, but no organism can be cultured. It is sometimes associated with abacterial urethritis and is commonly sexually acquired. Tuberculous infection and carcinoma in situ must be ruled out. The underlying causative organism may be mycoplasma or herpes.

Frequency—dysuria syndrome (urethral syndrome)

This is common in women. It consists of symptoms suggestive of urinary infection, but with negative urine cultures and absent pus cells. Carcinoma in situ, tuberculosis and interstitial cystitis should be excluded. No significant abnormalities in these patients have been found and most urologists advise patients to adopt general measures such as wearing cotton underwear, using simple soaps, general perineal hygiene and voiding after intercourse. Other treatments include cystoscopy and urethral dilatation, although the benefits remain doubtful.

Tuberculous urinary infection

Tuberculous urinary infection is secondary to renal tuberculosis. Cystoscopy shows that early tuberculosis of the bladder commences around the ureteric orifice or trigone, the earliest evidence being pallor of the mucosa due to submucous oedema. Subsequently tubercles may be seen, and in long-standing cases there is much fibrosis and the capacity of the bladder is greatly reduced (Fig. 65.41).

Treatment

Tuberculous infection usually responds rapidly to antituberculous drugs (see Chapter 7), but occasionally, in cases with advanced renal changes, may not subside until the involved kidney and ureter have been removed.

If the bladder remains of low capacity, patients will have severe symptoms and the upper tracts are at risk of dilatation because of high filling pressures plus vesicoureteric reflux. Such patients after appropriate chemotherapy respond very well to bladder augmentation. The ureters may need reimplantation into the neo-bladder.

Bladder augmentation by ileocystoplasty or caecocystoplasty. The fibrosed supratrigonal bladder is removed and the bladder augmented with a segment of bowel. This may consist of an intact segment of caecum, a detubularised segment of ileum or a detubularised ileocaecal segment. After pre-operative preparation bowel preparation (see Chapter 56) a segment of bowel with an ample blood supply as demonstrated by transillumination is disconnected, leaving its mesentery intact, and the continuity of the intestine is restored by anastomosis. The segment of bowel is opened longitudinally and sutured together as a ‘U’ shape. This can then be anastomosed to the trigone of the bladder. Alternatively, an intact segment of caecum may be used (Figs 65.20, 65.21, 65.22 and 65.23).

Interstitial cystitis (Hunner’s ulcer)

For practical purposes, this is confined to women. The symptoms commence when the patient is in her 40s and cause significant distress.

Aetiology

This is as obscure as it was when Guy Hunner’s first described the condition in 1914. It does not appear to start as an ordinary UTI, but consists of a chronic pancytisitis, often with marked infiltration with lymphocytes and macrophages.

Pathology

As a result of the pancytisitis, fibrosis of the vesical musculature ensues, leading to contraction of the bladder and areas of avascular atrophy of the epithelium. Ulceration of the mucosa occurs in the fundus of the bladder. In severe cases, the bladder capacity is reduced to 30–60 ml. The characteristic linear bleeding ulcer is due to splitting of the mucosa when the bladder is distended under anaesthesia for cystoscopy.

Microscopically, inflammation of all coats of the bladder is present with granulation tissue in the submucosa underlying the ulcer. The muscularis is hypertrophied and the peritoneum in proximity to the area of maximum disease is thickened. The inflammation may involve the trigone, the urethra and, in severe cases, the peritoneum. Pronounced mast cell infiltration is seen, but is not specific to the condition.

Clinical features

The first symptom is increased frequency. Pain, relieved by micturation and aggravated by jarring and over-distension of the bladder, is a characteristic symptom. In most patients pyuria and urinary infection are absent. Haematuria also occurs.

Cystoscopy

The characteristic ulcer is found in the fundus, but it may be absent. This area bleeds readily as the bladder is decompressed.

Treatment

Treatment is difficult and unsatisfactory. Hydrostatic dilatation under anaesthesia may give relief for some months. Light diathermy fulguration of the ulcer may help. Instillation of dimethylsulphoxide (Rimso 50®) improves some patients. Other drugs that have been tried include ranitidine. Patients with severe symptoms may well come to bladder substitution. In patients with severe inflammation involving the trigone and urethra, this operation may not result in complete relief and some type of urinary diversion may be needed.

Alkaline encrusting cystitis

Alkaline encrusting cystitis is rare and is due to urea-splitting organisms causing phosphatic encrustations on the bladder mucosa of elderly women. There are symptoms of chronic UTI and a plain X-ray shows the bladder outline. The encrustations may be removed by bladder irrigation and the infection treated with appropriate antibiotics.

Cystitis cystica

Glands are not found in the normal bladder mucosa. Under the influence of chronic inflammation, the surface epithelium sends down buds, resulting in minute cysts filled with clear fluid, most abundant on the trigone. This is frequently found in patients with recurrent frequency and
dysuria. Whilst very rarely cases of adenocarcinoma of the bladder may arise in these areas of glandular metaplasia, there is no doubt that cystitis cystica is usually completely innocuous.
Schistosomiasis of the bladder

Geographical distribution

The disease is endemic in many parts of Africa, in Israel, Syria, Saudi Arabia, Iran, Iraq and along the shores of China’s great lakes. Dwellers of the Nile valley have suffered for centuries. Marshes or slow-running fresh water provide a favourable habitat for the particular freshwater snail (Bulinus truncatus) which is the intermediate host.

Mode of infestation

The disease is acquired while bathing in infected water. The free-swimming, bifid-tailed embryos (cercaniae) of the trematode Schistosoma haematobium penetrate the skin. Shedding their tails, they enter blood vessels and are swept to all parts of the body, but flourish in the liver where they live on erythrocytes. They develop into male and female worms. The female is long, smooth and slender, and is furnished with two weak suckers anteriorly. The male is broader, shorter (11 mm in length), bosselated and provided with a strong sucker at either end. Sexual maturity having been attained, the nematodes leave the liver and enter the portal vein. The male bends into the shape of a gutter (the gynaecophoric canal), into which a female nestles and the pair makes its way towards the inferior mesenteric vein. Schistosoma haematobium has an affinity for the vesical venous plexus which they reach through the portosystemic anastomotic channels.

Having reached the bladder, the female moves forward until she enters a submucous venule so small that she completely blocks it. She now proceeds to lay about 20 ova in a chain. Each ovum is provided with a terminal spine which penetrates the vessel wall. A heavily infected subject passes many hundreds of ova a day. If the ova reach fresh water, the low osmotic pressure causes their envelope to burst and the ciliated miracidium emerges. To survive, it must reach and penetrate the intermediate host within 36 hours. Within the snail’s liver the miracidium enlarges and gives rise to myriads of daughter cysts which are set free on the death of the snail. A single miracidium begets thousands of cercaniae to complete the life cycle.

Clinical features

After penetration of the skin, urticaria lasting for about 5 days can occur (swimmer’s itch). After an incubation period ranging from 4 to 12 weeks, high evening temperature, sweating and asthma, together with leucocytosis and eosinophilia, occur. Usually, an asymptomatic period of several months supervenes before the ova are released, causing the typical early sign and symptom of intermittent, painless, terminal haematunia. Men are three times more often affected than women. Patients often present at a very late stage.

Examination of the urine

The last few millilitres of an early morning urine specimen are collected and centrifuged in a dry container. Examination on several consecutive days may be required, but a negative result does not exclude bilharziasis, especially in patients no longer resident in bilharzial districts.

Cystoscopy

Dependent on the length of time for which the disease has remained untreated, cystoscopy will reveal one or more of the following.

1. Bilharzial pseudotubercles are the earliest specific appearance. The pseudotubercles are larger, more prominent, more numerous, more yellow and more distinctly grouped (Fig. 65.42) than those of tuberculosis.

2. Bilharzial nodules (Fig. 65.43) are due to the fusion of tubercles in the presence of secondary infection. They are larger and greyer than those in 1.

3. ‘Sandy patches’ are the result of calcified dead ova with degeneration of the overlying epithelium. They occur in the first instance around one or both ureteric orifices (Fig. 65.44). Considerable calcification of this nature is visible on the radiograph.

4. Ulceration is the result of sloughing of mucous membrane containing dead ova or, what is even more common, sloughing of a bilharzial papilloma. The ulcer is shallow (Fig. 65.45) and bleeds readily, and its common position is the posterior wall of the bladder.

5. Fibrosis is mainly the result of secondary infection. The capacity of the bladder becomes much reduced and contracture of the bladder neck may be found.

6. Granulomas. Bilharzial masses are due to an aggregation of nodules. They are sessile and soft, and bleed readily when touched.

7. Papillomas are distinguished from those in 6, above, by being more pedunculated (Fig. 65.46). They vary in size and may be single or multiple.

8. Carcinoma is a common end result in grossly infected bilharziasis of the bladder which has been neglected for years. It usually commences, not in a papilloma, but in an ulcer, and is therefore a squamous celled carcinoma (due to metaplasia). It is usually advanced and will require radical cystectomy (see the section on ‘Carcinoma of the bladder’).

Treatment

Lesions 1—6, inclusive, can be expected to heal in response to systemic treatment by antimony or other preparations (e.g. praziquantel and metrifonate). It takes many months for dead ova to be expelled, and even after repeated courses and healing of the bladder lesion living bilharzial worms have been found at necropsy in the portal system. In addition to general treatment, healing of bilharzial ulcers and granulomas is expedited by light diathermy coagulation. Bilharzial papillomas and carcinomas do not respond and require the same surgical measures as nonbilharzial papillomas and carcinomas.

Other complications and their treatment

- Secondary bacterial cystitis is commonly present and requires treatment.
- Urinary calculi, especially vesical and ureteric, occur more frequently when bilharzial lesions of the bladder are present.
- Stricture of the ureters affects the last inch of the ureters. These often respond to dilatation, but sometimes re-implantation of the affected ureter is necessary.

Bilharzial pseudotubercles

The typical early sign and symptom of intermittent, painless, terminal haematunia. Men are three times more often affected than women. Patients often present at a very late stage.

Examination of the urine

The last few millilitres of an early morning urine specimen are collected and centrifuged in a dry container. Examination on several consecutive days may be required, but a negative result does not exclude bilharziasis, especially in patients no longer resident in bilharzial districts.

Cystoscopy

Dependent on the length of time for which the disease has remained untreated, cystoscopy will reveal one or more of the following.

1. Bilharzial pseudotubercles are the earliest specific appearance. The pseudotubercles are larger, more prominent, more numerous, more yellow and more distinctly grouped (Fig. 65.42) than those of tuberculosis.

2. Bilharzial nodules (Fig. 65.43) are due to the fusion of tubercles in the presence of secondary infection. They are larger and greyer than those in 1.

3. ‘Sandy patches’ are the result of calcified dead ova with degeneration of the overlying epithelium. They occur in the first instance around one or both ureteric orifices (Fig. 65.44). Considerable calcification of this nature is visible on the radiograph.

4. Ulceration is the result of sloughing of mucous membrane containing dead ova or, what is even more common, sloughing of a bilharzial papilloma. The ulcer is shallow (Fig. 65.45) and bleeds readily, and its common position is the posterior wall of the bladder.

5. Fibrosis is mainly the result of secondary infection. The capacity of the bladder becomes much reduced and contracture of the bladder neck may be found.

6. Granulomas. Bilharzial masses are due to an aggregation of nodules. They are sessile and soft, and bleed readily when touched.

7. Papillomas are distinguished from those in 6, above, by being more pedunculated (Fig. 65.46). They vary in size and may be single or multiple.

8. Carcinoma is a common end result in grossly infected bilharziasis of the bladder which has been neglected for years. It usually commences, not in a papilloma, but in an ulcer, and is therefore a squamous celled carcinoma (due to metaplasia). It is usually advanced and will require radical cystectomy (see the section on ‘Carcinoma of the bladder’).

Treatment

Lesions 1—6, inclusive, can be expected to heal in response to systemic treatment by antimony or other preparations (e.g. praziquantel and metrifonate). It takes many months for dead ova to be expelled, and even after repeated courses and healing of the bladder lesion living bilharzial worms have been found at necropsy in the portal system. In addition to general treatment, healing of bilharzial ulcers and granulomas is expedited by light diathermy coagulation. Bilharzial papillomas and carcinomas do not respond and require the same surgical measures as nonbilharzial papillomas and carcinomas.

Other complications and their treatment

- Secondary bacterial cystitis is commonly present and requires treatment.
- Urinary calculi, especially vesical and ureteric, occur more frequently when bilharzial lesions of the bladder are present.
- Stricture of the ureters affects the last inch of the ureters. These often respond to dilatation, but sometimes re-implantation of the affected ureter is necessary.
• Prostato seminal vesiculitis.

• Fibrosis of the bladder and bladder neck (Fig. 65.47) should be treated in the same way as that of nonbilharzial origin.

• Bilharzial urethral strictures are often accompanied by fistulae, and can be cured only by excision of the fistulous tracks and urethroplasty.
Neoplasms of the bladder

Ninety-five per cent of primary bladder tumours originate in the epithelium; the remainder arise from connective tissue angioma, myoma, fibroma and sarcoma) or are extra adrenal phaeochromocytomas.

Secondary tumours of the bladder are not rare and most commonly arise from a neighbouring organ, particularly the sigmoid and rectum, the prostate, the uterus or ovary, although bronchial neoplasms also may spread to bladder.

Pathology

Benign papillary tumours.

Many histopathologists will not diagnose benign papillomas of the bladder, stating that most of them are merely better differentiated types of superficial bladder cancer. The papilloma consists of a single frond with a central vascular core with villi; it looks like a red sea-anemone (Figs 65.48 and 65.49). Inverted papilloma is a condition where the proliferative cells penetrate under normal mucosa so that the lesion is covered with smooth urothelium — it is benign.
Carcinoma of the bladder

Carcinoma arising within the bladder may be of three cell types: transitional, squamous and adenocarcinoma or mixed owing to metaplasia in a transitional cell carcinoma (TCC). Over 90 per cent are transitional cells in origin. Pure squamous carcinoma is uncommon (approximately 5 per cent), apart from areas where bilharzia is endemic. Primary adenocarcinoma, which arises either from the urachal remnant or from areas of glandular metaplasia, accounts for 1—2 per cent of cases.

Transitional cell carcinoma

Aetiology. The first suspicion of a chemical cause for bladder cancer was raised by Rehn in 1894 when he recorded a series of tumours in workers in aniline dye factories. Hueper was able to show that 2-naphthylamine was carcinogenic in dogs. Subsequent investigation demonstrated that the following compounds may be carcinogenic:

- 2-naphthylamine;
- 4-aminobiphenyl;
- benzidine;
- chlornaphazine;
- 4-chloro-o-toluidine;
- o-toluidine;
- 4,4'-methylene bis(2-chloraniline);
- methylene dianiline;
- benzidine-derived azo dyes.

Occupations which have been reported to have a significantly excess risk of bladder cancer are shown below

Occupations with an excess risk of bladder cancer

- Textile workers
- Dye workers
- Tyre rubber and cable workers
- Petrol workers
- Leather workers
- Shoe manufacturers and cleaners
- Painters
- Hairdressers
- Lorry drivers
- Drill press operators
- Chemical workers
- Rodent exterminators and sewage workers

Bladder cancer became a prescribed industrial disease (No. 39) in 1953 and ex-workers may be entitled to compensation. Cigarette smoking is associated with a two to three-fold excess risk, and certain genetic polymorphisms for N-acetyl tranferase, glutathione transferase and one of the cytochrome P450s (CYP2D6) may increase the risk of occupationally acquired bladder cancer. In areas where S. haematobium endemic bladder cancer is more common, and this tends to be squamous in type. Balkan nephropathy has been associated with an increased incidence of upper tract urothelial tumours (see Chapter 63).

A series of genetic events has been clearly implicated in cancer formation that is outside the remit of this chapter. Activation of dominantly acting oncogenes such as ras and c-erbB-2 has been reported in bladder cancer, as has the inactivation of tumour suppressor genes such as p53, p16 and retinoblastoma. Activation of other genes is responsible for the phenotypic changes seen in the cancer cell. These include the activation of enzymes which may dissolve the basement membrane such as the metalloproteinases (stromelysin, colla-genases and elastase), lysosomal enzymes such as the cathepsins and others including urinary plasminogen activators; angiogenic factors [vascular endothelial growth factor (VEGF)] and other peptide growth factors such as the epidermal growth factor and its receptor also have a role to play. These changes are common to several tumour types including prostate cancer.

Tumour staging and grading (Fig. 65.50)

Study of the biological behaviour of transitional cell cancer of the bladder shows that they fall into the three following groups.

- Non muscle invasive tumours (pTa) and pT1 account for 70 per cent of all new cases. These tumours may be single or multiple. Histological examination may reveal invasion of the lamina propria (pT1) but not of the muscle or no invasion of lamina propria (pTa)—single papillary pTa tumours account for a significant proportion of bladder cancers and carry an excellent prognosis.

- Muscle invasive disease (accounts for 25 per cent of new cases). Such tumours carry a much worse prognosis as they are subject to local invasion and distant metastasis.

- Flat, noninvasive carcinoma in situ (primary cis — accounts for 5 per cent of new cases). Unless diagnosed and treated promptly, this carries a poor prognosis.

Superficial bladder cancer (pTa and pT1)

These are usually papillary tumours which grow in an exophytic fashion into the bladder lumen. They may be single or multiple and may appear pedunculated arising on a stalk with a narrow base, but if the 'tumours are less well differentiated they are more solid with a wider base. The
mucosa around the tumour is often rather oedematous with angry-looking, dilated blood vessels. These areas may contain in situ changes (concomitant cis).

Some patients with bladder cancer have urinary infection, although this is more common with muscle invasive disease. Occasionally, calcium salts are deposited on these tumours, giving them a crusted exterior. The urothelium elsewhere in the bladder may also appear rather oedematous and velvety; this suggests a generalised ‘field change’ with the presence of widespread carcinoma in situ. The most common sites for superficial tumours are the trigone and lateral walls of the bladder.

After initial complete treatment by endoscopic transurethral resection (TURT) patients with pTa or pT1 disease may develop two problems:

• 50—70 per cent develop recurrent tumours which may be single or multiple, and the recurrences may occur on one or on many occasions. Usually the recurrent tumours are of the same stage or grade as the primary tumour. Highgrade, multiple tumours with concomitant cis are most likely to develop recurrent disease;

• about 15 per cent will develop a recurrent tumour which is invading the bladder muscle. The risk of such progression increases with high grade, with pT1 disease, with multiple primary disease and with concomitant cis. Many urologists now regard the presence of pT1 G3 tumours as an indication for more radical treatment.

This behaviour provides the rationale for performing check cystoscopies. The factors which result in an increased recurrence and progression rates are:

• high grade;
• pT1 disease;
• concomitant cis;
• multiple primary tumours;
• recurrent disease at the first check cystoscopy.

Patients presenting with a solitary grade 1 or grade 2 pTa tumour, without concomitant cis and which do not recur within the first 6 months have an excellent outcome.

**Muscle invasive transitional cell carcinoma**

The tumour with muscle invasion is nearly always solid (Fig. 65.5), although there may be a low tufted surface. These tumours are often large and broad based, having an irregular, ugly, sometimes ulcerated, appearance within the bladder. The incidence of metastases, whether from lymphatic invasion in the pelvis or blood-borne to the lung, liver or bones, is much more common and will cause the death of 30—50 per cent of patients.

**In situ carcinoma**

The histological appearance of irregularly arranged cells with large nuclei and a high mitotic index replacing the normally well ordered urothelium is known as carcinoma in situ. This may occur alone (primary cis) or in association with a new tumour (concomitant cis) or occur later in a patient who has previously had a tumour (secondary cis). This change may be appreciated macroscopically at the time of cystoscopy, although often is only diagnosed when a biopsy is examined under the microscope. The association of in situ carcinoma with papillary tumours increases the chance of recurrent disease and progression. It may cause severe symptoms of dysuria, suprapubic pain and frequency (hence its old name of malignant cystitis).

World-wide experience of this condition seems to indicate that symptomatic cis carries a high malignant potential. Fifty per cent of patients will die of bladder cancer.

**Pure squamous cell carcinoma of the bladder**

Squamous cell tumours tend to be solid and are nearly always associated with muscle invasion. This is the most prevalent form of bladder cancer in areas where bilharzia is endemic. Squamous cell tumours may be associated with chronic irritation caused by stone disease in the bladder as a result of metaplasia.

**Pure adenocarcinoma**

This accounts for approximately 1—2 per cent of bladder cancer. It usually arises in the fundus of the bladder at the site of the urachal remnant. Occasionally, primary adenocarcinomas arise at other sites and probably originate from areas of glandular metaplasia. Such tumours need to be distinguished from secondary cancer.

**Clinical features**

Painless haematuria is by far the most common symptom and should be regarded as indicative of a bladder carcinoma until proven otherwise. The haematuria may occur on only one or two occasions, and because the urine once again becomes clear patients only too often fail to declare the symptom to their general practitioner. Many months may elapse before it recurs and causes concern. The bleeding if more severe may give rise to clot formation and subsequent clot retention. It is fairly uncommon for the bleeding to be so profuse that emergency admission to hospital and blood transfusion is necessary. Occasionally, a pedunculated tumour or clot may occlude the bladder neck, causing retention of urine. The development of recurrent urinary tract infections, particularly in women in the later decades of life, should also arouse one’s suspicions.

Constant pain in the pelvis usually heralds extravasational spread. There is often frequency and discomfort associated with urination. Pain in the loin or pyelonephritis may indicate ureteric obstruction and hydronephrosis. A late manifestation is nerve involvement causing pain referred to the suprapubic region, groins, perineum, anus and into the thighs.

It is also important to assess the patient as a whole. Many are elderly men who have been life-long smokers and suffer from chronic obstructive airways disease or cardiovascular disease. Their suitability for anaesthesia must be borne in mind.
Investigation

**Urine.** Urine should be cultured and examined cytologically for malignant cells. This is not a good screening test for patients with haematuria as, particularly with low-grade tumours, malignant cells may not be identified unless a specimen obtained from a bladder washout is examined. False-positive results occur infrequently and are usually associated with stone disease. New tests are being developed based on the presence of antigens, such as nuclear matrix proteins, which may be good at detecting new or recurrent tumours.

**Blood.** Estimation of the haemoglobin and the serum electrolytes and urea should be carried out.

**IVU.** This should be performed on patients with haematuria. Occasionally, the preliminary film shows a faint shadow of an encrusted neoplasm of the bladder. The most common radiological sign is a filling defect. Occasionally, irregularity of the bladder wall may herald the presence of an invasive tumour (Fig. 65.52). Hydronephrosis may occur if a superficial tumour grows up the intramural ureter or if direct invasion of the ureteric wall occurs. Ultrasound scanning should be carried out if the kidney is nonfunctioning.

**Cystourethroscopy.**

Cystourethroscopy is the mainstay of diagnosis and should always be performed on patients with haematuria. It can be done with a rigid instrument under general anaesthesia or with a flexible instrument under local anaesthesia. The urethra is inspected at the initial insertion of the instrument (urethroscopy) and the bladder is then examined in a systematic fashion (cystoscopy).

**Bimanual examination.** A bimanual examination with the patient fully relaxed under general anaesthesia should be performed both before and after endoscopic surgical treatment of these tumours. The bladder should be empty and the bimanual examination is executed with the right index finger in the rectum of a male and placed *per vaginam* in a female. The four fingers of the left hand push down on the anterior abdominal wall in the suprapubic region. Occasionally, a very large superficial fronded tumour may be felt as a soft but mobile thickening prior to resection. Superficial tumours are not usually palpable bimanually at the beginning and by definition are not palpable after resection. Once there is muscle invasion the differentiation between T2 and T3 disease depends on whether a mass is palpable bimanually at the end of the procedure (T3). Where invasion has spread into the prostate in a male or the vagina in a woman it is classified as T4a. If the tumour is fixed to the lateral pelvic side wall it is staged as T4b.
Treatment for carcinoma of the bladder

Noninvasive tumours

Endoscopic surgery

It is not acceptable to take a tiny biopsy from the top of a papillary tumour and apply a fulgurating coagulation current to the rest unless a small recurrence is being dealt with. The tumour should be carefully resected in layers using a resectoscope. The base of the tumour is sent separately for histological examination. Small biopsies are taken near to and distant from the primary lesion to diagnose unsuspected cis. After removal of the tumour, two or three further loops of tissue from the base should be sent separately so that the pathologist can accurately determine whether there is lamina propria or muscle invasion. The base of the tumour is then coagulated, so achieving haemostasis. The appearance of pale yellow glistening fat will indicate a perforation of the bladder. Should this occur before the resection is complete, it may be prudent to stop the resection and place a catheter in the bladder for a few days. In this instance the procedure could be completed some 2 weeks later. The bimanual examination is repeated at the end of each endoscopic procedure.

Patients with solid tumours should have adequate material resected for histological staging and grading. These patients will usually need some other form of treatment. It is likely that a debulking resection of these tumours is helpful prior to radiotherapy. Following these procedures an irrigating catheter is left in situ for 48 hours to prevent clot retention of urine. There is good evidence that a single dose of mitomycin C (40 mg in 60 ml of fluid) instilled into the bladder prior to catheter removal decreases the risks of recurrence in patients with pTa, PT1 grade 1 and 2 disease.

Follow-up. Most urologists agree that patients with a single, low- or medium-grade pTa tumour can safely be treated by resection alone and followed up by means of regular cystoscopies.

The treatment of patients with multiple low- or medium-grade pTa tumour can be by either means of resection alone or resection followed by a 6-week course of intravesical chemotherapy with mitomycin C, adriamycin or epirubicin.

The treatment of PT1 disease is difficult. Many urologists, including many North American and European urologists, would offer immediate cystectomy to a patient with a high-grade PT1 tumour — particularly if it was multiple or accompanied by cis, because of the 30—50 per cent risk of progression to muscle invasion. Others will treat such patients by means of endoscopic treatment followed by intravesical immunotherapy with intravesical bacille Calmette—Guérin (BCG) — although there is no firm evidence that this decreases the risk of progression. The treatment of solitary medium-grade PT1 disease remains uncertain, but a reasonable approach would be endoscopic resection followed re-resection of the area in 6 weeks followed by intravesical chemotherapy with BCG.

Follow-up cystoscopies are essential; they may be carried out by means of local anaesthesia with a flexible cystoscope on by means of general anaesthesia if the urologist feels that the patient has a high risk of recurrence. They should initially be performed at 3-monthly intervals over the year, following this the time interval between cystoscopies can be determined according to the presence or absence of further disease. Thirty per cent of patients will never develop another tumour, so that after 2 years if the bladder has remained clear annual inspection may be adequate. For patients who go on to develop multiple recurrences within the bladder at each examination, the cystoscopies need to be maintained at frequent intervals so that the growths can be resected. These patients are at a greater risk from developing progression of their disease; whilst intravesical chemotherapy can decrease the recurrence rate, no reduction in progression rates has been found.

Intravesical chemotherapy and immunotherapy

Various agents have been used. These include thiopeta (which may be absorbed because of its low molecular weight and cause blood dyscrasias), mitomycin C, epirubicin and adriamycin. They are of equal efficacy and the cheapest should be chosen. They are administered by means of a urethral catheter and held in the bladder for 1 hour, the patients are turned from side to side and try to hold their urine for as long as possible. Usually the patients are treated weekly for 8—10 weeks and then re-cystoscoped. BCG is now frequently used as intravesical immunotherapy. It carries a greater risk of local side effects such as ‘cystitis-like’ symptoms and also risks of systemic side effects — including systemic BCGosis. Nevertheless, it is probably more effective than intravesical chemotherapy and is the treatment of choice for cis. Currently, ‘booster’ doses of maintenance BCG treatment are being given in addition to the initial 6-week course.

Open surgical excision

This should be totally avoided. If by some error a bladder containing a tumour is entered, then the tumour may be removed with a diathermy needle and the base coagulated and the bladder closed. Postoperative radiotherapy to the wound will diminish the chance of tumour implantation.

Invasive tumours

The treatment of cancer with proven muscle invasion remains a subject for debate. Whatever the modality of treatment employed, few centres have 5-year survival figures of more than 40 per cent. The controversy is centred around whether primary surgery (radical cystectomy), radical radiotherapy, or a combination of the two, provides the best result. There is a move towards primary surgical treatment in most centres. The use of systemic chemotherapy by means of a combination of agents using cis-platinum, methotrexate, adriamycin and vinblastine (MVAC) in addition to conventional treatment is presently being studied.

Radiotherapy

Deep external beam X-ray therapy. External beam radiotherapy is usually given by means of high-powered linear accelerators. Radical radiotherapy giving 60 Gy over a 4—6-week period will produce a 40—50 per cent complete response. The difficulty with radiotherapy is in patients who do not respond at all or those who have a partial response, having a bladder with pTa or PT1 tumour in it, and who are subject to recurrence. Patients with residual disease after radiotherapy should be offered ‘salvage cystectomy’ if they are fit. The protagonists of radiotherapy would claim that for most patients it saves the need to remove the bladder and allows men to retain potency. Radiotherapy is not always without complications, and during the course of treatment will cause urinary frequency and also diarrhoea. Late complications affecting the rectum should be uncommon, especially if lateral fields of irradiation are employed.

Local radiotherapy. For small invasive lesions, local radiotherapy can be delivered by open placement of a radioactive tantalum wire (iB²Ta)
or iridium wire or the implantation of gold grains ($^{198}$Au). It is used infrequently today.

**Surgery**

Partial cystectomy. This should be limited to the treatment of small adenocarcinomas of the bladder.

**Radical cystectomy and pelvic lymphadenectomy.** This is now standard treatment for localised pT2—pT3 disease without evidence of secondary spread or of cis which has not responded to BCG. Before contemplating radical surgery to remove the bladder, it is important to have evidence that surgical cure is attainable. A CT scan of the pelvis may over-stage the bladder if a recent resection has been carried out, although the finding of grossly enlarged pelvic, iliac or para aortic nodes on liver metastases will alter the decision for cystectomy. A bone scan [technetium-99m ($^{99m}$Tc)] will help to show whether there is spread to bone.

**Operation**

Alternative drainage for the urine is necessary following removal of the bladder. The standard procedure is to perform an ileal conduit. Patients should be counselled about the onset of erectile impotence and absent ejaculation following the operation; they should also be told about alternative forms of urinary diversion which include continent urinary diversions and orthotopic bladder replacement.

Patients should be seen by a stoma care therapist who will help to advise the patient and will try different ileostomy bags to ensure that the correct site is chosen avoiding skin creases so that one does not end up with the disaster of a leaking urinary ileostomy. A decision is made about whether the male urethra is to be removed (depending on the estimated risk of recurrence within the urethra); a urethrectomy is usually indicated in patients with primary cis or those with tumour invading the prostate stroma. Many surgeons are now offering total replacement of the bladder after cystectomy (Fig. 65.53).

Preoperatively, the bowel is prepared with a balanced solution of polyethylene glycol (Golytely or Kleanprep). The patient should receive prophylactic antibiotics including metronidazole, cefuroxime and amoxycillin, and low-dose heparin.

The abdomen is opened through a long lower midline incision extending down to the symphysis pubis. The liver and the retroperitoneum are checked for evidence of metastases and the operability of the bladder is assessed. A bilateral pelvic lymphadenectomy is performed removing external iliac nodes, internal iliac nodes and the nodes in the obturator fossae. The vessels passing to the bladder from the side wall are ligated in continuity; these include the obliterated hypogastric vessels, the superior vesical artery, the middle vesical veins, and the inferior vesical arteries and veins. The ureters are then divided. The posterior ligaments extending from the pararectal area to the back of the bladder are ligated and divided, and the layer posterior to Denonvillier’s fascia is opened up. The endopelvic fascia is then divided on each side and the puboprostatic ligaments are divided. A ligature is passed between the dorsal vein complex and the urethra, and the former is ligated and divided. The urethra is then mobilised and divided. The ligaments lateral to the prostate are divided and the bladder is removed. In women, the uterus and anterior vaginal wall need to be included. **Women must be counselled about the loss of ovarian and uterine function.**

An isolated loop of ileum is then prepared on its own mesentery, and continuity of the small bowel restored. The ureters are then implanted into the bowel and the ileostomy is created. Meticulous care must be taken to close all mesenteric windows, thus avoiding internal hernias. If the bladder is to be replaced orthotopically, a reservoir made from detubularised bowel (usually an ileocaecal segment or ileum) is created and anastomosed to the urethra after implantation of the ureters.

The operative mortality associated with cystectomy used to be considerable, but should be in the order of 2 per cent. Late complications include urethral recurrence (about 5—8 per cent) which is increased in the presence of multifocal tumours, cis and, particularly, invasion of prostatic stroma (Fig. 65.54).

**Leukoplakia**

This condition is simply squamous metaplasia of the bladder. Profuse production of keratin may result in the passing of white particles in the urine. It cannot be treated easily. Localised areas may be resected endoscopically. Diffuse leukoplakia of the bladder is premalignant and results in squamous bladder cancer. Careful cystoscopic assessment is required. The condition may require cystectomy.

**Endometriosis**

Endometriosis within the bladder wall is rare, but can have the appearance of a vascular bladder tumour or a tumour which contains chocolate-coloured or bluish cysts. The swelling enlarges and bleeds during menstruation. If medical management fails, by means of danazol or luteinising hormone-releasing agonists (LHRH), further treatment is usually by means of partial cystectomy or full-thickness endoscopic resection, depending on its site. The condition may be part of more widespread disease. Endometriosis is also a cause of ureteric stricture.
Internal and external urinary diversion

This chapter closes with an account of the principles of this important subject, and includes indications, the methods employed and their attendant problems, and some operative details.

Indications

Diversion of the urine may be either a temporary expedient to relieve distal obstruction, or a permanent procedure when:

(1) the bladder has been removed; (2) the sphincters of the bladder have been damaged or have lost their normal neurological control; (3) there is an incurable fistula; (4) there is an irremovable obstruction; and (5) in late cases of ectopia vesicae.

Methods of urinary diversion

The urinary tract may be diverted at most sites extending from the kidney, the ureter, the bladder and the urethra or it may involve the creation of new structures such as an ileal or colonic conduit, continent diversions or bladder substitutions (Fig. 65.55). The diversion may be achieved by any of the following methods, but the choice in each case will be decided largely by the primary disease, patient comorbidity and motivation:

- pyelostomy on nephrostomy (now carried out percutaneous-ly by means of interventional percutaneous nephrostomy — Chapter 62) on catheter drainage (or ureterostomy);
- cutaneous uneterostomy or the use of indwelling ‘double J’ pigtail ureteric stents;
- suprapubic cystostomy (with indwelling catheter);
- cutaneous vesicostomy (cystostomy);
- ureterosigmoidostomy: (1) in continuity; (2) making a rectal bladder and colostomy; or (3) creating a rectal reservoir;
- external diversion of urine by a number of surgical techniques. The following problems may occur: (1) collection of the urine; (2) stricture formation at any anastomosis; and (3) reflux and reabsorption of urinary solutes. The problems of infection are intimately related to all three;
- internal urinary diversion by means of bladder replacement.

Collection of urine

Catheters

In the past, indwelling catheters have been used for permanent diversion. They invariably result in bacteriuria and carry a risk of infection, and they often become blocked by phos-phate encrustation. Temporary nephrostomy drainage is very useful in the management of patients with acute upper tract obstruction. For temporary cutaneous ureterostomy drainage, the tubes should be of soft silicone.

Bladder drainage. In elderly patients unfit for prostatectomy and in some terminal cases of carcinoma of the prostate, an indwelling silicone urethral Foley catheter changed every 3 months is a satisfactory method of drainage. Other methods include the use of prostatic urethral stents passed under ultrasound or direct vision to hold open the prostatic urethra and bladder neck.

Cutaneous stomas

Superpubic vesicostomy or urethrostomy. Collection from a formal suprapubic vesicostomy (cystostomy) is unsatisfactory because the local incisions result in skin creases which make it difficult to apply a water-tight collecting appliance.

Cutaneous ureterostomies. These are very liable to stricture formation. In addition, two openings (Fig. 65.55d) and appliances add to the patient’s burden. Mobilisation of the ureters and the making of a central abdominal stoma may be useful in children with grossly dilated ureters as a temporary measure (Fig. 65.55e).

Ileal or colonic conduit. At present, the most generally useful form of external diversion is to implant each ureter with as little mobilisation as possible into an isolated segment of gut (ileum on colon), which conducts the urine onwards to a cutaneous stoma (Fig. 65.55a). Urine is then collected in an ileostomy bag. This form of diversion limits infection and avoids the problems of reabsorption of urine as contact time with the mucosa is minimal. In some cases in which the pelvic area has been subjected to radiation, the lower ureters may be unhealthy. A high division with insertion of the ureters into an ileal loop above the root of the mesentery may be wiser (Fig. 65.56).

Siting of stoma. The site for the stoma must be chosen before operation in consultation with a stoma care therapist. The site of the future stoma is marked indelibly on the skin.

Colon and rectum

The advantage of diverting urine into the colon is that no collecting apparatus is necessary (Fig. 65.55b and f). Clearly, however, the anal sphincter must be competent. Before ureterosigmoidostomy is undertaken, the patient must prove that he or she can control at least 200 ml of fluid in the rectum. The disadvantage of the operation is that the renal tract is exposed continuously to infection from the faeces. This can be minimised by performing some type of anti-reflux procedure or by establishing a terminal left iliac colostomy, and closing the upper rectum to make a rectal bladder (Fig. 65.55c). This prevents the urine refluxing retrogradely round the colon to the caecum. diminishes reabsorption (see below) and protects renal function. Cancer can develop at long-standing ureterocolic junctions (Fig. 65.57). More recent developments include the formation of a detubularised sigmoid segment that provides a low-pressure reservoir in continuity.

Stricture formation

Ureterosigmoidostomy was first used by Chaput (1894). Subsequent modifications included those made by Coffey and Grey Turner. In these methods, the ureters were cut obliquely and pulled into the gut by a stitch — the ends were not stitched to the gut wall. Stenosis was common. Nesbit, Cordonnier and Leadbetter all recognised that these strictures could be prevented by anastomosing mucosa to mucosa.
Reflux of urine and reabsorption of urinary solutes

Reflux of urine

High-pressure activity within a segment of gut can cause reflux of infected urine at high pressure to the kidneys. In the long term this can cause renal impairment.

Reabsorption of urinary solutes

This depends upon the following factors: (1) the area of bowel which is exposed to urine; and (2) the length of time for which the urine is in contact with the bowel epithelium.

The biochemical changes associated with urinary diversion are due to a combination of reabsorption of chloride and urea, and progressively diminishing tubular function as a result of chronically impaired tubular function due to pyelonephritis. Diarrhoea with loss of potassium-containing mucus may exacerbate the loss of potassium. The typical changes of a hyperchloraemic acidosis with potassium depletion occur frequently in patients with uroterosigmoid diversion. When severe, the patient develops loss of appetite, weakness, thirst and diarrhoea. Coma may ensue. Mild acidosis, unrecognised even a long period, produces osteomalacia. Bone pain and even pathological fracture can occur. Renal impairment from pyelonephritis and reabsorption from the mucosa are seen less frequently after ileal or colonic conduit formation, continent urinary diversion or orthotopic bladder substitution. In particular, they are seen very infrequently except in patients with pre-existing renal impairment and unsatisfactory emptying of the urinary reservoir.

Treatment

Prevention. Patients should be instructed to empty the rectum or continent reservoir or neo-bladder 3-hourly by day. In cases of uroterosigmoidostomy where acidosis is present a rectal tube should be inserted at night to drain the urine continuously. The patient should take a mixture of potassium citrate and sodium bicarbonate t.d.s. (2 g of each, either as crystals or as tablets). Regular serum biochemical analyses, including calcium, are required.

Established hyperchloraemic acidosis is usually associated with marked dehydration and the mainstay of treatment is intravenous saline. The patient may be given small doses of sodium bicarbonate to half-correct the pH deficit if it is severe and additional intravenous potassium. This should be coupled with appropriate systemic antibiotic treatment.

Operative details

Bowel preparation is by means of 3 litres of balanced polyethylene glycol solution (Golytely or Kleanprep). The abdomen is opened by a lower midline incision. The patient is then placed in the Trendelenberg position.

Ureterocolic anastomosis

The right ureter is sought at the pelvic brim and dissected towards its entry into the bladder. The ureter is divided and its distal stump ligated; the proximal end is trimmed obliquely and split for 1 cm. An incision 3 cm long is made in the anterior wall of the colon and the peritoneal and muscular coats are divided, but not the mucous membrane. An incision is made into the extreme lower end of the exposed mucous membrane and the full thickness of the ureteric wall is joined by interrupted 4/0 chromic catgut sutures to the mucosal opening. The incision in the outer coats of the bowel is approximated over the ureter. A drain is left down to the area. The left ureter is implanted into the colon above in a similar manner. A full-sized Foley’s catheter is inserted through the anus no further than the rectal ampulla and the balloon is inflated, which permits urine output to be measured.

Uretero-ileostomy (ileal loop conduit)

A coil of ileum, approximately 15—20 cm long and 30 cm from the ileocaecal valve, with its blood supply intact, is isolated. The left ureter is brought behind the mesorectum. The ureters may be joined to the ileum either end-to-side or end-to-end after anastomosing of the distal spatulated ureters to form a plate (Wallace). The ileal loop is tacked lightly to the peritoneum of the posterior abdominal wall at the level of the pelvic brim. The distal end of the coil is brought out through an incision at the site which had been identified before operation; a disc of skin and fat is removed, a cruciate incision is made in the fascia and the muscle is split. The stoma is made about 2—3 cm long. It is evaginated initially by means of four sutures passing through the skin, the ileal loop as it passes through the opening, and the cut edge of the ileum (Fig. 65.57).

Bladder replacement

Over the past decade, various techniques have become available to form a near spherical urinary reservoir out of various lengths of bowel which are detubularised. These may consist of ileum, ileum and caecum on sigmoid colon. The ureters can then be reimplanted in these reservoirs in an antireflux manner and the reservoir can then be anastomosed to the membranous urethra in the male (Figs 65.20, 65.21). These reservoirs usually need to be emptied by means of CISC. The results are good in selected younger men after radical cystectomy.

Continent urinary diversion

A similar concept is used in the construction of continent diversions. A urinary reservoir is made as described above and the ureters are attached to the reservoir. A continence mechanism is then made to connect the reservoir to the skin. This is the complication prone part of the operation. The continence mechanism may be made of an invaginated loop of ileum supported by three rows of staples (Kock pouch) or made from the appendix buried in an antireflux manner in a submucosal tube (Mitrofanoff; Fig. 65.58) or a length of ileum can be made into a tube (of similar size to the appendix) after excision of the antimesenteric ileum and buried in a submucosal tunnel in an antireflux way. Clearly, these operations are complex, with the potential for increased postoperative complication.

Bladder substitution and augmentation

In patients with contraction of the bladder due to tuberculosis or with neuropathic dysfunction and a small bladder capacity, the bladder may need to be augmented. Similar techniques to those used to perform a bladder replacement can be utilised to make a near-spherical pouch from detubularised bowel which can then be attached to the trigone or bladder neck after a near-total cystectomy (Figs 65.20, 65.21, 65.22 and 65.23). The ureters are then reimplanted. The facility to provide a continence mechanism must be available if needed in the neuropathic patient. This may comprise an artificial urinary sphincter on a colposuspension in the female.
the submucous group of glands in the transitional zone, forming a nodular enlargement. Eventually, this overgrowth compresses the PZ glands

breast dysplasia (see Chapter

BPH affects both glandular epithelium and connective tissue stromal to variable degrees. These changes are similar to those occurring in breast dysplasia (see Chapter 45), where adenosis, epitheliosis and stromal proliferation are seen in differing proportions. BPH typically affects the submucous group of glands in the transitional zone, forming a nodular enlargement. Eventually, this overgrowth compresses the PZ glands
into a false capsule and causes the appearance of the typical ‘lateral’ lobes.

When BPH affects the sub cervical central zone glands, a ‘middle’ lobe develops which projects up into the bladder within the internal sphincter (Fig. 66.3). Sometimes both lateral lobes also project into the bladder, so that when viewed from within, the sides and back of the internal urinary meatus are surrounded by an intravesical prostatic collar.

**Effects of benign prostatic hyperplasia**

It is important to realise that the relationship between anatomical prostatic enlargement (BPH), symptoms of prostatism and urodynamic evidence of bladder outflow obstruction (BOO) is complex (Fig. 66.4). Pathophysiologically, bladder outflow obstruction may be caused in part by increased smooth muscle tone which is under the control of alpha-adrenergic agonists. **Consequences of BPH**

- No symptoms, no bladder outflow obstruction (BOO)
- No symptoms, but urodynamic evidence of BOO
- Symptoms of prostatism, no evidence of BOO
- Symptoms of prostatism and BO
- Others (acute/chronic retention, haematuria, urinary infection and stone formation)

Anatomically, the effects are as follows.

**Urethra**

The prostatic urethra is lengthened, sometimes to twice its normal length, but it is not narrowed anatomically. The normal posterior curve may be so exaggerated that it requires a curved catheter to negotiate it. When only one lateral lobe is enlarged, distortion of the prostatic urethra occurs.

**Bladder**

If BPH causes bladder outflow obstruction, the musculature of the bladder hypertrophies to overcome the obstruction and appears trabeculated (Fig. 66.6). Significant BPH is associated with increased blood flow and the resultant veins at the base of the bladder are apt to cause haematuria.
Lower urinary tract symptoms or 'prostatism'
In both sexes nonspecific symptoms of bladder dysfunction become more common with ageing, probably owing to impairment of smooth muscle function and neurovesical coordination. Not all symptoms of disturbed voiding in ageing men should therefore be attributed to BPH causing BOO. Many urologists prefer the term ‘lower urinary tract symptoms’ (LUTS).

The following conditions can coexist with BOO, leading to difficulty in diagnosis and in predicting the outcome of treatment:

(a) idiopathic detrusor instability (see Chapter 65);
(b) neuropathic bladder dysfunction as a result of strokes, Alzheimer’s disease or Parkinson’s disease (see Chapter 65);
(c) degeneration of bladder smooth muscle giving rise to impaired voiding and detrusor instability;
(d) BOO due to BPH.

Episodes of near retention

The symptoms of prostatism are now usually assessed by means of scoring systems which give a semiobjective measure of severity. However, some symptoms do not give an accurate picture of the underlying pathophysiological problem. For instance, a man with severe detrusor instability may only void small volumes and hence he will have a sensation of poor flow because low voided volumes (<100 ml) are associated with low flow rates.

Severe irritative symptoms are usually associated with detrusor instability. Postmicturition dribbling is now realized not to be a consequence of bladder outflow obstruction and is usually not improved by prostatectomy.
Bladder outflow obstruction

This is a urodynamic concept based on the combination of low flow rates in the presence of high voiding pressures. It can be diagnosed definitively only by pressure—flow studies. This is because symptoms are relatively nonspecific and can result from detrusor instability, neurological dysfunction and weak bladder contraction. Even low measured peak flow rates (<10—12 ml/second) are not absolutely diagnostic because in addition to BOO, weak detrusor contractions or low voided volumes (owing to instability) can be the cause.

Urodynamically proven bladder outlet obstruction may result from:

- BPH
- bladder neck stenosis
- bladder neck hypertrophy
- prostate cancer
- urethral strictures
- functional obstruction due to neuropathic conditions

Primary effects of BOO on the bladder

- Urinary flow rates decrease [for a voided volume >200 ml; a peak flow rate of >15 ml/second is normal (Fig. 66.6), one of 10—15 ml/second equivocal and one <10 ml/second low (Fig. 66.7)]
- Voiding pressures increase [pressures >80 cmH₂O are high (Fig. 66.8), pressures between 60 and 80 cmH₂O are equivocal, pressures <60 cmH₂O are normal]

The long-term effects of bladder outflow obstruction are as follows.

1. The bladder may decompensate so that detrusor contraction becomes progressively less efficient and a residual urine develops.
2. The bladder may become more irritable during filling with a decrease in functional capacity partly caused by detrusor instability (see Chapter 65) which may also be caused by neurological dysfunction or ageing, or be idiopathic.

Aside from symptoms, the complications of BOO are as follows.

1. **Acute retention of urine** is sometimes the first symptom of BOO. Postponement of micturition is a common precipitating cause; overindulgence in beer, confinement to bed on account of intercurrent illness or operation are other causes.

2. **Chronic retention**. In patients in whom the residual volume is >250 ml or so (Fig. 66.9), the tension in the bladder wall increases owing to the combination of a large volume of residual urine and increased resting and filling bladder pressures (a condition known as high-pressure chronic retention. The increased intramural tension results in functional obstruction of the upper urinary tract with the development of bilateral hydronephrosis (Figs 66.10 and 66.11). As a result, upper tract infection and renal impairment may develop. Such men may present with overflow incontinence, enuresis and renal insufficiency. These symptoms should alert the doctor to the presence of this condition.

3. **Impaired bladder emptying**. If the bladder decompensates with the development of a large volume of residual urine, urinary infection and calculi are prone to develop.

4. **Haematuria**. This may be a complication of BPH. Other causes must be excluded by carrying out an IVU, cystoscopy, urine culture and urine cytological examination.

5. **Pain** is not a symptom of BOO and its presence should prompt the exclusion of acute retention, urinary infection, stones, carcinoma of the prostate and carcinoma in situ of the bladder.
Assessment of the patient with prostatism

Abdominal examination is usually normal. In patients with chronic retention, a distended bladder will be found on palpation, percussion and sometimes on inspection with loss of the transverse suprapubic skin crease. General physical examination may demonstrate signs of chronic renal impairment with anaemia and dehydration. The external urinary meatus should be examined to exclude stenosis, and the epididymes are palpated for signs of inflammation.

Rectal examination

In benign enlargement, the posterior surface of the prostate is smooth, convex and typically elastic, but the fibrous element may give the prostate a firm consistency. The rectal mucosa can be made to move over the prostate. Residual urine may be felt as a fluctuating swelling above the prostate. It should be noted that if there is a considerable amount of residual urine present, it pushes the prostate downwards, making it appear larger than it is.

The nervous system

The nervous system is examined to eliminate a neurological lesion. Diabetes mellitus, tabes, disseminated sclerosis, cervical spondylosis, Parkinson’s disease and other neurological states may mimic prostatic obstruction. If these are suspected then a pressure—flow urodynamic study should be carried out to diagnose BOO. Examination of perianal sensation and anal tone is useful in detection of an S2 to S4 cauda equina lesion.

Serum prostate-specific antigen

The difficulty here is the uncertain benefit of early detection and radical treatment of prostate cancer — this is dealt with in the section on prostate cancer. Certainly men should be informed about the test, the risks of the prostate biopsy that might be required and the risks of the detection of a cancer that we are not certain how best to treat. After suitable counselling, measurement of serum PSA may be helpful. Men in whom a diagnosis of early prostate cancer might influence treatment option such as those under 60 or those with a positive family history who might be offered radical treatment — should be offered a PSA measurement. If this is in excess of 4 nmol/litre, then transrectal ultrasound scanning (TRUS) plus multiple transrectal biopsies should be considered.

If rectal examination is quite normal with no suspicion of cancer and if no change in treatment policy would result anyway from the diagnosis of early prostate cancer then there seems little point in the routine measurement of PSA in men with uncomplicated BOO.

Flow rate measurement

For this to be meaningful two or three voids should be recorded and the voided volume should be in excess of 150—200 ml. This usually means the patient attending a special flow rate clinic. A typical history and a flow rate <10 ml/second [for a voided volume of >200 ml (Fig. 66.7)] will be sufficient for most urologists to recommend treatment. Usually a flow rate measurement will be coupled with ultrasound measurement of postvoid residual urine.

There are pitfalls in the measurement of flow rates. The machine must be accurately calibrated. The patient must void volumes in excess of 150 ml and two or three recordings are needed to obtain a representative measurement. Decreased flow rates and symptoms of prostatism may be seen in:

* BOO;
* low voided volumes (characteristically in men with detrusor instability);
* men with weak bladder contractions (low pressure—flow voiding).

Pressure—flow urodynamic studies (Fig. 66.8)

Details of these studies are outlined in Chapter 65. They should be performed on the following patients:

* men with suspected neuropathy (Parkinson’s disease, dementia, long-standing diabetes, previous strokes, multiple sclerosis)
* men with a dominant history of irritative symptoms and men with life-long urgency and frequency
* men with a doubtful history and those with flow rates in the near-normal range (— or >15 ml/second)
* men with invalid flow rate measurements (because of low voided volumes)

Blood tests

Serum creatinine, electrolytes and haemoglobin should be measured.

Examination of urine

The urine is examined for glucose and blood, a midstream specimen should be sent for bacteriological examination and cytological examination may be carried out if carcinoma in situ is thought possible.

Upper tract imaging

Most urologists no longer carry out imaging of the upper tract in men with straightforward symptoms. Obviously if infection or haematuria is present then the upper tract should be imaged by means of an IVU or USS.

Cystourethroscopy

Inspection of the urethra, the prostate and the urothelium of the bladder should always be done immediately prior to prostatectomy, whether it is being done transurethrally or by the open route to exclude a urethral stricture, a bladder carcinoma and the occasional non opaque vesical calculus. The decision whether to perform prostatectomy must be made before cystoscopy. This should be based on the patient’s symptoms,
signs and investigations. Direct inspection of the prostate is a poor indicator of BOO and need for surgery.

Transrectal ultrasound scanning

This increases the rate of detection of associated early prostate cancer but, as pointed out above, unless this would substantially affect treatment there is no need to carry it out routinely. Accurate estimation of prostatic size is possible by means of transrectal or transabdominal ultrasound scanning.
Management of men with benign prostatic hyperplasia or bladder outflow obstruction

Strong indications for treatment (usually prostatectomy) include:

1. **Acute retention** (see Chapter 65) in fit men with no other cause for retention (drugs, constipation, recent operation, etc.) (accounts for 25 per cent of prostatectomies);

2. **Chronic retention and renal impairment**: a residual urine of 200 ml or more, a raised blood urea, hydroureter or hydronephrosis demonstrated on urography, and uraemic manifestations (accounts for 15 per cent of prostatectomies);

3. **Complications of bladder outflow obstruction**: stone, infection and diverticulum formation;

4. **Haemorrhage**: occasionally, venous bleeding from a ruptured vein overlying the prostate will require prostatectomy to be performed;

5. **Elective prostatectomy for severe symptoms of ‘prostatism’**: this accounts for about 60 per cent of prostatectomies. Increasing difficulty in micturition, with considerable frequency day and night, delay in starting, and a poor stream are the usual symptoms for which prostatectomy is advised. Frequency alone is never an indication for prostatectomy. The natural progression of outflow obstruction is variable and rarely gets worse after 10 years. Severe symptoms, a low maximum flow rate (<10 ml/second) and an increased residual volume of urine (100—250 ml) are relatively strong indications for operative treatment. The exact cut off for operative or nonoperative treatment will depend on careful discussion between patient and urologist.

**Acute retention**

The management of retention is discussed in detail in Chapter 65. Once the bladder has been drained by means of a catheter, the patient’s fitness for treatment is determined. If retention was not caused by drugs or constipation then prostatectomy would usually be the correct management. Unfit men or those with dementia may be treated by means of indwelling prostatic stents or a catheter. Similar comments apply to men with chronic retention once renal function has been stabilized by catheterization.

**Special problems in the management of chronic retention (see Chapter 65 for general management of retention)**

Men who do not have symptoms suggestive of coexistent infection and with good renal function do not necessarily require catheterization before proceeding to prostatectomy on the next available list. For those who are uraemic, urgent catheterization is mandatory to allow renal function to recover and stabilize. Haematuria often occurs following catheterization owing to collapse of the distended bladder and upper tract, but settles within a couple of days.

Uraemic patients with chronic retention are often dehydrated at the time of admission. Owing to the chronic back pressure on the distal tubules within the kidney, there is loss of the ability to reabsorb salts and water. The result, following release of this pressure, may be an enormous outflow of salts and water which is known as postobstructive diuresis. It is for this reason that a careful fluid chart, daily measurements —will require pressure—flow studies to be performed. BOO. Some men — particularly those with irritative symptoms, suspected neurological disease or those with technically imperfect flow rate measurements —will require pressure—flow studies to be performed.

**Indications for elective treatment in men with symptoms of prostatism**

Following careful assessment (see section of assessment of men with prostatism), the following questions should be answered.

1. **Is bladder outflow obstruction present?**

   In many cases, the findings of significant symptoms (assessed by symptoms scoring), a benign prostate supplemented by the finding of a low maximum flow rate (≤10—12 ml/second for a good voided volume (>200 ml)) will suffice to make a reasonable working diagnosis of BOO. Some men — particularly those with irritative symptoms, suspected neurological disease or those with technically imperfect flow rate measurements —will require pressure—flow studies to be performed.

2. **How severe are the symptoms and what are the risks of doing nothing?**

   Severe symptoms and a large residual volume of urine will usually require treatment. Men with mild symptoms, good flow rates (>10 ml/second) and good bladder emptying (residual urine <100 ml) may be safely managed by reassurance and review: such patients rarely develop severe complications such as retention in the long term.

3. **Is the man fit for operative treatment?**

4. **What treatments are available, what are the outcomes and do the side effects justify treatment?**

   In men who do not have a strong indication for operative treatment the options for treatment are shown below

   **Nonoperative treatment for BPH**

   • Conservative ‘watchful waiting’ — general advice about fluid intake, use of anticholinergic medication in men with mild symptoms

   • Use of prostatic stents in men with retention who are unfit or have dementia

   • Balloon dilatation of the prostate (experimental)

   • Drug treatment to supplement conservative treatment in men with mild symptoms (a-adrenergic blocking agents and 5a-reductase inhibitors)

   • Use of permanent indwelling catheters in unfit men with retention or associated dementia

**Minimally invasive methods**

These are new and their roles are not yet determined:
• contact laser of the prostate;
• microwave treatment of the prostate (thermo therapy);
• other new minimally invasive methods of prostate destruction including microwave hyperthermia and thermal ablation and high—energy ultrasound.

**Conventional operative treatment**

This includes:

• transurethral resection of the prostate (TURP);
• bladder neck incision for the small prostate (<20 g);
• open prostatectomy for the big gland (—80—100 g).

**Men with symptoms attending for elective treatment (excluding acute and chronic retention)**

**Conservative treatment**

It is in men with relatively mild symptoms, reasonable flow rates (>10 ml/second) and good bladder emptying (residual urine <100 ml) that careful discussion over the merits and side effects of operative treatment is warranted. Waiting for a period of 6 months after careful discussion of the diagnosis indicated. After this a repeat assessment of symptoms, flow rates and ultrasound scan is helpful; many men with stable symptoms will elect to leave matters be. Advice over limiting fluid intake in the evening and careful use of propantheline to help with irritative symptoms is also useful.

**Drugs**

In men who are very concerned about the development of sexual dysfunction after TURP, the use of drugs may be helpful. Two classes of drugs have been used in the treatment of men with BOO. These include alpha-adrenergic blocking agents which inhibit the contraction of smooth muscle which is found in the prostate. The other class of drug is the 5alpha-reductase inhibitors, which inhibit the conversion of testosterone to DHT, the androgen which is effective. These drugs, when taken for a year, result in a 25 per cent shrinkage of the prostate gland. On average, both drugs seem to be of similar efficacy, and although the 5alpha-reductase inhibitors have fewer side effects, alpha-blockers work more quickly. They result in improvements in maximum flow rates by about 2 ml/second greater than placebo and result in mild (20 per cent) improvement in symptom scores. TURP, however, results in improvements in maximum flow rates from 9 to 18 ml/second and 75 per cent improvements in symptom scores. These drugs are expensive in comparison to their effectiveness and a significant proportion of men who try these drugs will subsequently undergo TURP. Their role may be best targeted on men who have failed an initial trial of watchful waiting and who wish to avoid surgery for a period.

**Operative treatment**

Apart from the strong indications for operative treatment mentioned above, the commonest reason for TURP is a combination of severe symptoms and a low flow rate <12 ml/second. The key is to assess symptoms carefully and to counsel men about side effects and likely outcome before advising operative treatment.

**Counselling men undergoing prostatectomy**

Men undergoing prostatectomy need to be advised about the following.

1. **Retrograde ejaculation** occurs in about 65 per cent of men after prostatectomy.

2. **Erectile impotence** occurs in about 5 per cent of men, usually in those whose virility is waning.

3. **The success rate** — on the whole men with acute and chronic retention do well from the symptomatic point of view. Ninety per cent of men undergoing elective operation for severe symptoms and urodynamically proven BOO do well in terms of symptoms and flow rates. Only about 65 per cent of those with mild symptoms or those with weak bladder contraction as the cause of their symptoms do well. Men with unobstructed detrusor instability do not respond well to TURP. This is the reason for carefully documenting the severity of symptoms and flow rates — supplemented when necessary by pressure—flow studies — before deciding on treatment.

4. **The risk of reoperation** after TURP is about 15 per cent after 8—10 years.

5. The morbidity rate: death after TURP is infrequent (<0.5 per cent), severe sepsis is found in about 6 per cent and severe haematuria requiring transfusion >2 units is found in about 3 per cent. After discharge about 15—20 per cent of men subsequently require antibiotic treatment for symptoms of urinary infection. Risk factors for complications include admission with retention, prostate cancer, renal impairment and advanced age.

**Methods of performing prostatectomy**

The prostate can be approached (1) transurethrally — TURP, (2) retropubically — RPP, (3) through the bladder (transvesical — TVP) or (4) from the perineum (Fig. 66.12). **Preliminary vasectomy** is now no longer performed.

**Transurethral resection of the prostate**

TURP has largely replaced other methods unless diverticulectomy or the removal of large stones necessitates open operation; over 95 per cent of men being treated by trained urologists can be dealt with by TURP. The earlier instruments designed by McCarthy have been replaced by single-hand-operated instruments often being used under video control. Perhaps the greatest advance in the history of transurethral surgery was marked by the development of the rigid lens system of Professor Harold Hopkins. His lenses illuminated by a fibre-optic light source permit unparalleled visualisation of the working field. Men with indwelling catheters, those with recent urinary infection, those with chronic retention or those with prosthetic material or heart valves should receive broad-spectrum prophylactic antibiotics with amoxycillin plus cefuroxime.
intravenously at induction of anaesthesia.

Strips of tissue are cut from the bladder neck down to the level of the verumontanum (Fig. 66.13). Cutting is performed by a high-frequency diathermy current which is applied across a loop mounted on the hand-held trigger of the resectoscope. Coagulation of bleeding points can be accurately achieved and damage to the external sphincter is avoided provided one uses the verumontanum as a guide to the most distal point of the resection. The ‘chips’ of prostate are then removed from the bladder using an Ellik evacuator. Hypo-natraemia is avoided by using 1.5 per cent isotonic saline for irrigation and the recent introduction of continuous flow resectoscope makes the procedure swift and safe in experienced hands. At the end of the procedure, careful haemostasis is performed and a three-way, self-retaining catheter irrigated with isotonic saline is introduced into the bladder to prevent any further bleeding from forming blood clots. Irrigation is continued until the outflow is pale pink and the catheter usually removed on the second or third post-operative day. In men with small prostates or bladder neck dyssynergia or stenosis, it is better to divide the bladder neck and prostatic urethra with a diathermy ‘bee-sting’ electrode.

Retro public prostatectomy (Millin, 1945)

Using a low, curved transverse suprapubic Pfannenstiel incision, which includes the rectus sheath, the recti are split in the midline and retracted to expose the bladder with its typical appearance of pale brown muscle bundles with a loose covering of fatty tissue and veins. With the patient in the Trendelenberg position, the surgeon separates the bladder and the prostate from the posterior aspect of the pubis. In the space thus obtained the anterior capsule of the prostate is incised with diathermy below the bladder neck, care being taken to obtain complete control of bleeding from divided prostatic veins by suture ligation. The prostatic adenoma is exposed and enucleated with a finger. A wedge is taken out of the posterior lip of the bladder neck to prevent secondary stricture in this region. The exposure of the inside of the prostatic cavity is good, and control of haemorrhage is achieved with diathermy and suture ligation of bleeding points before closure of the capsule over a Foley catheter (inserted per urethram) draining the bladder.

Transvesical prostatectomy

The bladder is opened, and the prostate enucleated by putting a finger into the urethra, pushing forwards towards the pubes to separate the lateral lobes, and then working the finger between the adenoma and the false capsule. In Freyer’s operation (1901) the bladder was left open widely and drained by a suprapubic tube with a 16-mm lumen, in order to allow free drainage of blood and urine. Harris (1934) advocated control of the prostatic arteries by lateral stitches inserted with his boomerang needle, the bladder wall was closed and the wound drained.

Perineal prostatectomy (Young)

This has now been abandoned for the treatment of BPH.

After-treatment

Most urologists irrigate the bladder with sterile saline by means of a three-way Foley catheter for 24 hours or so.

Complications

Local

Haemorrhage is a major risk following prostatectomy whatever the surgical approach. Care should be taken in diathermising arterial bleeding points after TURP; they are often better seen when the rate of inflow of fluid is decreased. In the recovery room one should check that the bladder is adequately draining, if it is not this may indicate that a clot is blocking the eye of the catheter. The bladder should be promptly washed out using strict aseptic technique. The catheter should be changed by the surgeon. Only rarely is it necessary to return the patient to the operating room.

Secondary haemorrhage tends to occur after the patient has been discharged. All men should be warned about this possibility and given appropriate advice to rest and to have a high fluid intake. It is usually minor in degree, but if clot retention occurs, the patient will need to be readmitted, a catheter will have to be passed and the bladder washed out.

Perforation of the bladder or the prostatic capsule can occur at the time of transurethral surgery. This usually occurs from a combination of inexperience in association with a large prostate or heavy blood loss. If the field of vision becomes obscured by heavy blood loss, it is often prudent to achieve adequate haemostasis and abandon the operation, swallowing one’s pride on the understanding that a second attempt may be necessary. A large perforation with marked extravasation may require the insertion of a small suprapubic drain. Rectal perforation should be extremely rare.

Sepsis. Bacteraemia is common even in men with sterile urine and occurs in over 50 per cent of men with infected urine, prolonged catheterisation or chronic retention. Septicaemia can occur in these patients shortly after operation or when the catheter is removed. In men at high risk the use of prophylactic antibiotics is recommended. Wound infection following open prostatectomy is common if a urethral catheter has been in situ for a number of days before the operation. Perhaps the most worrying aspect of infection is the early rigor following surgery. If left undetected and untreated this may progress to frank septicaemia with profound hypotension. A blood culture should be taken and antibiotics given parenterally, e.g. amoxycillin plus cefuroxime.

Incontinence. Incontinence is inevitable if the external sphincter mechanism is damaged. The bladder neck is rendered incompetent by these operations and therefore an intact distal sphincter mechanism is essential for continence. Damage to the sphincter may occur at open prostatectomy and following transurethral surgery if the resection extends beyond the verumontanum. If pelvic floor physiotherapy is ineffective, then the only satisfactory treatment is the fitting of an artificial urinary sphincter. In some patients, detrusor instability contributes to incontinence. The use of anti-cholinergic agents or imipramine may help.

Retrograde ejaculation and impotence — see previous section.

Urethral stricture. This may be secondary to prolonged catheterisation, the use of an unnecessarily large catheter, clumsy instrumentation or to the presence of the resectoscope in the urethra for too long a period. These strictures arise either just inside the meatus or in the bulb urethra. An early stricture can usually be managed by simple bougination but later on it may be necessary to cut the densely fibrotic stricture with the optical urethrotome. The routine use of an Otis urethrotomy prior to TURP reduces the incidence of postoperative stricture.

Bladder neck contracture. Occasionally a dense fibrotic stenosis of the bladder neck occurs following overaggressive resection of a small prostate. It may be due to the overuse of the coagulating diathermy. Transurethral incision of the scar tissue is necessary.
Reoperation

It is now known that after 8 years, 15—18 per cent of men with BPH will undergo repeat TURP (the rate after open prostatectomy is about 5 per cent). The reasons include a technically imperfect primary procedure and a speculative repeat operation in men with symptoms who are cystoscoped after operation.

General complications

Death occurs in about 0.2—0.3 per cent of men undergoing elective prostatectomy. In very elderly men, in men with prostate cancer admitted as an emergency with acute or chronic retention, or those with very large prostates the 30-day death rate may be in the order of 1—1.5 per cent.

Cardiovascular. Pulmonary atelectasis, pneumonia, myocardial infarction, congestive cardiac failure and deep venous thrombosis are all potentially life-threatening conditions that can affect this elderly and often frail group of men.

Water intoxication. The absorption of water into the circulation at the time of transurethral resection can give rise to congestive cardiac failure, hyponatraemia and haemolysis. Accompanying this there is frequently confusion and other cerebral events often mimicking a stroke. The incidence of this condition has been reduced since the introduction of isotonic glycine for performing the resections and the use of isotonic saline for postoperative irrigation. The treatment consists of fluid restriction.

Osteitis pubis is rare.

Newer treatments

In general, newer, minimally invasive treatments occupy a position intermediate between TURP and drug treatment. As yet, there are no long-term data on duration of effectiveness.

Microwave and laser treatments and other methods of tissue destruction

Microwave treatment aims at providing an external source of microwaves which are then focused within the prostate gland. The source may be within the rectum or the urethra, although recent machines use the intraurethral route. With the first-generation machines, the prostate heats to between 40°C and 45°C (hyperthermia). There is very minimal tissue destruction and there is no rise in serum PSA, confirming that little of the prostate is damaged. Although there may be symptom improvement, there are no improvements in voiding pressures. The next generation of microwave machines is able to provide an increased source of energy which destroys some of the prostate (thermotherapy — temperature >50°C). The outcome appears to be better than hyperthermia.

Laser treatments can be of several types. In one a noncontact probe is used to vaporize prostatic tissue under direct vision. There is no bleeding and this treatment can be used to carry out bladder neck incisions in men with small prostate glands as day-case treatment and a catheter may not be necessary. Hence this treatment would be potentially cost-effective in this setting. The cost of the probes at present, however, is £500, which would balance out any cost saving in terms of hospital stay. These probes are not useful in the treatment of men with large glands as the treatment would take too long.

Another type of laser is a contact side-firing laser of lower energy but greater penetration. This energy results in necrosis of the prostate gland to a varying thickness. The energy can be applied transurethrally under direct vision or transurethrally under the control of ultrasound. The potential advantage of the latter technique is that it means that greater energy can be applied to thicker areas of BPH, ensuring a more complete treatment. A suprapubic catheter is inserted for several weeks whilst the necrotic prostate sloughs — significant symptoms can occur during this period. There is little or no bleeding and the treatment can be given as a short-stay procedure or day-case procedure. Laser treatment, however, requires a general anaesthetic. The cost of the probes is about £400. A laser can be purchased for about £45000.

The outcome of contact laser treatment appears to be better than microwave hyperthermia, with improvement in flow rates from 9 to about 14 ml/second and improvement in symptom score by about 50 per cent. It is as yet unclear how effective it is in comparison to TURP in terms of cost-effectiveness, symptomatic and urodynamic outcome. Other types of laser treatment include interstitial laser therapy, which involves the insertion of laser probes into the substance of the prostate, and Holmium laser treatment. The latter approach involves excision of parts of the prostate using a cutting laser and then morcellating the excised prostate fragments which fall back into the bladder so that they can be removed.

There are newer methods of treatment becoming available including focused high-frequency ultrasound and direct treatment of the prostate with needles providing high-energy electromagnetic treatment. The outcome of these treatments is unknown.

Intraurethral stents (Fig. 66.14)

These devices are helpful in the management of men with retention and who are grossly unfit (classified by the American Society of Anesthesiologists as ASA grade IV or V). These men are rare cases.
Bladder outflow obstruction due to the bladder neck

Aetiology

This condition usually occurs in men, but can rarely affect children of both sexes and women. It may be due to muscular hypertrophy, or fibrosis of the tissues at the bladder neck following TURP.

Clinical syndromes

1. **Due to muscle hypertrophy or dyssynergia.** Marion described a series of cases in which muscular hypertrophy of the internal sphincter in a young person had resulted in the development of a vesical diverticulum or hydronephrosis (Marion's disease or prostatism sans prostate). It is thought that dyssynergic contraction of the smooth muscle of the bladder neck (bladder neck dyssynergia) may account for some cases of bladder outflow obstruction.

2. **Due to fibrosis.** The symptoms are similar to those of prostatic enlargement, but are a consequence of scarring after TURP

Treatment

The management of these patients depends on achieving an accurate diagnosis. For this, urodynamic investigation is often necessary, which should demonstrate raised voiding pressures and diminished flow rate.

**Drugs**

The presence of alpha-adrenergic receptors in the region of the bladder neck and prostatic urethra allows pharmacological manipulation of the outflow to the bladder. Alpha-blocking drugs: alfuzosin — 2.5 mg b.d. to t.d.s. (to a total maximum of 10 mg/day); doxazosin — 1 mg nocte (up to maximum of 8 mg/day); indoramin — 20 mg b.d. (increased to total maximum of 100 mg/day in divided doses); prazosin 500 mg b.d. (maintenance up to 2 mg/day); and terazosin 1 mg nocte (to a total maximum of 10 mg/day) can be very useful, causing relaxation of the bladder neck. These drugs are not target specific and the patients must be warned of the possibility of possible postural hypotension.

**Transurethral incision**

Transurethral incision of the bladder neck is the operation of choice. Sometimes symptoms recur, but this is usually due to inadequate division of the fibres of the bladder neck.

**Congenital valves of the prostatic urethra**

See Chapter 60.
Prostatic calculi are of two varieties: endogenous, which are common, and exogenous, which are comparatively rare.

An exogenous prostatic calculus is a urinary (commonly ureteric) calculus that becomes arrested in the prostatic urethra. This is considered in Chapter 60.

Endogenous prostatic calculi are usually composed of calcium phosphate combined with about 20 per cent of organic material.

Clinical features
Prostatic calculi are usually symptomless, being discovered on TRUS, radiography of the pelvis, during prostatectomy, or associated with carcinoma of the prostate or chronic prostatitis. In cases associated with severe chronic prostatic infection, the associated fibrosis and nodularity are difficult to differentiate from carcinoma. On X-ray or ultrasound scanning, these stones often form a horseshoe (Fig. 66.15) or a circle.

Treatment of prostatic calculi
They usually require no treatment.

Conservative measures
Associated chronic prostatic infection may be treated by means of ciprofloxacin or trimethoprim.

Transurethral resection
Transurethral resection will often release small calculi as the strips of prostatic tissue are excised. Others are passed per urethram at a later date.

Corpora amylaceae
Corpora amylaceae are tiny calcified lamellated bodies found in the glandular alveoli of the prostates of elderly men and apes, but not in the prostates of animals lower in the phylogenetic scale than anthropoids. Corpora amylaceae are probably the forerunners of endogenous prostatic calculi.
Carcinoma of the prostate

Carcinoma of the prostate is the commonest malignant tumour in men over the age of 65 years. In England and Wales in 1998 11,000 men were registered and 8000 died from it; the corresponding figures in the USA were 130,000 and 25,000, respectively. If histological section of prostates at autopsy is performed increasingly frequent foci of microscopic prostate cancers are found with increasing age. These foci of prostate cancer have variable potential for progressing clinically to metastatic disease. About 10—15 per cent of younger men who develop prostate cancer have a positive family history of the disease, but the aetiology is unclear. Throughout the world, rates of microscopic foci of prostate cancer are constant, but rates of clinically evident disease are low in men in Japan and China. Carcinoma of the prostate usually originates in the peripheral zone of the prostate (Fig. 66.2), so ‘prostatectomy’ for benign enlargement of the gland confers no protection from subsequent carcinoma.

Types of prostate cancer

Latent carcinoma of the prostate

Serial sections of prostates obtained at routine necropsy demonstrate prostate carcinoma in 15—20 per cent of men between 50 and 65 years of age. The incidence in men over 80 is in the region of 50 per cent (Franks). Most of these neoplasms are tiny and (if life had continued) might have remained latent for years.

Types of prostate cancer

- Microscopic latent cancer found on autopsy or at cystoprostatectomy
- Tumours found incidentally during TURP (ha and Tlb); or following screening by PSA measurement — T1c
- Early, localised prostate cancer (T2)
- Advanced local prostate cancer (T3 and T4)
- Metastatic disease which may arise from a clinically evident tumour (T2, T3 or T4) or which may arise from an apparently benign gland (T0, T1), i.e. occult prostate cancer

It should be noted that only the last two groups cause symptoms and such tumours are not curable. Only screening or the treatment of incidentally found tumours can result in cure of the disease. The problem is that many such tumours would never progress during the patient’s lifetime — herein lies the problem with prostate cancer.

Histological appearances

The prostate is a glandular structure consisting of ducts and acini; therefore the histological pattern is one of an adeno-carcinoma. The prostatic glands are surrounded by a layer of myoepithelial cells. The first change associated with carcinoma is the loss of the basement membrane with glands appearing to be in confluence. As the cell type becomes less differentiated more solid sheets of carcinoma cells are seen. A classification of the histological pattern based on the degree of glandular de differentiation and its relation to stroma has been devised by Gleason; this (and the volume of the cancer) appears to correlate well with the likelihood of spread and of prognosis.

Local spread

Locally advanced tumours tend to grow upwards to involve the seminal vesicles, the bladder neck, trigone and, later, the tumours tend to spread distally to involve the distal sphincter mechanism. Further upward extension obstructs the lower end of one or both ureters, the latter terminating in anuria. The rectum may become stenosed by tumour infiltrating around it, but direct involvement is rare.

Spread by the bloodstream

Spread by the bloodstream occurs particularly to bone; indeed the prostate is the most common site of origin for skeletal metastases, being followed in turn by the breast, the kidney, the bronchus and the thyroid gland. The bones involved most frequently by carcinoma of the prostate are the pelvic bones and the lower lumbar vertebrae. The femoral head, rib cage and skull are other common sites.

Lymphatic spread

Lymphatic spread may occur (1) via lymphatic vessels passing to the obturator fossa or along the sides of the rectum to the lymph nodes beside the internal iliac vein and in the hollow of the sacrum and (2) via lymphatics which pass over the seminal vesicles and follow the vas deferens for a short distance to drain into the external iliac lymph nodes. From retroperitoneal lymph nodes, the mediastinal nodes and occasionally the supraclavicular nodes may become implicated.

Staging using the tumour, node, metastasis (TNM) system (Fig.66.16)

1. T1a, T1b and T1c: these are incidentally found tumours in a clinically benign gland after histological examination of a prostatectomy specimen. T1a is a well or moderately well-differentiated tumour involving less than 5 per cent of the resected specimen. T1b is a poorly differentiated tumour or a tumour involving >5 per cent of the resected specimen. T1c tumours are impalpable tumours found following PSA screening

2. T2a disease presents as a suspicious nodule (Fig. 66.17) on rectal examination of <2 cm

- T2b disease is a nodule involving greater than 2 cm
  - T2c is tumour in both lobes but still clinically confined

3. T3 is a tumour involving the seminal vesicles or bladder neck

4. T4 is a tumour involving the rectum or pelvic side wall

Clinical features
Only advanced cases give rise to symptoms, but even advanced cases may be asymptomatic. Symptoms of advanced disease include:

- BOO;
- pelvic pain and haematuria;
- bone pain, malaise, 'arthritis', anaemia or pancytopaenia;
- renal failure;
- locally advanced disease or even asymptomatic metastases may be found incidentally on investigation of other symptoms.

Early prostate cancer is asymptomatic and it may be found:

- incidentally following TURP for clinically benign disease (T1);
- as a nodule (T2) on rectal examination.

Rectal examination

Examination under anaesthesia together with cystoscopy and needle biopsy (Fig. 66.18) or TRUS may be used to assess the local stage. Irregular induration, characteristically stony hard in part or in the whole of the gland — with obliteration of the median sulcus — suggests carcinoma. Extension beyond the capsule up into the bladder base and vesicles (Fig. 66.19) is diagnostic, as is deformity and projection outwards of the capsule (Fig. 66.20).

General blood tests

These are normal in early disease, but in metastatic disease there may be leucoerythroblastic anaemia secondary to extensive marrow invasion or anaemia may be secondary to renal failure. There may be thrombocytopenia and evidence of disseminated intravascular coagulopathy with increased fibrinogen degradation products (FDPs).

Liver function tests

These will be abnormal if there is extensive metastatic invasion of the liver. The alkaline phosphatase may be raised from either hepatic involvement or secondaries in the bone. These can be distinguished by measurement of isoenzymes or gamma-glutamyl transferase.

Prostate-specific antigen

This is discussed earlier in this chapter. It is good at following the course of advanced disease. It is lacking in sensitivity and specificity in the diagnosis of early localised prostate cancer. Nevertheless, the finding of a PSA >10 nmol/ml is suggestive of cancer and >35 ng/ml is diagnostic of advanced prostate cancer. A decrease of PSA to the normal range following hormonal ablation is a good prognostic sign.

Acid phosphatase

Acid phosphatase has been superseded by measurement of PSA.

Radiological examination

X-ray of the chest may reveal metastases either in the lung fields or the ribs. An abdominal X-ray may show the characteristic sclerotic metastases in lumbar vertebrae and pelvic bones (Fig. 66.21). The bone appears dense and coarse and sometimes difficulty is found distinguishing the change from that in Pager's disease of bone. Osteolytic metastases nevertheless are very common in prostate cancer and may coexist with sclerotic ones. Information about the upper urinary tracts can be obtained by excretion urography or ultrasound.

Ultrasonography

TRUS remains the most accurate method of staging the local disease. It can be used in the early detection of tumours in screening programmes. Local (T2) disease can be diagnosed with increased sensitivity by TRUS (Fig. 66.17) compared with rectal examination, but nevertheless many tumours will be missed. This problem remains a real one in screening for early prostate cancer; in comparison with breast cancer where mammography will detect 70—80 per cent of tumours, TRUS plus rectal examination and measurement of PSA will detect only 30—50 per cent of cancers that are known to be present on autopsy studies (although it may detect the larger, more significant cancers).

Bone scan

Once the diagnosis has been established, it would be normal to perform a bone scan as part of the staging procedure if the PSA is >20 nmol/ml. If the PSA is <20 nmol/ml then a bone scan would only be performed on clinical indications. The bone scan is performed by the injection of technetium-99m, which is then monitored using a gamma camera. It is more sensitive in the diagnosis of metastases (Fig. 66.22) than a skeletal survey, but false positives occur in areas of arthritis, osteomyelitis or a healing fracture.

Lymphangiography

This is no longer carried out. If accurate information is required then pelvic lymphadenectomy can be performed by means of laparoscopic surgery.

Bone marrow aspiration

Sometimes examination of the bone marrow will reveal the presence of metastatic carcinoma cells.
Treatment of carcinoma of the prostate

Natural history of prostate cancer

T1 and T2
The progression rate of well-differentiated ha prostate cancer is very low, being about 10—14 per cent after 8 years
For moderately differentiated tumours the rate is about 20 per cent, but for T1b tumours the rate is in excess of 35 per cent
Similar rates of progression (20—30 per cent) are found for T2 disease

T3 and T4 (MO)
About 50 per cent progress to bony metastases after 3—5 years

M1
The median survival of men with metastatic disease is about 3 years

Prostatic biopsy
If there is suspicion of prostate cancer, because of either local findings, a raised PSA or metastatic disease, then a transrectal biopsy using an automated gun with appropriate antibiotic cover is indicated. Several cores may be needed to make a diagnosis. The incidence of sepsis from transrectal biopsy increases if more than three biopsies are taken. If there are associated symptoms of BOO then either:
• a TURP can be performed which will provide diagnostic material and symptomatic relief;
• transrectal biopsy can be carried out. If the diagnosis is positive and there is locally advanced disease, then hormone ablation can provide good symptomatic relief without the need for operation.

Early disease
Curative treatment can only be offered to patients with early disease (T1a, T1b, T1c and T2). The treatment of patients with advanced disease (T3, T4 or any MO) is only palliative.

Radical prostatectomy
Radical prostatectomy is only suitable for localised disease (T1 and T2) and should only be carried out in men with a life expectancy of >10 years. Exclusion of metastases would require a negative bone scan, chest X-ray and a serum PSA <20 nmol/ml. It is a major surgical procedure and should only be performed by experienced surgeons when there is a high chance of cure. It results in a high incidence of impotence, but a low incidence of severe stress incontinence (<5 per cent) which may require the fitting of an artificial urinary sphincter. It involves removal of the prostate down to the distal sphincter mechanism in addition to the seminal vesicles (Fig. 66.23). The bladder neck is reconstituted and anastomosed to the urethra. Recent modifications to this operation by Professor Patrick Walsh of the Johns Hopkins Hospital in Baltimore have led to the realisation that careful dissection in early stage disease can lead to preservation of the neurovascular bundles which lie behind the prostate. This modification has led to the preservation of erectile function in about 60—70 per cent of cases.

Pelvic lymph node dissection
Pelvic lymph node dissection is carried out immediately prior to radical prostatectomy when radical treatment is being considered. In some centres this was combined with the open open implantation of 125I seeds, although with recent surgical modification of radical prostatectomy this is now only rarely performed.

Radical radiotherapy for early prostate cancer
Radical radiotherapy to the prostatic bed and pelvic lymph nodes rather than radical surgery has tended to be the treatment of choice in the UK for locally confined prostate cancer. The survival rates in the treatment of T1 to T2 disease are not greatly different from radical prostatectomy, although histological evidence of persistent tumour is found within the prostate in about 30 per cent of treated patients. Patients with locally advanced disease (T3) may be treated by radiotherapy, but most urologists treat such patients by means of androgen ablation. The treatment requires the patient to attend hospital on a daily basis for between 4 and 6 weeks. Some local complications are inevitable, namely irritation of the bladder with urinary frequency, urgency and sometimes urge incontinence and similar problems affecting the rectum with diarrhoea and, occasionally, late radiation proctitis.

Advanced disease
There is still debate about the timing of androgen ablation treatment in patients with locally advanced or metastatic disease without symptoms. The options are androgen deprivation at diagnosis or careful review, reserving active treatment for the later development of symptoms. Patients with local or general symptoms should be offered androgen deprivation.

Orchidectomy
Orchidectomy is performed to carry out androgen ablation in the treatment of locally advanced (T3 or T4) disease or of metastatic disease. In 1941 prostate cancer was shown to be responsive to such treatment by Charles Huggins — the only urologist to win the Nobel Prize. Bilateral orchidectomy, whether total or subcapsular, will eliminate the major source of testosterone production.

Hypophysectomy and adrenalectomy
These treatments are no longer carried out. In the past, patients who had initially responded to hormone treatment but subsequently relapsed were thought to have a small chance of obtaining further relief if a hypophysectomy was performed.

General radiotherapy
General radiotherapy for symptomatic metastases is an excellent form of palliative treatment often producing dramatic pain relief in men with hormone-relapsed prostate cancer. More recently, hemibody irradiation has been shown to decrease symptoms in men with widespread bony metastases.

**Strontium**

Strontium is now being employed as a bone-seeking isotope which delivers effective radiotherapy to metastatic areas. It appears to be as effective as hemibody irradiation in the treatment of men with metastatic hormone-relapsed disease.

**Medical forms of androgen ablation**

Medical forms of androgen ablation have been available since the discovery of stilboestrol. Initially there was great enthusiasm for this treatment and Honvan® (phosphorylated diethylstilboestrol) could be given intravenously. Both treatments are effective in producing regression of prostate cancer, but are associated with significantly increased thrombotic complications and cardiovascular mortality. Even if stilboestrol is used at a dose of 1 mg three times a day complications can occur. Other hormones that have been tried include progesterone and Provera®.

The other commonly available treatment to reduce testosterone levels to the castrate range is LHRH agonists. These agents initially stimulate hypothalamic LHRH receptors, but because of their constant presence (rather than the normal diurnal rhythm) they then down-regulate them, resulting in cessation of pituitary LH production and hence a decrease in testosterone production. In the first 10 days or so, serum testosterone levels may increase and it is wise to give flutamide, bicalutamide (Casodex) or Cyproterone acetate for this period. LHRH agonists may be given by monthly or 3 monthly depot injection.

Other treatments have become available recently which block the androgen receptor. Cyproterone acetate also has some progestogenic effect, whilst flutamide and bicalutamide are pure antiandrogen. In general, oral monotherapy has not been shown to be as good as LHRH agonists or orchidectomy.

**Complete androgen blockade**

Complete androgen blockade has been advocated as being likely to result in increased life expectancy and an increased time to progression in a fitter subgroup of men with advanced prostate cancer. The concept is that of abolishing the testicular secretion of testosterone by means of orchidectomy or the use of LHRH therapy and then inhibiting the effects of adrenal androgenic steroids by means of androgen receptor blockade with flutamide, bicalutamide (Casodex) or the use of cyproterone acetate. Recent overviews of randomised trials do not confirm earlier reports of effectiveness.

**Cytotoxic agents** in the treatment of these elderly men have proved disappointing, but whether this is because the tumour is inherently insensitive or because these elderly men will not tolerate effective doses is uncertain.

**Summary of treatment**

1. **Incidentally diagnosed T1a and T1b disease.** For men in their 70s conservative treatment would usually be the correct approach. Radical surgical treatment might be considered in the younger (<65 years) man with this form of the disease, although even in this group some men will elect to pursue a conservative course when counselled about risks versus benefits.

2. **Localised T2 disease.** In younger fitter men (<65 years), this may be treated by radical prostatectomy or radical radiotherapy. Watchful waiting remains an option — particularly for more elderly patients. In the elderly patient with outflow obstruction transurethral resection with or without hormone therapy is indicated. The benefit of radical treatment over a conservative approach is likely to be at most 25 per cent, given that progression to metastatic disease is in this order of magnitude after 10 years.

3. **Locally advanced T3 and T4 disease.** These patients are at significant risk of disease progression. Early androgen ablation is favoured if close follow-up is not possible. For the sexually active a careful conservative approach with the adoption of androgen ablation when symptoms arise is reasonable.

4. **Metastatic disease.** Once metastases have developed the outlook is poor. For patients with symptoms there is no dilemma; androgen ablation will provide symptomatic relief in over two-thirds of the patients. For patients with asymptomatic metastases the timing of treatment is less clear.

There are few hard and fast rules in the treatment of this cancer, but the surgeon should avoid making the patients worse through creating more complications as a result of treatment than the disease would have caused in its own right.
Prostatitis

In both acute and chronic prostatitis the seminal vesicles and posterior urethra are usually also involved.

Acute prostatitis

A etiology

Acute prostatitis is common, but underdiagnosed. The usual organism responsible is Escherichia coli, but Staphylococcus aureus and albus, Streptococcal faecalis and Neisseria gonorrhoea may be responsible. The infection may be haematogenous from a distant focus or it may be secondary to acute urinary infection.

Clinical features

General manifestations overshadow the local: the patient feels ill, shivers, may have a rigor, has ‘aches’ all over, especially in the back, and may easily be diagnosed as having influenza. The temperature may be up to 39°C. Pain on micturition is usual, but not invariable. The urine contains threads in the initial voided sample which should be cultured. Perineal heaviness, rectal irritation and pain on defecation can occur; a urethral discharge is rare. Frequency occurs when the infection involves the bladder. Rectal examination reveals a tender prostate, one lobe may be swollen more than the other and the seminal vesicles may be involved. A frankly fluctuant abscess is uncommon.

Treatment

Treatment must be rigorous and prolonged or the infection will not be eradicated and recurrent attacks may ensue. Spread of infection to the epididymes and testes may occur. Prolonged treatment with an antibiotic which penetrates the prostate well is indicated (trimethoprim or ciprofloxacin).

Prostatic abscess

In addition to the foregoing symptoms and signs, the advent of a prostatic abscess is heralded by the temperature rising steeply with rigors. Antibiotics disguise these features. Severe, unremitting perineal and rectal pain with occasional tenesmus often cause the condition to be confused with an anorectal abscess. Nevertheless, if a rectal examination is performed, the prostate will be felt to be enlarged, hot, extremely tender and perhaps fluctuant. Retention of urine is likely to occur and in such men suprapubic catheterization is best.

Treatment. The abscess should be drained without delay.

1. The abscess can be drained by perurethral resection —un-roofing the whole cavity.
2. The perineal route is rarely indicated unless there is marked periprostatic spread.

Chronic prostatitis

Many urologists find the syndromes of chronic prostatitis and ‘prostatodynia’ very difficult, for many men present with perigenital pain, testicular pain, prostatic pain exacerbated by sexual intercourse or pain which apparently renders sexual intercourse out of the question. Psychosexual dysfunction in such patients may be the underlying problem. The diagnosis of chronic prostatitis has to be based on:

• persistent threads in voided urine;
• prostatic massage showing pus cells with or without bacteria in the absence of urinary infection.

Aetiology

This is thought to be sequel of inadequately treated acute prostatitis. While pus is present in the prostatic secretion, often the responsible organism is difficult to find. Other organisms such as Chlamydia species may be responsible for chronic abacterial prostatitis.

Clinical features

The clinical features are extremely varied. Only men with symptoms of posterior urethritis, prostatic pain and perigenital pain accompanied by intermittent fever and pus cells or bacteria in the postprostatic massage specimen should be diagnosed as having chronic prostatitis.

Diagnosis

1. The three-glass urine test is valuable. If the first glass with the initial voided sample shows urine containing prostatic threads, prostatitis is present.
2. Rectal examination of the prostate may be normal or may show a soft, boggy and tender prostate.
3. Examination of the prostatic fluid obtained by prostatic massage should show pus cells and bacteria.
4. Urethroscopy may reveal inflammation of the prostatic urethra, and pus may be seen exuding from the prostatic ducts. The verumontanum is likely to be enlarged and oedematous. In many men with the symptoms described above all investigations are normal.

Treatment

Antibiotic therapy should only be administered in accordance with bacteriological sensitivity tests. Trimethoprim penetrates well into the prostate. Where trichomonas or anaer-obes are the responsible agent, a rapid response is obtained from administration of flagyl (metronidazole, 200 mg b.d.s. for 7 days to both partners). If Chlamydia is suspected, doxycycline is the antibiotic treatment of choice. It is uncertain whether prostatic massage helps in eradicating the infection.
Prostatodynia

This diagnosis is made by the presence of perigenital pain in the absence of any objective evidence of prostatic inflammation. Whether the syndrome has any relationship with the prostate is unclear.
Tuberculosis of the prostate and seminal vesicles

Tuberculosis of the prostate and seminal vesicles is rare and associated with renal tuberculosis. In 30 per cent of cases, there is a history of pulmonary tuberculosis within 5 years of the onset of genital tuberculosis.

Tuberculosis of one or both seminal vesicles may be found when examining a patient with chronic tuberculosis epididymitis, no symptoms being referable to the internal geni-talia. On rectal examination, the affected vesicle is found to be nodular.

When the prostate is involved, rectal examination reveals nodules in one or both lateral lobes. Patients with tuber-culous prostatitis usually present with the following:

• urethral discharge;
• painful, sometimes bloodstained, ejaculation;
• mild ache in the perineum;
• infertility;
• dysuria;
• abscess formation.

Special forms of investigation

Radiography sometimes displays areas of calcification in the prostate and/or the seminal vesicles.

Bacteriological examination of the seminal fluid yields positive cultures for tubercle bacilli.

Treatment

The general treatment is that for tuberculosis. If a prostatic abscess forms it should be drained transurethrally.
Seminal vesicles

Acute seminal vesiculitis

Acute seminal vesiculitis occurs in association with prostatitis. Prior to the antibiotic treatment of gonorrhoea, gonococcal vesiculitis was common.

Chronic seminal vesiculitis

Chronic seminal vesiculitis usually presents with haematospermia and pain on intercourse. TRUS demonstrates the features of distension, thickening and the presence of turbid fluid. The treatment is the same as for chronic prostatitis.

Tuberculous seminal vesiculitis

The clinical features and treatment have been discussed above.

Diverticulum of the seminal vesicle

Diverticulum of the seminal vesicle occurs occasionally. In such cases, the kidney of that side is absent and the diverticulum represents an abortive ureteric bud. It is a cause of persistent infection.

Cyst of the seminal vesicle

A cyst of the seminal vesicle is uncommon and rarely requires treatment. It may be removed by dissection through an incision similar to that for perineal prostatectomy, if it is large or giving rise to symptoms.
The male urethra

The most common congenital abnormalities of the male urethra are:

- meatal stenosis;
- congenital urethral stricture;
- congenital valves;
- hypospadias;
- epispadias.

Meatal stenosis

A congenital stenosis of the external urinary meatus, normally the narrowest part of the male urethra, is associated with phimosis. After circumcision, meatal ulceration may lead to stricturing of the meatus. When the meatal opening is reduced to a pinhole there may be chronic retention of urine with back-pressure effects and eventually chronic renal failure. Lesser degrees of stenosis lead to loss of the normal urinary stream with spraying or dribbling.

Treatment by meatotomy or meatal dilatation is indicated for symptomatic stenosis, if the stricture is sufficient to prevent free drainage of discharge in a patient with urethritis or there is a need to pass endoscopic instruments transurethrally.

Meatotomy

The tightened meatus is opened by cutting down on to a fine probe placed in the anterior urethra. The cut edges of urothelium and skin are sewn together with absorbable suture. If the stenosis recurs a skin flap can be laid in as a meatoplasty to widen the meatus (Fig. 67.1).

Congenital urethral stricture

This condition is rare. Some cases are associated with duplication of the urethra. Usually symptoms are delayed until adolescence, when it may be difficult to be sure that a supposedly congenital stricture of the bulbar urethra is not due to unrecognised urethral injury in childhood. A single treatment by optical urethrotomy or dilatation is usually effective.

Congenital valves of the posterior urethra

These are symmetrical folds of urothelium which can cause obstruction to the urethra of boys. They are usually found just distal to the verumontanum but they may be within the prostatic urethra. They behave as flap valves so, although urine does not flow normally, a urethral catheter can be passed without difficulty. In some instances, the valves are incomplete and the patient remains without symptoms until adolescence or adulthood. In such cases the prostatic urethra is grossly dilated and saccules and diverticula are present within it.

The valves are difficult to see on urethroscopy because the flow of irrigant sweeps them into the open position. If the bladder is filled with contrast medium, the dilatation of the urethra above the valves can be demonstrated on a voiding cystogram.

Treatment

A suprapubic catheter is inserted to relieve the back pressure and allow the effects of renal failure to subside before definitive treatment by transurethral resection of the valves using a paediatric resectoscope.

Hypospadias

Hypospadias occurs in one in 350 male births and is the most common congenital malformation of the urethra. The external meatus opens on the underside of the penis or the perineum, and the inferior aspect of the prepuce is poorly developed (‘hooded prepuce’).

Hypospadias is classified according to position of the meatus.

Glandular hypospadias — this is the most common type and does not usually require treatment. The normal site of the external meatus is marked by a blind pit, although it occasionally connects by a channel to the ectopic opening on the underside of the glans.

- Coronal hypospadias — the meatus is placed at the junction of the underside of the glans and the body of the penis.
- Penile and penoscrotal hypospadias — the opening is on the underside of the penile shaft (Fig. 67.2).
- Perineal hypospadias — this is the most severe abnormality. The scrotum is split and the urethra opens between its two halves. There may be testicular maldescent which may make it difficult to determine the sex of the child.

The more severe varieties of hypospadias represent an absence of the urethra and corpus spongiosum distal to the ectopic opening. The absent structures are represented by a fibrous cord which deforms the penis in a downward direction (chordee). The more distant the opening from its normal position, the more pronounced the bowing.

Treatment

Glandular hypospadias does not need treatment unless the meatus is stenosed, in which case a meatotomy is performed. Surgery is indicated for other forms of hypospadias to improve sexual function and for cosmetic reasons. A bewilering variety of plastic surgical procedures is described to correct the chordee and to bring the urethra to an opening at the tip of the penis. Most of these procedures make use of prepuceal skin and so circumcision should be avoided until the hypospadias has been repaired. Operations for hypospadias are best performed by a specialist paediatric urologist and will not be detailed here.

Epispadias

Epispadias is very rare, occurring in one in 30000 males and one in 400000 females. In penile epispadias the opening on the dorsum is
associated with upward curvature of the penis (Fig. 67.3). Total epispadias usually goes with ectopia vesicae and other severe developmental defects.
Injuries to the male urethra

Rupture of the bulbar urethra

Rupture of the bulbar urethra is the most common urethral injury. There is a history of a blow to the perineum usually due to a fall astride a projecting object. In the days of sailing ships, the common cause was falling astride a spar; the modern equivalent is seen among workers losing their footing on scaffolding. Cycling accidents, loose manhole covers (Fig. 67.4) and gymnasium accidents astride the beam account for a number of cases.

Clinical features

The triad of signs of a ruptured bulbar urethra is retention of urine, perineal haematoma and bleeding from the external urinary meatus.

Preliminary assessment and treatment

The patient will be in pain and should be treated with appropriate analgesic drugs. He should be discouraged from passing urine if rupture of the urethra is suspected. Instead, if the bladder is full, a simple percutaneous suprapubic puncture should be performed and a fine catheter inserted to drain (Fig. 67.3). This will reduce the likelihood of urinary extravasation and allow appropriate investigations to establish the full extent of the urethral injury. If the patient has already passed urine when first seen and there is no extravasation the rupture, if any, is partial and a catheter is not needed. Either case, it is probably wise to administer a course prophylactic antibiotics.

Treatment. The initial management of bulbar urethral injuries has been controversial but a consensus is emerging. The main worry is the injudicious urethral catheterisation will convert a partial tear into a complete transection of the urethra. The initial treatment described above to be recommended for most of those who go into urinary retention after the accident, especially if there is bleeding from the urethra. More information may be obtained by an ascending urethrogram or even flexible cystoscopy to assess the injury. Very occasionally, if the facilities for passing a percutaneous suprapubic catheter are not available, it may be permissible to try to pass a soft, small-calibre urethral catheter without force. This may allow a few patients to avoid the open placement of suprapubic tube into the bladder.

If investigations show a complete tear of the urethra, the suprapubic catheter should be left in place until arrangements can be made to repair it. Some surgeons advocate early open repair of the urethra with excision of the traumatised section and spatulated end-to-end reanastomosis of the urethra (Fig. 67.6). Others wait longer before embarking upon repair operation but may attempt to find a way across the gap in the urethra using a urethroscope. This allows a urethral catheter to be placed so that the alignment of the urethra is as near as possible to normal when healing occurs.

Complications

Subcutaneous extravasation of urine occurs in complete rupture if the patient attempts to pass urine.

Stricture is a common sequel to urethral trauma, whether there is a partial or complete tear or simply periurethral bruising. Infection may also play a part.

Rupture of the membranous urethra

Extra peritoneal rupture of the urethra

Intrapelvic rupture of the membranous urethra occurs near the apex of the prostate (Fig. 67.7). Like extraperitoneal rupture of the bladder, it may be due to penetrating wounds but in civilian life it is most usually a result of pelvic fracture.

Fracture of the pubic and ischial rami is most likely to result when sudden force is applied to one lower limb in a car accident or in landing on one leg after falling from a height. There is an associated disruption of the sacroiliac joint so that one half of the pelvis and ischiopubic rami is pushed up above the other. This applies a traction force on the prostate which is firmly bound by ligaments to the back of the symphysis pubis. The torn ends of the urethra may be widely displaced by this type of injury.

In another type of pelvic fracture the patient suffers a front-to-back compression of the pelvis in a blow directly from the front. A ‘butterfly fracture’ of the pubic rami on each side occurs. If the compressive force is relieved, the pubic fragment springs back so that the ends of the torn urethra are close to each other. About 10–15 per cent of cases of fractured pelvis have associated urethral injury.

Clinical features

The most common causes of pelvic fracture are road traffic accidents, severe crush injuries and falls. There is often multiple trauma with injury to the head, thorax and abdomen, and fracture of long bones. Often the management of these injuries must take precedence and the over-riding priority is to keep the patient alive by appropriate resuscitation.

The urethral injury can be managed in the short term by inserting a suprapubic catheter, and this should be done as soon as it is practicable. The type of urethral injury can often be deduced from the plain radiograph—a major urethral disruption is almost certain if there is significant displacement of the pubic bones. If the prostate is displaced, it may be impossible to reach or appear to be very ‘high’ on rectal examination. An ascending urethrogram may be justified if there is doubt. There may be associated injury to the bladder with either an intraperitoneal or extraperitoneal rupture. The former is associated with the onset of peritonitis and if suspected demands exploration and repair of the bladder even if laparotomy is not indicated by other injuries. Extraperitoneal rupture of the bladder causes symptoms which are difficult to distinguish from those of rupture of the membranous urethra. There is pain, bruising and dullness to percussion above the umbilicus. If there is a significant bladder rupture it must be repaired, a suprapubic catheter inserted and the retroperitoneal space drained.

Stricture. The main complication of urethral trauma is urethral stricture. When the injury is severe and the disrupted ends of the urethra are far apart the stricture is likely to be very difficult to treat. Because of this worry, some surgeons urge that an attempt should be made to realign the urethra as soon as the emergency is over and the patient is well enough to be taken to theatre. Often the orthopaedic surgeons will want to improve the position of the pelvic fragments at this stage with the possibility of external fixation. In some cases a urethral catheter can be inserted if a way through the stricture can be found with a flexible or rigid urethroscope. In others an open repair of the urethra can be attempted. Other surgeons feel that it is better to allow a longer period of recovery before attempting to correct the urethral injury.

If the urethra is relatively well aligned, an established urethral stricture may be treatable by optical urethrotomy (Sachse) but many of these patients need a full-scale urethroplasty. Sometimes the ends of the urethra are widely displaced and there is extensive fibrosis and even ectopic calcification where the urethra should be. Occasionally there is such a gap that the ends can only be brought together by cutting away...
the pubic bone. The management of a severe urethral stricture should be in the hands of a specialist urologist.

**Urinary incontinence.** If the external urethral sphincter is destroyed, continence of urine will depend upon the competence of the bladder neck mechanism. Subsequent surgical manoeuvres such as prostatectomy which destroy the bladder neck may cause incontinence.

**Impotence.** Erectile impotence is common after pelvic fracture with urethral injury. It is assumed that this is the result of damage to the nerve supply of the penis. The patients are usually able to achieve erection with prostaglandin injections or a vacuum device.

**Orthopaedic**

For management of the fractured pelvis, see Chapter 21 on ‘Fractures and dislocations’.
Extravasation of urine

Superficial extravasation is likely with complete rupture of the bulb urethra and in ruptured urethral abscess.

The extravasated urine is confined in front of the midperineal point by the attachment of Colles fascia to the triangular ligament, and by the attachment of Scarpa’s fascia just below the inguinal ligament. The external spermatic fascia stops it getting into the inguinal canals. Extravasated urine collects in the scrotum and penis and beneath the deep layer of superficial fascia in the abdominal wall.

Treatment is by urgent operation to drain the bladder by suprapubic cystostomy. This prevents further extravasation.

Deep extravasation (Fig. 67.7) occurs with extraperitoneal rupture of the bladder or intrapelvic rupture of the urethra. It can also occur if the ureter is damaged or if there is perforation of the prostatic capsule or bladder during trans-urethral resection. Urine extravasates in the layers of the pelvic fascia and the retroperitoneal tissues.

Treatment is by suprapubic cystostomy and drainage of the retropubic space.
Inflammations of the urethra

Inflammatory conditions of the urethra include:

• meatal ulcer;
• urethritis:
  — gonococcal urethritis;
  — nonspecific urethritis;
  — Reiter’s syndrome.

Ulceration of the urethral meatus

Meatal ulcer is quite common in circumcised boys. It may occur soon after the operation or may be delayed for up to 2 years from circumcision. Lack of protection by the prepuce seems to be the excitatory cause with friction from clothing and ammoniacal dermatitis as contributory factors. The ulcer forms a scab which blocks the meatus and the child can only pass urine by bursting the scab. This hurts so the boy screams and a tiny amount of blood may be passed as well. The process causes fibrosis which can result in an acquired pinhole meatus.

Treatment

Local measures to soften the scab and alkalinise the urine are often curative. A few need meatotomy.

Gonorrhoeal urethritis

Gonorrhoea is a sexually transmitted disease caused by Neisseria gonorrhoeae (gonococcus), a Gram-negative kidney-shaped diplococcus that infects the anterior urethra in the male, the urethra and cervix in females, and the oropharynx, rectum and anal canal in both sexes, but especially men.

**Gonorrhoea in men** usually declares itself by urethral discomfort and urethral discharge up to 10 days after exposure. There is often scalding dysuria. In some there may be no symptoms other than slight discharge.

**Investigations.** Pus and gonococci are present in the Gram-stained urethral smear. The passage of pus in the first part of the urinary stream can be demonstrated as haziness in the first glass of a two-glass test. Treatment should not wait upon the results of urethral culture when the clinical picture and urethral smear are typical.

**Complications** are uncommon in the UK and are all prevented by effective treatment. Local complications include posterior urethritis, prostatitis — acute or chronic, acute epididymo-orchitis, periurethral abscess and urethral stricture. Gonococcal arthritis, iridocyclitis, septicaemia and endocarditis are even more unusual.

**Treatment** is by antibiotics, usually penicillin. The effective concentration may be increased by probenecid and high doses may be needed for resistant strains. Completely resistant beta lactamase-producing strains, rare in the UK, will not respond to penicillin whatever the dose. Patients with these organisms and those allergic to penicillin must be treated with second-line drugs such as kanamycin.

Contact tracing is important in controlling the spread of the disease.

**Gonorrhoea in women** affects primarily the urethra and cervix, and is often symptomless. It can never be diagnosed on clinical grounds alone. Almost three-quarters of all female cases attend initially as a result of contact tracing. Symptoms which are present in 50 per cent or less often consist of a mild dysuria or slight urethral discharge which can go unnoticed by the patient. If Skene’s tubules are emptied by milking the urethra against the posterior pubic ramus, a bead of pus may appear at the urethral meatus. There may be some reddening or erosion of the cervix with a mucopurulent cervical plug but copious vaginal discharge is more likely to be due to concomitant trichomonal vaginitis.

**Complications.** Gonococcal proctitis occurs in at least 60—70 per cent of cases and is usually symptomless. Ten per cent suffer from salpingitis which, if bilateral, may lead to infertility.

**Gonorrhoea in the newborn** is now rare. It used to be an important cause of blindness.

Nonspecific urethritis (syn. nongonococcal urethritis)

This is a form of urethritis which is diagnosed by exclusion when gonorrhoea and other known infections have been excluded. At present some 40 per cent of cases are due to Chlamydia trachomatis and some are shown to be caused by Urea plasma urealytica. The causative agent in up to 50 per cent is unknown.

**Clinical features.** Dysuria and a mucopurulent urethral discharge appear up to 6 weeks after sexual intercourse. The urine is usually grossly clear but may contain ‘threads’ or pus cells. Epididymitis is not uncommon and urethral stricture rarely results. In women the condition presents as a form of urethrotitis and may be very resistant to diagnosis.

**Treatment** with oxytetracycline or doxycycline is usually effective, although relapse is common especially in men in whom the prostate may act as a reservoir of infection. It is important to treat both partners as re-infection is probable if this is not done.

Reiter’s disease

Reiter’s disease (syn. sexually acquired reactive arthritis) is usually Sexually transmitted in the UK but abroad it is more commonly dysenteric in origin. Subacute urethritis 4—6 weeks after contact is associated with a clear, viscid discharge which is free from organisms.

A few days later, conjunctivitis, unilateral then bilateral, occurs in50 per cent. In more severe cases there is anterior uveitis. Usually in10 days to 2 weeks arthritis supervenes but it is not an invariable feature of the condition. Another concurrent manifestation is keratoderma blennorrhagicum, consisting of nodules, vesicles and pustules frequently found on the sole of the foot (Fig. 67.8).

**Differential diagnosis.** This is principally from gonorrhoea, which must be excluded by blood culture. In Reiter’s disease, the urethritis and
arthritis are milder and the incubation period is longer than gonorrhoea.

**Prognosis.** The urethritis and conjunctivitis frequently subside in a few weeks but the arthritis may persist for months. Severe anterior uveitis and frequently recurrent attacks suggest a bad outlook.

**Treatment.** The ophthalmic complications are treated with eye baths and shades. Mydriatics and topical steroids are indicated for iritis. Other symptoms may prove difficult to control and severe cases should be under the care of a specialist in genitourinary medicine.
Urethral stricture

The causes of urethral stricture are:

- congenital;
- traumatic;
- inflammatory:
  - postgonorrhoeal;
  - post urethral chancre;
  - tuberculous;
- instrumental:
  - indwelling catheter;
  - urethral endoscopy;
- postoperative:
  - open prostatectomy;
  - amputation of penis.

Postgonorrhoeal stricture

This is less common since the introduction of effective antibiotic treatment for gonorrhoea. The stricture is most com-monly in the bulbar urethra but postmeatal strictures are also seen.

Pathology. Infection in the periurethral glands persists after inadequately treated gonorrhoea. The infection spreads to cause a perurethritis which heals by fibrosis to result in a stricture. Most strictures appear within 1 year of infection but they may not cause difficulty in micturition for 10—15 years.

Clinical features

The first symptoms are usually those of bladder outflow obstruction with straining to void and poor urinary stream. The relative youthfulness of the patient often distinguishes these from the symptoms of prostatic enlargement which characteristically occur after the age of 50. As the stream becomes narrower, micturition is prolonged with dribbling after it seems to have ended. This is due to urine trickling from the dilated urethra proximal to the stricture. Increased urinary frequency by day and night is also common, and is due to incomplete bladder emptying or infection, or both.

When the stricture is well established, it may be possible to palpate the scarring along the line of the urethra. If the stricture is tight enough, the patient will go into acute retention. If this happens, there is a danger that ham-fisted attempts to pass a urethral catheter will result in a false passage. If a patient has gone into retention because of a urethral stricture, the urethra will be too narrow to allow even a tiny catheter to pass safely.

Urethroscopy allows the stricture to be viewed as a circumferential scar (Fig. 67.9). The openings of false passages may be seen if there have been misguided attempts to pass a urethral catheter.

Urethrography using a water-miscible gel containing contrast medium will show the extent and severity of the stricture or failure of the medium to pass beyond the tightness indicating complete stenosis (Figs 67.10 and 67.11).

Treatment of urethral stricture is by:

- dilatation:
  - gum-elastic bougie;
  - filiform and follower;
  - metal sounds;
  - self-dilation with Nélaton catheter;
- urethrotomy:
  - internal visual urethrotomy;
- urethroplasty:
  - excision and end-to-end anastomosis;
  - patch urethroplasty.

Intermittent dilatation is the traditional treatment for stricture. Under aseptic conditions, the urethra is stretched using a graduated series of dilators. With care and gentleness, the procedure can be performed under local urethral anaesthesia with lignocaine gel. The main drawback of dilatation is that it is performed ‘blind’ so there is always a danger of causing a false passage which will make the stricture worse. This is most likely to occur when the operator is inexperienced or unfamiliar with the complexities of an individual patient’s urethra. As with any instrumentation of the urinary tract, infection is a danger and fatal septicaemia has been known to follow a supposedly straightforward dilatation. Urethral dilatation still has a place in elderly gentlemen who have a short stricture which recurs at infrequent intervals. In these patients, occasional bougienage may be preferable to more complex procedures. It may be possible for some patients to dilate their own urethras by intermittently passing a soft Nélaton catheter.

Instruments. Strictures have been treated by surgeons for centuries and there are many different dilating instruments on the shelves of surgical museums, each with the name of the surgeon who invented it. A simple stricture may be dilated using metal sounds (Fig. 67.12), so called because they were originally used to ‘sound’ for stones in the bladder or gum-elastic bougies (French ‘candle’) (Fig. 67.13). These must be wielded with great care as it is easy to make a false passage with them. Filiform gum-elastic filaments which can be passed through the lumen of a urethral stricture (Fig. 67.15). This is usually best done under direct vision using a urethroscope, although the ‘faggot method’ may be helpful if endoscopes are not available (Fig. 67.14). Once the lumen has been located with its tip, the other end of the filiform is screwed on to a ‘follower’: a gum-elastic bougie with a screw thread at its tip for the purpose (Fig. 67.15). As the follower is advanced the filiform guides it safely through the stricture. Once the stricture has been partially dilated by followers of increasing size, it is often safe to change to metal dilators. Patients who have had an optical urethrotomy are sometimes taught to keep the stricture open by regular self-dilatation with a urethral catheter of a suitable size.

Operative treatment. Internal urethrotomy is performed using the Sachse optical urethrotome. The stricture is cut under visual control using a tiny knife passed through the sheath of a rigid urethroscope. The stricture is usually cut at the 12 o’clock position taking care not to cut too deeply into the vascular spaces of the corpus spongiosum which surrounds the urethra. If one cut is insufficient, others can be made until there is a wide passage through the strictured segment of urethra. After the procedure, many surgeons leave a catheter for 1—2 days, but there is no evidence that this makes a significant difference to the effectiveness of the procedure. A single urethrotomy seems to give a
confirmed by urethroscopy.

Urethral calculi. A stone formed within the urethra is less likely to cause recognisable symptoms and is usually detected during urethroscopy or bouginage. Migratory calculi cause sudden pain in the urethra soon after an attack of ureteric colic. There is blockage to the flow of urine and, if the stone is small, the force of the jet will expel it from the external urethral meatus. Larger stones become stuck and have to be removed endoscopically. It is sometimes possible to feel the calculus as a hard lump in the urethra, but if there is doubt the diagnosis is confirmed by urethroscopy.

Treatment. A stone in the prostatic urethra is displaced back into the bladder and treated by litholapaxy or suprapubic cystotomy as if it

Urethroplasty. The simplest urethroplasty involves excision of the stenosed length of urethra and reanastomosis of the spatulated cut end (Fig. 67.6). This operation is only possible if the stricture is relatively short because there must be no tension at the suture line. If end-to-end anastomosis is not feasible, there is a large number of different plastic surgical procedures to replace part or all of the wall of the strictured urethra using free full-thickness or pedicled skin grafts. The Orandi—Blandy operation makes use of a myocutaneous patch of perineal skin and darts muscle (Fig. 67.16): Turner-Warwick favours penile skin.

Urethroplasty should be considered when more simple means fail to give lasting relief of symptoms. The procedure can be very demanding, especially when the stricture is the result of pelvic trauma and the urethra is encased in woody, hard fibrosis. A prolonged hospital stay is usual while the graft heals.

Other causes of urethral stricture

Congenital stricture has been considered previously.

Traumatic stricture. The stricture which follows neglected or untreated rupture of the membranous urethra is sometimes a complete loss of continuity. These patients often need a transpubic urethroplasty to bridge the gap.

Post instrumental stricture. This follows endoscopy or catheterisation and may affect any part of the urethra. Some surgeons recommend prophylactic dilatation or urethroscopy before transurethral surgery to try to avoid this complication. Some cases of stricture seem to be due to a sensitivity to chemicals from the catheter but most are the result of a combination of trauma, infection and pressure necrosis.

Postoperative stricture. Postoperative stricture develops after about 4 per cent of prostatectomies, irrespective of the method employed. The stricture is usually in the proximal part of the prostatic urethra and is also known as bladder neck stenosis. If it cannot be managed by dilatation, bladder neck stenosis should be treated by transurethral incision and resection of the stricture.

Postoperative stricture is also a complication of amputation of the penis (see below).

Complications of urethral stricture

Complications include:
• retention of urine;
• urethral diverticulum;
• periurethral abscess;
• urethral fistula;
• hernia, haemorrhoids and rectal prolapse due to abdominal straining to void urine.

Diverticulum of the male urethra (syn. urethral pouch). This is usually congenital and represents a partial duplication of the urethra. Acquired cases are uncommon. They are sometimes seen as a result of increased intraurethral pressure behind a stricture. Others are due to the long-standing presence of a foreign body such as a stone or calculus in the urethra.

Treatment is by excision of the diverticulum and removal of the cause if possible.

Periurethral abscess. Periurethral abscesses can be either penile, bulbar or chronic.

A penile periurethral abscess usually arises as an acute gonococcal infection of one of the glands of Littré. The tender induration felt on the underside of the penis points and discharges externally, often leaving a fistula.

Treatment. An anterior urethrotomy will encourage the abscess to burst into the urethra. When the abscess lies behind a stricture, it should be opened externally.

A bulbar periurethral abscess is a spreading cellulitis due to infection with streptococci and anaerobic organisms. It may or may not be associated with a urethral stricture, and extravasation of urine is not unusual.

Clinical features. There is perineal pain with pyrexia, rigors and a rapid pulse rate. Tenderness and swelling rapidly spread from the perineum to the penis and the anterior abdominal wall.

Treatment. Appropriate antibiotics are essential. Collections of pus should be drained and the urethra should be defunctioned by inserting a suprapubic urinary catheter.

A chronic periurethral abscess sometimes results from a long-standing urethral stricture (Fig. 67.17). The multiple loculi of pus should be drained and the stricture treated appropriately. Urethral fistula may occur either spontaneously or as a result of incision of the abscess.

Urethral fistula. The most frequent cause of urethral fistula is bursting or incision of a periurethral abscess. If the fistulae arise behind a tight stricture, there may be multiple openings (watering-can perineum). A fistula can also follow urethroplasty if there is necrosis of part of the graft.

Treatment. If the stricture is cured, some fistulae heal themselves. Occasionally urethroplasty is indicated.

Urethral calculi. Urethral calculi can arise primarily behind a stricture or in an infected urethral diverticulum. More commonly, the stone is a renal calculus which has migrated to the urethra via the bladder.

Clinical features. Migratory calculi cause sudden pain in the urethra soon after an attack of ureteric colic. There is blockage to the flow of urine and, if the stone is small, the force of the jet will expel it from the external urethral meatus. Larger stones become stuck and have to be removed endoscopically. It is sometimes possible to feel the calculus as a hard lump in the urethra, but if there is doubt the diagnosis is confirmed by urethroscopy.

A stone formed within the urethra is less likely to cause recognisable symptoms and is usually detected during urethroscopy or bouginage.

Treatment. A stone in the prostatic urethra is displaced back into the bladder and treated by litholapaxy or suprapubic cystotomy as if it
were a bladder stone. Calculi in more distal parts of the urethra are removed by basketing under vision or fragmented in situ using the electrohydraulic or ultrasonic lithotriptor. It may be necessary to perform a meatotomy to deliver the stone. Open removal by external urethrotomy is rarely necessary.

**Neoplasms**

**Polyps** are a relatively common finding in the prostatic urethra where they may result from chronic infection.

**Genital warts** acquired by sexually transmitted infection are sometimes found in the anterior urethra as an extension of warts on the skin of the glans penis.

**Angioma** of the urethra is a very rare cause of urethral bleeding.

**Carcinoma of the urethra** is relatively rare. Multifocal transitional cell cancers of the bladder are sometimes associated with tumours in the prostatic urethra and occasionally more distally. Although these tumours are usually superficial and can be destroyed locally by diathermy or laser, they seem to be associated with a tendency to distant spread. Squamous carcinoma can develop in an area of squamous metaplasia sometimes seen downstream of a urethral stricture. It carries a poor prognosis even if the patient is treated by radical surgery. A bloody discharge from the urethra in the absence of infection should raise the suspicion that the patient has a urethral tumour.

**The female urethra**

Abnormalities of the female urethra include:

- prolapse;
- stricture;
- diverticulum;
- carbuncle;
- carcinoma.

**Prolapse.** Prolapse occurs in later life and is usually symptomless. Prolapse of the urethral lining also occurs as a congenital abnormality when it causes discomfort proportional to the degree of prolapse.

**Stricture.** This is uncommon in women but it may follow urethritis or, more commonly, the trauma of a difficult labour. Urinary retention, usually chronic, is an occasional result. True urethral strictures in women respond well to dilatation and should not be confused with a spasm of the urethral muscle of obscure cause which sometimes causes retention in women, particularly after they have had unrelated surgery. The condition, which was described by Fowler and Kirby, is associated with an abnormal myotonic discharge in the urethral sphincter which can be detected on an electromyogram. The patients remain in retention after urethral dilatation and many of them require intermittent self-catheterisation for life.

**Diverticulum** (syn. urethrocele). Diverticulum is more common in women than men. Some seem to be congenital. Others are acquired by rupture of a distended urethral gland or injury of the urethra during childbirth. Urine within the diverticulum becomes infected causing local pain and repeated bouts of cystitis. Purulent urine is discharged if the urethra is compressed with a finger placed in the vagina. Excision of the diverticulum through the anterior vaginal wall is effective but care must be taken not to damage the urethral sphincter.

**Carbuncle.** This is common in elderly women. It presents as a soft, raspberry-like, pedunculated granulomatous mass about the size of a pea attached to the posterior urethral wall near the external meatus. It is composed of highly vascular connective tissue stroma infiltrated with pus cells.

**Clinical feature.** There may be frequency of micturition and pain afterwards. Occasionally there is bleeding. A urethral prolapse is less tender and is not pedunculated.

**Treatment.** Treatment is by excision and diathermy coagulation of the base of the stalk. The patient should be given antibiotics to treat the underlying chronic urethritis.

**Papilloma acuminata.** Papilloma acuminata are the same as the sexually transmitted warts which occur on the penis. They are treated in the same way. In female Africans, papilloma acuminata are common and may grow to such a large size during pregnancy that they obstruct labour and necessitate a Caesarian section (Bowesman).

**Carcinoma of the urethra.** This occurs twice as often in women as in men. Whether a carbuncle can become malignant is disputed but they often occur in a similar site. Malignant swellings of the urethra feel harder than benign ones.

**Treatment** by radiotherapy or radical surgery is often ineffective. The overall prognosis is poor.
**The penis**

**Phimosis**

Phimosis is sometimes congenital but is much over-diagnosed. The physiological adhesions between the foreskin and the glans penis may persist until the boy is 6 years of age or more, giving the false impression that the prepuce will not retract. Rolling back the prepuce causes its inner lining to pout and the meatus comes into view. This condition should not be confused with true phimosis in small boys where there is scarring of the prepuce which will not retract without fissuring. In these cases, the aperture in the prepuce may be so tight as to cause urinary obstruction. Urinary difficulty with residual urine and back-pressure effects on the ureters and kidney is more commonly due to meatal atresia which may be masked by the prepuce. Phimosis also occurs later in life as a result of **balanitis xerotica obliterans**, a curious condition in which the normally pliant foreskin becomes thickened and will not retract. It is difficult to keep the penis clean, and there is both a problem with hygiene and an increased susceptibility to carcinoma.

**Treatment** is by circumcision.

**Circumcision**

Apparently, circumcision did not originate among the Jews: they took the practice from either the Babylonians or the Negroes, probably the latter. It had been practised in West Africa for over 5000 years.

**Indications. In infants and young boys,** circumcision is most usually performed at the request of the parents for social or religious reasons. Occasionally, there is true phimosis with recurrent attacks of balanitis. As stated above, it is normal for the prepuce to be long and adherent to the glands during the first few years of life. Recurrent balanoprosthitis and phimosis may result from misguided attempts by parents to expose the glans forcibly.

**In adults,** circumcision is indicated because of inability to retract for intercourse, for splitting of an abnormally tight frenulum, balanitis and sometimes prior to radiotherapy for carcinoma of the penis.

**Technique in an infant.** The much advocated method of applying a clamp or bone forceps across the prepuce distal to the glans with blind division of the foreskin can no longer be condoned. To see one little boy with partial or total amputation of the glans is enough to realise the folly of this technique. It is far better to perform a proper circumcision under direct vision as in an adult.

The **Plastibel** (Hollister) is used as shown in Fig. 67.18: the ring separates between 5 and 8 days postoperatively.

**Technique in adolescents and adults.** In adolescents and adults the following method is preferable. The prepuce is held in haemostats and put on a gentle stretch. A circumferential incision in the penile skin is made at the level of the corona using a knife. The prepuce is then slit up the midline dorsally to within 1 cm of the corona. This converts the foreskin into two flaps connected at the midline anteriorly. When the undersurface of the prepuce has been separated from the glans, the inner layer of each flap is incised with a second circumferential incision leaving about 5 mm of the inner layer of the prepuce distal to the corona. Cutting the remaining connective tissue completes the excision (Fig. 67.19). Monopolar diathermy should be avoided in operations on the penis in small boys because there is a danger that the small current path will cause coagulation at the base of the penis. Haemostasis is important in circumcision, however, and should be secured by bipolar diathermy or ligated with catgut. The cut edges are approximated using catgut sutures and the layers in the immediate region of the frenulum are brought neatly together using a mattress suture (Fig. 67.20).

**Preputial calculi**

Late in life, chronic posthitis may lead to adhesions between the prepuce and the glans and closure of the orifice of the preputial sac. Preputial calculi result from inspissated smegma, urinary salts or both.

**Injuries**

**Avulsion of the skin of the penis**

Entanglement of clothing in rotating machinery is the usual cause. Repair is effected by burying the shaft of the penis in the scrotum (Fig. 67.21) with subsequent release at the time of a definitive plastic surgical repair. The prepuce is also at risk in the zip fastening of the trouser fly.

**Fracture of the penis**

Fracture of the penis is an uncommon accident usually occurring when the erect penis is bent violently downwards during over-enthusiastic intercourse. The extravasation of blood causes great pain and swelling. In early cases, incision and drainage of the clot with suture of the defect in the tunica of the ruptured corpus cavernosum give acceptable results.

**Strangulation of the penis**

Strangulation of the penis by rings placed on the penis, usually for sexual reasons, can cause venous engorgement which prevents their removal. It may help to aspirate the corpora cavernosa but often the ring must be cut off with a ring cutter or hacksaw.
**Paraphimosis**

When the tight foreskin is retracted, it may sometimes be difficult to return and a paraphimosis results. In this condition, the venous and lymphatic return from the glans and distal foreskin is obstructed and these structures swell alarmingly causing even more pressure within the obstructing ring of prepuce. Ice bags, gentle manual compression and injection of a solution of hyaluronidase in normal saline may help to reduce the swelling. Such patients can be treated by circumcision if careful manipulation fails. A dorsal slit of the prepuce under local anaesthetic may be enough in an emergency.
Inflammations

Balanoposthitis

Inflammation of the prepuce is known as posthitis; inflammation of the glans is balanitis. The opposing surfaces of the two structures are often involved — hence the term balanoposthitis. Skin conditions such as lichen planus and psoriasis affect the penis and may indeed be localised there. Drug hypersensitivity reactions can affect the skin of the penis.

In mild cases, the only symptom is itching and some discharge. In more severe inflammation, the glans and foreskin are red raw and pus exudes. Balanoposthitis is associated with penile cancer, diabetes and phimosis. Monilial infections are quite common under the prepuce.

Treatment is by broad-spectrum antibiotics and local hygienic measures.

Genital herpes

Genital herpes is caused by sexual transmission of the herpes virus hominis HPV (human papilloma virus type 2 — occasionally type 1). Recurrent attacks occur in 50 per cent or more. Pain along the distribution of the sensory nerve, usually genitofemoral, precedes the eruption by 2 days and may be particularly severe around the anus. A group of tiny vesicles rapidly erodes to form shallow yellow- or red-based ulcers. In females the ulcers often spread on to the thighs during the attack. Involvement of the urethra may cause retention of urine which may persist for up to 14 days if there is radiculitis of the S2 and S3 nerve roots. Acyclovir has been shown to be effective in treating genital herpenses but it does not prevent recurrences.

A child born to a mother with active infection is liable to a fatal generalised herpes in the neonatal period. Caesarean section should be considered in these circumstances. There is an increased risk of carcinoma of the cervix and annual cytology for life is recommended.

Lymphogranuloma venereum

Lymphogranuloma venereum is a sexually transmitted tropical disease caused by Chlamydia trachomatis (Chlamydia A) types L1—L3. The primary lesion is a fleeting, painless, genital papule or ulcer often unnoticed by the patient.

The inguinal glands become enlarged and painful in both sexes between 2 weeks and 4 months from infection. The masses of nodes mat together above and below the inguinal ligament to give the ‘sign of the groove’. The overlying skin reddens and there may be fluctuation. In women, there may be a proctitis which can go on to produce a rectal stricture if untreated. Lymphatic obstruction leads to lymphoedema in the perineum and occasionally the lower limbs. Urethritis and urethral stricture occur in the male.

Confirmation is by isolating Chlamydia A from the lesion and by immunological tests to detect antibodies against the organism.

Treatment is by a combination of antibiotics which may include sulphamamide, oxytetracycline and erythromycin. The multilocular bubo should not be incised — aspiration is permissible to reduce discomfort.

Granuloma inguinale

This is a chronic and slowly progressive ulcerative tropical disease —affecting the genitals and surrounding tissue but occasionally occurring elsewhere in the body. It is usually sexually transmitted and is most common among socially deprived people. The incubation period varies greatly but is frequently 7—30 days.

Clinical course

A painless vesicle or indurated papule usually on the external genitals but occasionally elsewhere on the skin gradually erodes into a slowly extending ulcer with a beefy red, granulomatous base. More chronic lesions may become greyish especially at the edges where, after months or years, malignant change may develop. The ulcerated area may bleed, if touched, but is surprisingly painless. Without treatment healing is only partial and keloid is common.

Diagnosis is by microscopy of material from the edges of the ulcer which shows the presence of short Gram-negative rods within the cytoplasm of the large mononuclear cells — Donovan bodies.

Treatment is by oxytetracycline, streptomycin or cotrimoxazole.

Condylomata acuminata (syn. genital warts)

Genital warts are caused by infection with human papilloma virus and are sexually transmitted. Ordinary skin warts can occur on the genitals by direct contact with a finger lesion but they are less moist, soft and less often pedunculated than the genital variety. The lesions most commonly occur under the prepuce in the coronal sulcus but may be found elsewhere, including inside the urinary meatus (Fig. 67.22). In women, genital warts are most commonly found on the vulva but they may line the vagina and occur on the cervix. Perianal warts are common.

Other associated sexually transmitted disease should be excluded — candidiasis and trichomonas mainly in women, and in men, syphilis or gonorrhoea. Genital warts may complicate human immunodeficiency virus (HIV) infection.

Treatment is by chemical or physical means. Podopyllin 25 per cent in spirit is often effective as a topical application. It is applied to the wart with great care to avoid the surrounding skin and washed off after 6 hours or so.

If chemical methods fail, the warts can be excised or they can be ablated with cryosurgery, electro surgery or laser. Circumcision is sometimes advised if there are florid lesions under the foreskin.

Other abnormalities

Chordee. Chordee (French = corded) is a fixed bowing of the penis due to hypospadias or, more rarely, chronic urethritis. Erection is deformed and sexual intercourse may be impossible. Treatment is usually surgical.

Peyronie's disease. Peyronie’s disease is a relatively common cause of deformity of the erect penis. On examination, hard plaques of fibrosis can be palpated in the tunica of one or both corpora cavernosa. The plaques may be calcified (Fig. 67.23). The presence of the unyielding plaque tissue within the normally elastic wall of the corpus cavernosum causes the erect penis to bend, often dramatically, towards
the side of the plaque. The aetiology is uncertain, but it may be a result of past trauma — there is an association with Dupuytren’s contracture (see Chapter 30).

**Treatment** is difficult. Some cases continue to progress. Others seem to remit after 3—5 years. Various drug treatments have been suggested but their beneficial effect is hard to prove in such a chronic condition. When the deformity of the penis is causing distress, it may be possible to straighten it by placing nonabsorbable sutures in the corpus cavernosum opposite the plaque. This reduces the elasticity in this region to balance that caused by the plaque (Nesbitt’s operation).

**Persistent priapism.** The penis remains erect and becomes painful. This is a pathological erection and the glans penis and the corpus spongiosum are not involved. The condition is usually seen as a complication of a blood disorder such as sickle cell disease or leukaemia. However, it can sometimes follow therapeutic injection of papaverine or even an abnormally prolonged bout of otherwise normal sexual activity. A tiny proportion is due to malignant disease in the corpora cavernosa or the pelvis. Priapism is rarely seen as a consequence of spinal cord disease.

**Treatment.** An underlying cause should be excluded. The patient should be referred for specialist urological care. If aspiration of the sludged blood in the corpora cavernosa fails to cause detumescence, and injection of metaraminol or 1:100 000 adrenaline solution is ineffective, it may be necessary to decompress the penis by an anastomosis between the corpus spongiosum and one of the corpora cavernosa. The outlook for normal erectile function is poor.
Carcinoma

Aetiology

Circumcision soon after birth confers almost complete immunity against carcinoma of the penis. Later circumcision does not seem to have the same effect and Moslems circumcised between the ages of 4 and 9 years are still liable to the disease. Chronic balanoposthitis is known to be a contributory factor and there are definite precarcinomatous states:

- **leucoplakia of the glans** is similar to the condition seen on the tongue;
- long-standing **genital warts** may rarely be the site of malignant change;
- **Paget's disease of the penis**.

**Paget's disease of the penis** (syn. **erythroplasia of Querat**) is ‘a persistent rawness of the glans like a long-standing balanitis followed by cancer of the substance of the penis’ (Sir James Pager). Treatment is by circumcision, observation and excision if the lesion does not resolve.

Pathology

Carcinoma of the penis may be flat and infiltrating or papillary (Fig. 67.24). The former often starts as leucoplakia and the latter results from an existing papilloma. Local growth continues for months or years. The earliest lymphatic spread is to the inguinal and then to the iliac nodes. Once the growth breaches the partial barrier formed by the fascial sheath of the corpora cavernosa it spreads rapidly and iliac lymph node involvement is common (Fig. 67.25). Distant metastatic deposits are infrequent.

Clinical features

Forty per cent of patients are under 40 years of age. The early symptoms of mild discomfort and light discharge are often neglected and the disease progresses slowly. By the time the patient presents, the growth is often large and secondary infection causes a foul bloody discharge. There is little or no pain.

Sixty per cent have inguinal lymph node enlargement when they present but in half this is reactive enlargement due to sepsis. In most the prepuce is non retractile and must be split to view the lesion. A biopsy should be performed to make the diagnosis.

Untreated, the whole glans may be replaced by a fungating offensive mass. Later the inguinal nodes erode the skin of the groin and the death of the patient may be due to involvement of the femoral or external iliac artery with torrential haemorrhage.

Treatment

**Radiotherapy** is effective (60—70 per cent survival at 5 years) if the growth is small. Circumcision precedes treatment which may be delivered by implanted radioactive tantalum wires, external beam radiation or by means of a radioactive mould applicator applied externally to the penis.

**Surgery** is needed for large anaplastic growths, if there is infiltration of the shaft and when radiotherapy fails. **Partial amputation** is used for distal growths when adequate clearance of the tumour is possible. When an advanced, infiltrating or anaplastic lesion is present, **total amputation** is necessary.

**Treatment of associated enlarged inguinal lymph nodes** should usually be delayed until at least 3 weeks after local treatment to the primary lesion. Enlargement due to infection will usually show signs of subsiding with antibiotic treatment if necessary. Block dissection is indicated if there is persistent enlargement which needle aspiration biopsy shows to be due to tumour. The 5-year survival rate falls to 35 per cent in these cases. If surgery to the nodes is impossible, radiotherapy may cause a worthwhile temporary regression.

**Buschke—Lowenstein tumour** is uncommon. It has the histological pattern of a verrucous carcinoma. It is locally destructive and invasive, but appears not to spread to lymph nodes or to metastasise. Treatment is by surgical excision.

**Secondary cancer of the penis** is uncommon as a result of spread from a primary tumour of the bladder, rectum or prostate.

Imperfect descent of the testis

Incomplete descent

The testis is arrested in some part of its path to the scrotum.

Ectopic testis

The testis is abnormally placed outside this path.

Development of the testis

The testes develop from the genital fold medial to the mesonephros (Wolffian body); in early foetal life, they lie in the retroperitoneum below the developing kidneys. The primitive testis is attached to the posterior abdominal wall by the mesorchium, a neurovascular pedicle derived from the lowermost thoracic segments. The mesonephros begins to disappear about the 10th week of intrauterine life but some of its tubules unite with the rete testis to become the vasa efferentia. The Wolffian duct becomes the epididymis and vas deferens. About the same time the precursor of the gubernaculum develops as a fold of peritoneum which can be traced from its attachment between the vas and the epididymis to the region of the developing phallus. The processus vaginalis starts as a dimple of peritoneum about the 10th week and precedes the testis in its journey through the abdominal wall down to the scrotum. The fully developed gubernaculum contains muscle fibres but there is still no certainty as to the part that it plays in testicular descent.

Maternal chorionic gonadotrophin stimulates growth of the testis and may stimulate its migration. Imperfectly developed testes tend to descend incompletely.

Comparative anatomy

Most misplacements of the testis in man are seen as the normal arrangement elsewhere in the animal kingdom. The testes of the whale and the elephant are intra abdominal throughout life. Rodents and creatures which hibernate, such as the hedgehog, the mole and the bat, have open inguinal canals. The testes descend into the scrotum ready for the breeding season.

Incompletely descended testis

Incidence

Scorer examined 2000 newborn boys. There was incomplete descent of one or both testes in 4 per cent of full-term infants and in 30 per cent of those born preterm. About 50 per cent of incompletely descended testes reached into the scrotum during the first month of life but full descent after that was uncommon. The incidence in later childhood and puberty is thus around 2 per cent. The genitals of all male infants are examined at birth but the condition is sometimes missed until the boy is examined by a school medical officer. In a few cases, the presence of a hernia, testicular pain or acute torsion directs attention to the abnormality. In an examination of 10 000 recruits during World War II, the incidence of incompletely descended testis was 0.28 per cent. In 10 per cent of unilateral cases there is a family history.

Pathology

Incompletely descended testes are often normal until the age of 6 years but by puberty the testis is flabby and poorly developed compared with its intrascrotal counterpart. Histologically the epithelial elements are grossly immature and by the age of 16 irreversible destructive changes have occurred which halt spermatogenesis and limit the production of androgens to around half of the normal output.

An incompletely descended testis brought down before puberty often develops and functions satisfactorily.

Clinical features

The condition is unilateral on the right in 50 per cent and on the left in 30 per cent. Arrested descent of both testes occurs in 20 per cent. Secondary sexual characteristics are normal but other abnormalities of the genitourinary tract may be present. The testis may be:

- **intra-abdominal**, lying extraperitoneally usually just above the internal inguinal ring;

- **in the inguinal canal**, whereit may or may not be palpable. When both testes are impalpable, the condition is known as cryptorchidism (hidden testes) (Fig. 68.1);

- **in the superficial inguinal pouch**, whereit must be distinguished from the much more common retractile testis which may be found in the same condition.

During childhood the testes are mobile and the cremasteric reflex is very active. In some boys, the least stimulation of the skin of the scrotum or thigh will result in the testis disappearing to the superficial ring or into the inguinal canal. Simply exposing the parts can have this effect so that the testis appears never to be in its proper intrascrotal position. Retractile testes should be suspected when the scrotum is normal as the scrotum is usually underdeveloped if there is true incomplete descent. After a while the cremaster relaxes and the telltale bulge of the testis reappears only to vanish when the scrotal skin is touched. A retractile testis can always be brought to the bottom of the scrotum by gently milking it from its position in the inguinal region. A diagnosis of true incomplete descent should be made only if this is not possible. In infancy, 80 per cent of inapparent testes are retractile. They are normal and require no treatment.

**Hazards of incomplete descent are:**

- **sterility** in bilateral cases;

- **pain** due to trauma;

- **an associated indirect inguinal hernia** that is often present and, in older patients, its frequently the hernia which causes symptoms;

- **torsion**;

- **epididymo-orchitis** that, in an incompletely descended testis, is extremely rare but of interest because, on the right side, it mimics appendixitis;
• **atrophy** of an inguinal testis that can occur even before puberty, possibly due to recurrent minor trauma;

• **increased liability to malignant disease.** All types of malignant testicular tumour are more common in incompletely descended testes even if they have been brought down surgically. It has been estimated that the chance of a tumour is about 35 times that in a normally positioned testis. Testicular tumours are relatively rare and there are no reliable statistics as to whether orchidopexy diminishes the liability.

**However, it does improve the prospect of early diagnosis.**

**Surgical treatment**

Operating on very small children needs the highly specialised skills of a paediatric surgeon so orchidopexy is not usually performed before the age of 2 years. Provided that safe anaesthetic services are available, however, testes should be brought down into the scrotum before the boy starts school. It is best to wait until he is dry because it is less easy to manage the inguinal wound if the child is wearing nappies. In cryptorchidism it is usual to operate on one side at a time.

**Orchidopexy**

Orchidopexy (syn. orchiopexy) consists firstly, of mobilisation of the testis and spermatic cord and secondly, retaining the testis in the scrotum. The operation is performed through a short groin incision over the deep inguinal ring. The inguinal canal is exposed by division of the external oblique aponeurosis in the direction of its fibres.

Mobilisation begins with isolation of the indirect inguinal hernial sac which is almost invariably present lying anterior to the cord. The sac is diaphanous and fragile but, with care, it can be swept laterally to reveal filmy fibrous strands which join the neck of the sac to the cord. The fibrous bands are divided and the spermatic vessels are dissected free of the peritoneum to which they are adherent until there is sufficient length of liberated cord to place the testis in the scrotum without tension. Division of the cremaster and the coverings of the cord may give a little more length but there is a risk of damage to the tiny vas and testicular artery. The empty half of the scrotum is stretched with a finger passed into it through the inguinal incision to give enough room for the testis.

Retaining the testis in the scrotum can be achieved by a number of means. In some cases it is enough simply to anchor it to the fundus of the scrotum with an absorbable suture. More commonly the testis is placed in a pouch constructed between the dartos muscle and the skin (Fig. 68.2). An alternative to the dartos pouch is to take the testis through the scrotal septum (Ombrédan’s operation).

**Failure to bring the testis down**

Sometimes a two-stage procedure is successful: the testis is mobilised as far as possible and anchored with a suture. The mobilisation is completed 6 months later. **Orchidectomy** should be considered if the other testis is normal, especially if the incompletely descended testis is hopelessly atrophic or the patient is past puberty.

Hormone treatment with human chorionic gonadotrophin is only appropriate when there is established hypogonadism.

**Ectopic testis**

The sites of ectopic testis are:

• at the superficial inguinal ring;
• in the perineum;
• at the root of the penis;
• in the femoral triangle.

An ectopic testis is usually fully developed. Its main hazard is a liability to injury.

**Injuries to the testis**

**Rupture** by a blow is uncommon because of its mobility within the scrotum. Both severe contusion and rupture are associated with a collection of blood around the testis and cannot usually be demonstrated without exploration. The haematocoele should be drained and the tunica albuginea repaired after evacuation of the haematoma. A very severely damaged testis may have to be removed.

**Haematocoele.** See **Fig. 68.3**.

**Traumatic displacement** occasionally follows a blow. The displaced testis usually lies in one of the sites of ectopic testis and can be returned to its normal position by manipulation before it becomes anchored by fibrosis.
Torsion of the testis

Predisposing causes

Torsion of the testis (syn. torsion of the spermatic cord) is uncommon because the normal fully descended testis is well anchored and cannot rotate. For torsion to occur one of several abnormalities must be present.

- **Inversion of the testis** is the most common predisposing cause. The testis is rotated so that it lies transversely or upside down.
- **High investment of the tunica vaginalis** causes the testis to hang within the tunica like a clapper in a bell (Fig. 68.4). Very occasionally, torsion occurs outside the tunica vaginalis.
- **Separation of the epididymis** from the body of the testis permits torsion of the testis without involving the cord. The twisting is confined to the pedicle which connects the testis with the epididymis (Fig. 68.5).

Normally, when there is a violent contraction of the abdominal muscles, the cremaster contracts as well. The spiral attachment of the cremaster favours rotation around the vertical axis when this is made possible by one of the abnormalities described above. Straining at stool, lifting a heavy weight and coitus are all possible precipitating factors. Alternatively, torsion may develop spontaneously during sleep.

Clinical features

Testicular torsion is most common between 10 and 25 years of age and a few cases occur in infancy. Symptoms vary with the degree of torsion. Most commonly there is sudden agonising pain in the groin and the lower abdomen. The patient vomits.

Torsion of a fully descended testis is usually easy to recognise by the high lie of the testis and thickening of the tender twisted cord which can be palpated above it. In mumps orchitis the cord is not particularly thickened. The onset of redness of the skin after 6 hours or so and the onset of a mild pyrexia may cause confusion with epididymo-orchitis in the older patient but there will usually be an associated urethritis. Elevation of the testis reduces the pain of epididymo-orchitis and makes it worse in torsion. Very occasionally, the condition can be convincingly mimicked by a small tense strangulated inguinal hernia compressing the cord and causing compression of the pampiniform plexus. If there is any doubt about the diagnosis, the scrotum should be explored without delay.

It is almost impossible to distinguish torsion of an imperfectly descended testis until the parts are exposed at operation. An empty oedematous hemiscrotum on the side suggests that a tender lump at the external inguinal ring is a torted testis.

Treatment

In the first hour or so it may be possible to untwist the testis by gentle manipulation. If manipulation is successful pain subsides and the testis is out of danger. However, arrangements should be made for early operative fixation to avoid recurrent torsion.

Exploration for testicular torsion can be performed through a scrotal incision. If the testis is clearly viable when the cord is untwisted, it should be prevented from twisting again by fixation by nonabsorbable sutures between the tunica vaginalis and the tunica albuginea. The opposite testis should also be fixed because the anatomical variation responsible for the torsion is likely to be bilateral. A totally infarcted testis should be removed — the patient can be counselled later about a prosthetic replacement if this is appropriate. If it is clear that there has been an established torsion for several days it will not be possible to recover the testis and little is gained by exploration. The affected testis will become woody-hard and atrophy to a fibrous nodule. The other testis should be fixed at an early date.

Torsion of a testicular appendage is sometimes mistaken for acute epididymo-orchitis and cannot be distinguished with certainty from testicular torsion. The most common structure to twist is the appendix of the testis (the pedunculated hydatid of Morgagni) but other vestigial structures related to the testis and epididymis may also rotate. Immediate operation with ligation and amputation of the twisted appendage cures the condition. Idiopathic scrotal oedema is a curious condition which occurs between the age of 4 and 12 years and has to be differentiated from torsion. The scrotum is very swollen but there is very little pain or tenderness. The swelling may extend into the perineum, groin and penis. It is thought to be an allergic phenomenon — occasionally there is eosinophilia. The swelling subsides after a day or so but may recur (Fig. 68.6).
**Varicocele**

A varicocele is a varicose dilatation of the veins draining the testis.

**Surgical anatomy.** The veins draining the testis and the epididymis form a bulky plexus called the pampiniform plexus. The veins become fewer as they traverse the inguinal canal and at or near the inguinal ring they join to form one or two testicular veins which pass upwards behind the peritoneum. The left testicular vein empties into the left renal vein, the right into the inferior vena cava below the right renal vein. The testicular veins may have valves near their terminations but these are often absent. There is an alternative (collateral) venous return from the testes through the cremasteric veins which drain mainly into the inferior epigastrics.

**Aetiology**

Most varicoceles are noticed in adolescence or early adult-hood. The left side is affected in 95 per cent. In many cases the dilated vessels are cremasteric veins and not part of the pampiniform plexus.

Obstruction of the left testicular vein by a renal tumour or after nephrectomy is an occasional cause of varicocele in middle life and after. *Characteristically the varicocele does not decompress in the supine position.*

**Clinical features**

Varicocele is more frequent and more troublesome in hot climates: in all parts of the world, tall, thin men with pendulous scrotum are frequently affected, whereas short, fat individuals are seldom so. Varicocele does not usually cause symptoms but there may be a vague and annoying dragging discomfort which is worse if the testis is unsupported by underwear. The scrotum on the affected side hangs lower than normal (Fig. 68.7) and on palpation, with the patient standing, the varicose plexus feels like a bag of worms. There may be a cough impulse. If the patient lies down the veins empty by gravity and this provides an opportunity to ensure that the underlying testis is normal to palpation. In long-standing cases the affected testis is smaller and softer than its fellow owing to a minor degree of atrophy. It has been said that varicocele causes infer-tility but statistical evidence supporting the claim is lacking.

**Varicocele and spermatogenesis**

Of all the possible causes of primary infertility, oligospermia is one of the most difficult to treat. Because varicocele is relatively common, some of those with oligospermia have a varicocele and it is tempting to blame this for the infertility. It is suggested that the presence of the unilateral varicocele somehow interferes with the normal temperature control of the scrotum which keeps the testes at some $2.5^\circ C$ below rectal temperature. Unfortunately, there is little evidence that varicocelectomy improves semen quality or the rate of conception.

**Treatment**

Operation is not indicated for varicocele unless it is causing symptoms. The simplest procedure is ligation of the testicular vein above the inguinal ligament where the pampiniform plexus has coalesced into one or two vessels. Recently this operation has been done laparoscopically. Because of the presence of plentiful potential collateral veins, recurrence is common after all types of surgery for varicocele.
Hydrocele

A hydrocele is an abnormal collection of serous fluid in some part of the processus vaginalis, usually the tunica. Four types of congenital hydrocele are encountered (Fig. 68.8). Acquired hydroceles are primary or idiopathic, or secondary to testicular disease.

Aetiology

A hydrocele can be produced in four ways:

• by excessive production of fluid within the sac, e.g. secondary hydrocele;
• by defective absorption of fluid. This appears to be the explanation for most primary hydroceles although the reason why the fluid is not absorbed is obscure;
• by interference with lymphatic drainage of scrotal structures;
• by connection with a hernia of the peritoneal cavity in the congenital variety.

Hydrocele fluid is amber coloured and sterile, and contains albumin and fibrinogen. If the contents of a hydrocele are allowed to drain into a collecting vessel, the liquid does not clot, but the fluid coagulates if it is mixed with even a small quantity of blood that has been in contact with damaged tissue. In long-standing cases, hydrocele fluid is sometimes opalescent with cholesterol and may occasionally contain crystals of tyrosine.

Clinical features

Hydroceles are almost invariably translucent and it is possible to ‘get above the swelling’ on examination of the scrotum.

Primary vaginal hydrocele

Primary vaginal hydrocele is most common in middle and later life but can also occur in early childhood. The condition is particularly common in hot countries. Because the swelling is usually painless it may reach a prodigious size before the man presents for treatment. The testis may be palpable within a lax hydrocele but an ultrasound may be necessary to visualise the testis if the hydrocele sac is tense. Be wary of an acute hydrocele in a young man; there may be a testicular tumour (Fig. 68.9).

About 5 per cent of inguinal hernias are associated with a vaginal hydrocele on the same side.

Infantile hydrocele

Infantile hydrocele does not necessarily appear in infants. The tunica and processus vaginalis are distended to the inguinal ring but there is no connection with the peritoneal cavity.

Congenital hydrocele

The processus vaginalis is patent and connects with the general peritoneal cavity. The communication is usually too small to allow herniation of intra-abdominal contents. Digital pressure on the hydrocele does not usually empty it but the hydrocele fluid may drain into the peritoneal cavity when the child is lying down. Ascites or even ascitic tuberculous peritonitis should be considered if the swellings are bilateral.

Encysted hydrocele of the cord

There is a smooth oval swelling near the spermatic cord which is liable to be mistaken for an inguinal hernia. The swelling moves downwards and becomes less mobile if the testis is pulled gently downwards.

Hydrocele of the canal of Nuck is a similar condition. It occurs in females and the cyst lies in relation to the round ligament. Unlike a hydrocele of the cord, a hydrocele of the canal of Nuck is always at least partially within the inguinal canal.

Complications of hydrocele

• Rupture usually occurs as a result of trauma but may be spontaneous. On rare occasions cure results after the fluid has been absorbed.
• Herniation of the hydrocele sac through the dartos muscle sometimes occurs in long-standing cases.
• Transformation into a haematocele occurs if there is spontaneous bleeding into the sac or as a result of trauma.
• The sac may calcify.

Treatment

A variety of surgical procedures is available. Congenital hydroceles are a special form of indirect inguinal hernia and are treated by herniotomy. The thin sac of an infantile hydrocele should be excised.

Established acquired hydroceles often have thickened walls. Unless great care is taken to stop bleeding after sub-total excision of the wall, haemorrhage from the cut edge is liable to cause a large scrotal haematoma, even if the wound is drained. Lord’s operation is suitable when the sac is reasonably thin-walled (Fig. 68.10). There is minimal dissection and the risk of haematoma is reduced. Eversion of the sac with placement of the testis in a pouch prepared by blunt dissection in the fascial planes of the scrotum is an alternative (Jaboulay’s procedure) (Fig. 68.11).

Drainage of the hydrocele fluid through a cannula is simple but the condition always recurs within a week or so. It may be suitable for very elderly infirm men who are unfit even for scrotal surgery under regional anaesthesia. Injection of sclerosants such as tetracycline is sometimes effective but tends to be very painful.

Secondary hydrocele is most frequently associated with acute or chronic epididymo-orchitis. It is also seen with torsion of the testis and with
some testicular tumours. A secondary hydrocele is usually lax and of moderate size: the underlying testis is palpable. If a tumour is suspected, the hydrocele should not be punctured for fear of implantation of malignant cells in the needle track. A secondary hydrocele subsides when the primary lesion resolves.

**Postherniorrhaphy hydrocele**

Postherniorrhaphy hydrocele is a relatively rare complication of inguinal hernia repair. It is possibly due to interruption to the lymphatics draining the scrotal contents.

**Hydrocele of a hernial sac**

Hydrocele of a hernial sac occurs when the neck is plugged with omentum or occluded by adhesions.

**Filarial hydroceles and chyloceles**

Filarial hydroceles and chyloceles account for up to 80 per cent of hydroceles in some tropical countries where the parasite is endemic. Filarial hydroceles follow repeated attacks of filarial epididymo-orchitis. They vary in size and may develop slowly or very rapidly. Occasionally the fluid contains liquid fat which is rich in cholesterol. This is due to rupture of a lymphatic varix with discharge of chyle into the hydrocele. Adult worms of the *Wuchereria bancrofti* have been found in the epididymis removed at operation or at necropsy. In long-standing chyloceles, there are dense adhesions between the scrotum and its contents. Filarial elephantiasis supervenes in a small number of cases.

*Treatment* is by rest and aspiration. The more usual chronic cases are treated by excision of the sac.

**Haematocele**

Haematocele usually results from damage to a small vessel during tapping of a hydrocele. Prompt refilling of the sac with pain, tenderness and poor or absent transillumination leave no doubt about the diagnosis. Acute haemorrhage into the tunica vaginalis sometimes results from testicular trauma and it may be difficult without exploration to decide whether the testis has been ruptured. If the haematocele is not drained, a clotted haematocele usually results.

**Clotted hydrocele**

Clotted hydrocele may result from a slow spontaneous ooze of blood into the tunica vaginalis. It is usually painless and by the time the patient seeks help, it may be difficult to be sure that the swelling is not due to a testicular tumour. Indeed a tumour may present as a haematocele.

*Treatment* is by orchidectomy unless the testis is indubitably benign. As a rule it is impossible to be certain of this until the mass has been bisected. The testis is often compressed and relatively useless (Fig. 68.12).
Cysts connected with the epididymis

Epididymal cysts

These are filled with a crystal-clear fluid (as opposed to the barley-water fluid of a spermatocele or the amber fluid of a hydrocele). They are very common, usually multiple and vary greatly in size at presentation. They represent cystic degeneration of the epididymis.

Clinical features

Cysts of the epididymis are usually found in middle age and the condition is often bilateral. The clusters of tense thin-walled cysts feel like a tiny bunch of grapes on palpation. They should be brilliantly transilluminable. The presence of a scrotal mass should always raise the possibility of a testicular neoplasm. Epididymal cysts are almost always quite separate from the testis proper and this is a reassuring sign.

Treatment

Aspiration is useless because the cysts are multilocular. If they are causing discomfort they should be excised. The man should be warned that excision may interfere with the export of sperms from the testis on that side.

Cyst of a testicular appendage

Cyst of a testicular appendage is usually unilateral and is felt as a small globular swelling at the superior pole. Such cysts are liable to torsion and should be removed if they cause symptoms.

Spermatocele

This is a unilocular retention cyst derived from some portion of the sperm-conducting mechanism of the epididymis.

Clinical features

A spermatocele nearly always lies in the head of the epididymis above and behind the upper pole of the testis. It is usually softer and laxer than other cystic lesions in the scrotum but like them it transilluminates. The fluid contains spermatozoa and resembles barley water in appearance. Spermatoceles are usually small and unobtrusive. Less frequently they are large enough to make the patient think that he has three testicles.

Treatment

Small spermatoceles can be ignored. Larger ones should be aspirated or excised through a scrotal incision.
Epididymo-orchitis

Acute disease

Inflammation confined to the epididymis is epididymitis; when infection spreads to the body of the testis, the condition is known as epididymo-orchitis.

Mode of infection

Infection reaches the globus minus of the epididymis via the lumen of the vas from a primary infection of the urethra, prostate or seminal vesicles. In men with outflow obstruction, epididymitis may result from a secondary urinary infection — a high pressure in the prostatic urethra causes reflux of infected urine up the vasa. A noninfective epididymitis sometimes arises from a similar cause when unusual exertion or violent strain when the bladder is full causes injection of urine into the vasa under pressure. In young men, the most common sexually transmitted infection causing epididymitis is now chlamydia but gonococcal epididymitis is still prevalent. Both are associated with urethritis. Blood-borne infections of the epididymis are less common but may be suspected when there is Escherichia coli, streptococcal, staphylococcal or proteus infection without evidence of urinary infection.

Clinical features

The initial symptoms are those of acute prostatitis. Some days later an ache in the groin and a fever herald the onset of epididymitis. The epididymis and testis swell rapidly and become exquisitely painful. The scrotal wall which is at first red, oedematous and shiny may become adherent to the epididymis. Resolution is signalled by scaling of the scrotal skin and may take 6—8 weeks to complete. Occasionally the infection may go on to abscess formation and discharge of pus may occur through the scrotal skin.

Acute epididymo-orchitis can follow any form of urethral instrumentation. It is particularly common when there is an indwelling catheter and an associated infection of the prostate. The incidence of acute postoperative epididymitis which was a serious and frequent complica-tion of prostatectomy has been greatly reduced by closed drainage, catheter care and the early use of antibiotics.

Acute tuberculous epididymitis should come to mind when the vas is thickened and there is little response to the usual antibiotics.

Acute epididymo-orchitis of mumps develops in about 18 per cent of males suffering from mumps, usually as the parotid swelling is waning. The main complication is testicular atrophy which may cause infertility if the condition is bilateral (which is not usual). Partial atrophy is associated with persistent testicular pain. The epididymitis of mumps sometimes occurs in the absence of parotitis, especially in infants. The epididymis and testis may be involved by infection with other entero-viruses and in brucellosis and lymphogranuloma venereum.

Treatment

The patient should rest in bed while the acute symptoms persist. Doxycycline (100 mg daily) is the treatment of choice for young men with chlamydial infection. If an organism is isolation-ed from the urine, this simplifies the choice of antibiotic. Otherwise treatment should be with an agent that is active across a broad spectrum of urinary tract pathogens. The patient should drink plenty of fluid. Local measures can help to reduce pain. The scrotum is supported on a sling made of broad adhesive tape attached between the thighs. The inflam-ed organ rests on a pad of cotton wool placed on the sling.

Antibiotic treatment should continue for 2 weeks or until the inflammation has subsided. If suppuration occurs, drainage is necessary. The patient should be warned that the testis may atrophy.

Chronic disease

Chronic tuberculous epididymo-orchitis usually begins insidiously.

Aetiology. The frequency with which the globus is first attacked indicates that the infection is retrograde from a tuberculous focus in the seminal vesicles.

Clinical features. Typically there is a firm discrete swelling of the lower pole of the epididymis which aches a little. The disease progresses until the whole epididymis is firm and craggy behind a normal-feeling testis. There is a lax secondary hydrocele in 30 per cent and in some a characteristic beading of the vas is apparent due to subepithelial tubercles. The seminal vesicle feels indurated and swollen. In neglected cases a tuberculous ‘cold’ abscess forms which may discharge. The body of the testis may be uninvolved for years but the contralateral epididymitis often becomes diseased.

In two-thirds of cases there is evidence of renal tuberculosis or previous disease. The other patients appear healthy.

The urine and semen should be examined repeatedly for tubercle bacilli in all patients with chronic epididymo-orchitis. An intravenous urogram and a chest X-ray should be performed.

Treatment. When the epididymitis is secondary, it may resolve when the primary tuberculous focus is treated.

Treatment with antituberculous drugs is less effective in genital tuberculosis than in urinary tuberculosis. If resolution does not occur within 2 months, epididymectomy or orchidectomy is advisable. A full course of antituberculous chemotherapy should be completed even if there is no evidence of disease elsewhere.

Chronic nontuberculous epididymitis usually follows the failure of an acute attack to resolve fully. The condition is difficult to distinguish from tuberculosis but the swelling may be larger and smoother. It is essential to exclude urethral stricture causing reflux of urine down the vas. If alternative granulomatous conditions such as sarcoidosis have been eliminated, chronic epididymitis should be treated with antibiotics. Epididymectomy or orchidectomy should be considered if there is no resolution after 4—6 weeks of conservative treatment.

Orchitis. Syphilitic orchitis affects the body of the testis and is now uncommon. There are three varieties:

- bilateral orchitis is a feature of congenital syphilis;
- interstitial fibrosis causes painless destruction of the testis;
- gumma of the testis presents as a unilateral painless swelling of the testis which grows slowly. It feels hard and heavy and is very difficult to
distinguish from a neoplasm without surgical exploration.

Leprous orchitis causes testicular atrophy in over 25 per cent of male lepers.
Tumours of the testes

The lymphatic drainage of the testes follows the spermatic cord to end in the para-aortic lymph nodes near the origin of the gonadal vessel. Lymphatics from the medial side of the testis may run with the artery to the vas and drain into a node at the bifurcation of the common iliac artery. The contra-lateral para-aortic lymph nodes are sometimes involved by tumour spread but the inguinal lymph nodes are only affected if the scrotal skin is involved.

Malignant

About 99 per cent of testicular neoplasms are malignant, and although they make up only about 1—2 per cent of malignant tumours in men, they are one of the commonest forms of cancer in the young male adult. Maldescend undoubtedly predisposes to malignancy. It is curious that despite the fact that the testis is usually easily palpable, a testicular tumour often escapes detection until after it has metastasised. There is a campaign to encourage men to perform regular testicular self-examination in the hope that tumours will be detected earlier but as yet this has not been as successful as a similar drive to get women to screen their own breasts for lumps.

Tumours of the testis are classified according to the predominant cellular type:

- **seminoma** (40 per cent);
- **teratoma** (32 per cent);
- combined seminoma and teratoma (14 per cent);
- interstitial tumours (1.5 per cent);
- lymphoma (7 per cent);
- other tumours (5.5 per cent).

Teratomas tend to occur in a younger age group, the peak incidence being between 20 and 35 while that of seminoma is between 35 and 45. Seminoma is extremely rare before puberty.

**Seminoma**

Seminoma compresses neighbouring testicular tissue as it grows (Fig. 68.13). The enlarged testis is smooth and firm. The cut surface is homogeneous and pinkish cream in colour. Occasionally fibrous septa give a lobulated appearance. In rapidly growing tumours there may be areas of necrosis of variable consistency.

**Histologically**, a seminoma is made of slightly oval cells with clear cytoplasm and large rounded nuclei with prominent acidophilic nucleoli. The cells are arranged in sheets separated by a fine fibrous stroma. Derived from seminiferous tubules, the cells resemble spermatocytes. Active infiltration of the tumour with lymphocytes suggests a good host response and a better prognosis.

Seminomas spread via the lymphatics (Fig. 68.14) and metastasis via the bloodstream is uncommon.

**Teratoma**

Teratoma arises from totipotent cells in the rete testis and often contains a variety of cell types of which one or more predominate. The tumour may be as small as a peanut or as large as a coconut. Even when large, the tumour is moulded by the tunica albuginea so the overall outline of the testis is maintained although the surface may be slightly irregular.

The usual variety is yellowish in colour with cystic spaces containing gelatinous fluid (Fig. 68.15). Nodules of cartilage are often present.

**Histology.** The Testicular Tumour Panel has classified teratomas as follows:

- **Teratoma differentiated (TD)** (uncommon) has no histologically recognisable malignant components but cannot be considered benign because such growth has metastasised. The best known variety is a dermoid cyst which may contain cartilage and muscle as well as glandular elements.

- **Malignant teratoma intermediate, teratocarcinoma (MTI — A and B)**
  
  (most common) contains definitely malignant and incompletely differentiated components. There is some mature tissue in type A but not in type B.

- **Malignant teratoma anaplastic (MTA), embryonal carcinoma** is composed of anaplastic cells of embryonal origin in parts. Cells presumed to be derived from yolk sac are often responsible for elevated ct-fetoprotein levels. MTA is not always radiosensitive.

- **Malignant teratoma trophoblastic (MTT)** (uncommon) contains within other cell types a syncytiotrophoblastic syncytiotrophoblast (chorioadenoma). It often produces human chorionic gonadotrophin (HCG). Spread by bloodstream and lymphatics is early. It is one of the most malignant tumours known.

**Interstitial cell tumours**

Interstitial cell tumours arise from Leydig or Sertoli cells. A Leydig cell tumour masculinises; a Sertoli cell tumour feminises.

Prepubertal interstitial cell tumours excrete androgens which cause sexual precocity and extreme muscular development. Regression of the symptoms after orchidectomy may be incomplete because of hypertrophy of the contralateral testis.

Postpubertal interstitial cell tumours usually arise from Sertoli cells with output of feminizing hormones leading to gynaecomastia, loss of libido and a-spermia. As a rule the tumour is benign and orchidectomy cures.
**Clinical features**

The patient may not seek advice for several months after first noticing that he has a testicular lump. A sensation of heaviness occurs when the testis is two or three times its normal size but there is pain in only 30 per cent or so. There is a history of trauma to the affected side in over 10 per cent. It is generally conceded that this merely calls attention to the testicular enlargement and in no way initiates the neoplasm.

On examination, the testis is enlarged, smooth, firm and heavy. Later one or more softer protuberances may be palpable. In no other disease is testicular sensation lost so early or so completely but the sign should be elicited with care for fear of disseminating the disease. Ten per cent have a lax secondary hydrocele which does not usually obscure the underlying tumour. The epididymis is normal at first but becomes more difficult to feel as it is flattened or incorporated in the growth. Thickening of the spermatic cord occurs later due to cremasteric hypertrophy and enlargement of the testicular vessels. The vas is never thickened and rectal examination shows the prostate and seminal vesicles to be normal.

Secondary retroperitoneal deposits may be palpable especially just above the umbilicus on the side of the tumour.

There may be hepatic enlargement. Occasionally, an enlarged supraclavicular node is the presenting sign of a testicular tumour. A chest radiograph is most likely to show pulmonary metastases when the primary tumour is a teratoma.

Occasionally, the predominant symptoms are those of metastatic disease. Intra-abdominal disease may cause abdominal or lumbar pain and the mass may be discovered in the epigastrium. Lung metastases are usually silent but they can cause chest pain, dyspnoea and haemoptysis in the later stages of the disease. The primary tumour may not have been noticed by the patient and may indeed be so tiny that it can only be detected by sophisticated ultrasound imaging or operative exploration. Atypical cases may simulate epididymo-orchitis; there may even be a urinary infection. All testicular swellings should be treated with suspicion and failure to respond to antibiotics should raise the possibility of a testicular tumour. Rarely, patients present with severe pain and acute enlargement of the testis due to haemorrhage into a neoplasm. Between 1 and 5 per cent have gynaecomastia (mainly the teratomas).

The testicular tumour is a ferocious malignancy which kills in a matter of weeks. A few teratomas grow slowly with increasing enlargement of the testis over 2 or 3 years.

**Treatment of testicular tumours**

Staging is an essential first step in planning treatment.

- Blood is collected for radioimmunoassay of tumour markers (human chorionic gonadotrophin, alpha-fetoprotein and lactate dehydrogenase). Their level in the blood can be used to monitor the response to treatment.
- A chest radiograph will show whether there are pulmonary deposits.
- Orchidectomy is essential to remove the primary tumour and to obtain information about the histological type of the tumour.
- Computerised tomography and magnetic resonance imaging are the most useful means of detecting intra-abdominal and intrathoracic secondaries and for detecting their response to therapy.

Scrotal exploration and orchidectomy for suspected testicular tumour. The spermatic cord is displayed by dividing the external oblique aponeurosis through a groin incision. A soft clamp is placed across the cord to stop dissemination of malignant cells as the testis is mobilised into the wound. If there is doubt about the diagnosis at this stage, the testis should be bisected along its anterior convexity so that its internal structure can be examined. If there is a tumour or doubts still remain even after frozen section, the cord should be double ligated at the level of the inguinal ring and divided so that the testis can be removed.

**Staging of testicular tumours**

The stages are:

- stage 1: testis lesion only—no spread;
- stage 2: nodes below the diaphragm only;
- stage 3: nodes above the diaphragm;
- stage 4: pulmonary or hepatic metastases.

**Management by staging and histological diagnosis (after orchidectomy)**

Seminomas are radiosensitive and excellent results have been obtained by irradiating stage 1 and stage 2 tumours. More recently, the tumour has been shown to be highly sensitive to cisplatin, which is already being used for patients with metastatic disease. The experts are divided as to whether patients with stage 1 disease should have adjuvant chemotherapy.

Teratomas are less sensitive to radiation. Stage 1 tumours can be managed by watching the level of serum markers and by repeated computerised tomography. Teratomas at stages 2—4 are managed by chemotherapy. Cisplatin, methotrexate, bleomycin and vincristine have been used in combination with great success. There are those who advocate adjuvant chemotherapy for stage 1 teratoma arguing that effective prophylaxis is less troublesome to the patient than prolonged surveillance.

Retroperitoneal lymph node dissection is sometimes needed when retroperitoneal masses remain after chemotherapy. The tissue removed may contain only necrotic tissue but a proportion of patients has foci of mature teratoma or active malignancy. The operations can be formidable if the tumour is large and retrograde ejaculation is likely unless steps are taken to preserve the sympathetic outflow to the bladder neck.

Prognosis of testicular tumours depends on the histological type and the stage of the growth.

**Seminoma.** If there are no metastases 95 per cent will be alive 5 years after orchidectomy and radiotherapy or chemotherapy. If there are
metastases survival drops to 75 per cent.

**Teratoma.** More than 85 per cent 5-year survival is achievable in stages 1 and 2 teratoma. In stages 3 and 4, the survival is about 60 per cent and getting better with improvements in chemotherapy.

**Testicular tumours in children** are usually anaplastic teratomas. They occur before the age of 3 years and are often rapidly fatal.

**Tumours of the epididymis** may be benign mesothelioma or malignant sarcoma or secondary carcinoma. They are extremely rare but should not be forgotten when the patient presents with a noncystic lump in the epididymis.
The scrotum

Prepenile scrotum

Prepenile scrotum is an exceedingly rare congenital condition in which the scrotum is suspended from the mons pubis in front of the penis. Idiopathic scrotal oedema is described above.

Idiopathic scrotal gangrene

Idiopathic scrotal gangrene (syn. Fournier’s gangrene) is an uncommon and nasty condition (Fig. 68.19). It is a vascular disaster of infective origin which is characterised by:

- sudden appearance of scrotal inflammation;
- rapid onset of gangrene leading to exposure of the scrotal contents;
- absence of any obvious cause in over half the cases.

It has been known to follow minor injuries or procedures in the perineal area, such as a bruise, scratch, urethral dilatation, injection of haemorrhoids or opening of a periurethral abscess.

The haemolytic streptococcus (sometimes microaerophilic) is associated with other organisms (staphylococcus, E. coli, Clostridium welchii) in a fulminating inflammation of the subcutaneous tissues which results in an obliterator arteritis of the arterioles to the scrotal skin (cf. gangrene of the abdominal wall, Chapter 62).

Clinical features

There is sudden pain in the scrotum, prostration, pallor and pyrexia. At first only the scrotum is involved but if unchecked, the cellulitis spreads until the entire scrotal coverings slough leaving the testes exposed but healthy.

Treatment. Expert microbiological advice should be obtained. The organisms are usually sensitive to gentamicin and a cephalosporin which should be given until the bacteriological report is available. Wide excision of the necrotic scrotal skin provides the best possible drainage and stops the spread of the gangrene. Many patients die despite active treatment.

Filarial elephantiasis of the scrotum

Filarial elephantiasis of the scrotum is due to obstruction of the pelvic lymphatics by Wuchereria bancrofti with superadded infection and lymphangitis. In long-standing cases, the enormously swollen scrotum may bury the penis (Fig. 68.20). There is no medical treatment for the condition. The principle of surgical treatment is the construction of new lymphatic pathways using plastic surgery. In very advanced cases excision of the affected skin with implantation of the testes into the thighs and a skin graft to the penis may be the only curative treatment.

Nonfilarial elephantiasis

Nonfilarial elephantiasis can result from fibrosis of the lymphatics due to lymphogranuloma venereum.

Sebaceous cysts

Sebaceous cysts are common in the scrotal skin. They are usually small and multiple (Fig. 68.21).

Carcinoma of the scrotum

In the nineteenth century squamous epithelioma of the scrotum was the chimney sweep’s cancer described by Percival Pott. With mechanisation of the cotton industry, impure lubricating oil from the spinning machine soaking the crutch of the mule spinners’ trousers proved even more carcinogenic than soot. Today a few cases of scrotal cancer occur in tar and shale oil workers but the majority of cases arises with no obvious aetiological factor. It is remarkable that, unlike carcinoma of the penis, carcinoma of the scrotum is almost unknown in India and Asiatic countries.

Clinical features

The growth starts as a wart or ulcer (Fig. 68.22). As it grows it may involve the testis.

Treatment

The growth is excised with a margin of healthy skin. If associated enlargement of the inguinal nodes does not subside with antibiotics, a bilateral block dissection should be carried out up to the external nodes.
Male Infertility

Testicular failure

The semen may contain no sperms (azoospermia), few sperms (oligospermia) or predominantly abnormal sperms. The cause is pre-sumably some form of testicular dysfunction which may follow mumps infection, exposure to radiation or testicular trauma but is more often unknown. The normal feedback mechanism to control the production of gonadotrophic hormones is disturbed if there is testicular atrophy and the serum levels of luteinising hormone and follicle-stimulating hormone will be high. In some cases of azoospermia the testicular biopsy shows a failure of sperm development. Many treatments have been attempted but the results have been disappointing.

Obstruction

Azoospermia may also be due to obstruction to the pathway of spermatozoa from the testis via the epididymis to the ejaculatory ducts. The testicular biopsies will show active spermatogenesis. If the site of the obstruction can be identified by vasography it may be possible to perform a bypass operation. Unfortunately, even in the best hands, the results of epididymovasostomy are poor.

In some couples there appears to be an immunological cause for the infertility with clumping of sperms exposed to serum or cervical mucus.

Intracytoplasmic sperm injection

Intracytoplasmic sperm injection has revolutionised the management of male factor infertility. Spermatozoa harvested from the ejaculate, by aspiration of the epididymis or even from testicular biopsy, can be injected in vitro into ova obtained from the mother. Embryos are then transferred into the mother's uterus at the 4—6 cell stage.

Vasectomy for sterilisation

Vasectomy for sterilisation is one of the most commonly performed operations throughout the world. It should only be undertaken after the couple has been carefully counselled. They need to know that the operation is performed to make the man permanently sterile. They should be warned that they should continue with their normal contraceptive precautions until the success of the operation has been confirmed by semen analysis performed 12—16 weeks after surgery. They should also be warned of the remote but important possibility of spontaneous recanalisation which may restore fertility unexpectedly.

Vasectomy is easily and painlessly performed under local anaesthetic. The vasa are delivered through tiny bilateral or a single midline scrotal incision. For medicolegal reasons it is wise to remove a segment of each vaso prove that it has been successfully divided. Burying the cut ends or turning them back on themselves probably helps to prevent them rejoining.

Vasectomy may not restore fertility even if technically successful because of the presence of autoantibodies developed against the sequestered sperms. A success rate of 60—80 per cent may be possible if the operation is performed within 3—4 years of vasectomy.

Introduction

Day surgery is an increasingly important part of elective surgery. It currently accounts for 50 per cent of elective surgery in the UK, and 60 per cent or more in the USA and Canada, with predictions of further increases. The impetus for this has been the high cost of keeping patients in in-patient beds, the reduction in availability of these beds and long surgical waiting lists in publicly funded healthcare systems. Improvements in anaesthesia and pain control, minimally invasive surgery and changing attitudes to recovery after surgery have all promoted the expansion of day surgery. Patients, particularly children, benefit from reduced stays in hospital and a rapid return to their home environment, provided that their surgery is uncomplicated and without significant pain or nausea. The quality of care in day surgery should be of the same high standard as that expected for in-patient surgery. Day Surgery Units (DSU) are the best way to achieve this.
Definition

Day surgery is defined as planned investigations or procedures on patients who are admitted and discharged home on the day of their surgery but require some facilities and time for recovery. Minor procedures in out-patient or accident and emergency departments are not included. In most countries, this means that the patient spends a few hours in hospital and does not stay overnight. However, in the USA, day surgery is termed ‘ambulatory surgery’ and includes patients who may spend up to 23 hours in hospital, allowing a greater range of procedures to be included.
Historical

Day surgery is not a new concept. In 1909 James Nicoll, a Scottish surgeon, reported operating on nearly 9000 children as day cases, for operations such as talipes, correction of hare lip, hernia repair and mastoid surgery. His motivation was to save money and use resources better, reasons which are equally valid today. In the USA Ralph Waters, an anaesthetist, founded his ‘downtown anaesthesia clinic’ for dental and minor surgery in 1912, the prototype for the free-standing DSU. Despite acclaim for these innovations at the time, the concept was slow to gain acceptance, and it was only when the disadvantages of prolonged bed rest after surgery were appreciated in the 1940s that day surgery could really progress.

In 1951 Eric Farquharson, an Edinburgh surgeon, carried out day-case adult hernia repairs under local anaesthesia in order to reduce long waiting lists in the newly introduced National Health Service (NHS). He initiated policies of careful patient assessment and cooperation with general practitioners (GPs) to ensure care after discharge. Hospital-based DSUs began to appear in the United States in the 1960s, and in 1969 Walter Reed, an American surgeon, set up the Phoenix Surgicenter, the first free-standing DSU. UK hospitals followed suit from the 1970s and DSUs became established in most hospitals, although the free-standing DSU is almost unknown in the UK.

Day surgery now began to take on a momentum of its own, and influential reports such as those from the Royal College of Surgeons of England in 1985 and 1992, and the Audit Commission in 1990, focused attention on the benefits of day surgery and set standards and guidelines.
The benefits and caveats of day-case surgery (Tab 69.1 and Tab 69.2)

Financial

Every healthcare system in the world is under financial pressure. Day surgery operations cost less, saving expensive out of hours nursing and in-patient beds, which may be closed or used for more major surgery. Extra capital and resources may be needed to set up DSUs.

Better use of resources

Efficient throughput of patients makes more effective use of operating theatre time. Good organisation, patient selection and assessment can virtually eliminate last-minute cancellations and expedite admission on the day of surgery. DSUs should be ‘ring fenced’ against use for emergency cases so that admission as arranged is guaranteed.

Care must be taken that complications do not increase owing to pressure to expand the range of day-case operations and that beds for the few inevitable patients who are unfit to go home are identified.

Reduction in waiting lists

Operations suitable for day surgery are usually those which can wait and so form a large part of waiting lists, which have usually been reduced where day surgery has been instituted. However, these more minor operations may be the first to be postponed or rationed when money runs out.

Patients

Day surgery would not have gained such widespread acceptance if patients did not prefer to go home after surgery, and numerous surveys have confirmed its acceptability to patients. Hospital-acquired infections, thromboembolism and pulmonary complications are reduced. For children in particular, day surgery is the ideal option because they spend as little time as possible away from their families and familiar surroundings, and most of the common operations of childhood lend themselves to day surgery.

This assumes that patients are not sent home in discomfort or to inadequate care. Day surgery may simply pass the expense and burden of care to relatives and GPs, although this has not been found to be true in practice. A small percentage of patients have commented that insufficient attention was paid to home circumstances, that more information should be given before admission and that they were sent home before they felt well enough.
The Day Surgery Unit (Tab 69.3)

The DSU is a self-contained dedicated day surgery facility with its own reception, operating and recovery areas, designed to ensure that all of the essentials for good day surgery practice are carried out. While it is possible to use an in-patient ward, and mixed in-patient and day-case operating sessions, in practice this achieves neither efficient throughput nor good-quality care. A compromise is to have a day-case ward close to the operating suite with dedicated day-case operating sessions, with the same good organisation found in self-contained DSUs. Hospitals without a DSU never achieve high percentages of day cases.

The DSU is usually part of a general hospital, and ideally should be purpose built. Nearby parking for escorts collecting patients should be provided. The design should maximise efficient patient flow The number of beds and theatres will be dictated by the workload of the specialities using the unit. In general, a throughput of 1.5 patients/bed day is possible, but may be less if more major procedures requiring longer recovery are undertaken. The balance of beds to operating theatres, and the scheduling of the operating sessions, should be planned with this in mind, but there should be flexibility for changing needs. The DSU may also be used for a variety of other procedures that require different facilities and equipment such as gastrointestinal endoscopy, flexible cystoscopy, interventional radiology, and chronic pain or minor medical procedures.

Children-only days or sessions may be planned. Procedures needing longer recovery should be scheduled early in the day, and local anaesthetic cases later. Many units now stay open into the evening to allow later operating sessions.

The unit layout

The reception area

The reception area should be welcoming and large enough to accommodate patients and their escorts on arrival and discharge, with adequate space for secretarial and reception staff. Admission procedures are completed here before the patients go to the ward.

The day surgery ward

This may be equipped with beds or trolleys. Preoperative assessment and investigations will already have been carried out, but the patient must be assessed before surgery by the surgeon and the anaesthetist. Basic preoperative checks are carried out, site of surgery marked and consent for the procedure signed, if not already done. Time must be allowed for this assessment so that the patient does not meet the anaesthetist in the anaesthetic room when it is too late to address any problems. Sedative premedication is usually avoided as it may prolong recovery time, and unsedated patients can walk to the anaesthetic room. After leaving the recovery room, the patient will return to this ward area to recover sufficiently to have light refreshment and be taken home.

The anaesthetic room and operating theatres

These should have precisely the same high-quality specification, monitoring, safety and surgical equipment as in-patient operating suites. Trained assistance must be provided throughout the perioperative period. The use of operating trolleys, on which the patients can also recover, can save considerable time and manpower as patients do not have to be moved between trolley and operating table.

The recovery area

The recovery area should be fully equipped to in-patient standards and be adjacent to the theatre. In the UK, patients usually spend only a short time here before returning to the ward to recover, but in the USA this area, called the Post Anesthesia Recovery Unit (PACU), may be used until the patient is ambulant and can to be sent to a ‘step-down area where they remain in a chair until fit to go home. Patients who have had local anaesthesia with no or mild sedation may be able to bypass this area and go straight to the ward.

Personnel

Staffing of the Day Surgery Unit

Experienced day surgery nurses excel at dealing with problems and giving reassurance and information. In many units, multitasking allows nurses and operating department personnel (ODP) to undertake ward, theatre and anaesthetic assistant duties. Specialised nurses may be needed for children or for certain types of surgery such as ophthalmic. Ancillary staff for portering and domestic duties are also needed.

Record keeping

This must be accurate and complete, often difficult with high-volume fast turnover. Unnecessary paperwork should be mini-mised while ensuring that vital information is logged. A folder containing all of the relevant records is ideal. Computerised systems can help greatly and are now commercially available.

Support services

Although the need for laboratory and radiology services is minimal, these should be available if required. In-patient and resuscitation back-up must be identified for the rare occasions when it will be needed.

Medical staff and training

Good-quality treatment with minimal complications means that day surgery must be consultant led and carried out by fully trained medical staff, surgical and anaesthetic, to achieve the best results and reduce complications and risk. However, senior staff may find the work unchallenging and be tempted to delegate it to trainees. Training in day surgery is essential, but trainees should be closely supervised and extra time allowed for this.

Clinical Director

The Clinical Director, usually a consultant surgeon or an anaesthetist, should manage the DSU and implement and audit good standards of care. Regular multidisciplinary meetings with all those using the unit are needed, as is liaison with GPs and community care.
Postoperative morbidity after day surgery (Tab 69.4)

Day surgery has an excellent safety record. Major morbidity with the potential for serious harm is rare. In a large study from the Mayo Clinic in 1993, Warner reported that the mortality and major morbidity in the 30 days after day surgery was 0.0007 per cent — lower than in the general population who had not had surgery.

Minor morbidity, however, is common and apparently minor problems can have significant consequences. For the hospital, it results in longer stays in the DSU and increased rates of overnight admission, which may cause problems if no bed is available or the bed is earmarked for another patient. For the patient, it is not only unpleasant but delays their recovery and return to normal life and is a cause of dissatisfaction. For GP, it may increase workload.

Postoperative morbidity is related to the type of anaesthesia used and the surgery itself. The procedure is generally the most important predictor of complications. The requirement to discharge patients within a relatively short time of their surgery demands meticulous and safe anaesthetic and surgical techniques to ensure good recovery with minimal postoperative morbidity.
The essentials of good day surgery

In order to achieve good results in day surgery and avoid the pitfalls described above the following are essential:

• selection of appropriate procedures and patients;
• preadmission assessment and information;
• anaesthesia and surgery with minimal morbidity and complications;
• postoperative and postdischarge analgesia;
• discharge criteria and postoperative instructions;
• follow-up and audit.

Day surgery selection

The aim of day surgery selection is to avoid predictable complications and morbidity. In selecting suitable procedures and patients, consider:

• the procedure to be undertaken;
• the social circumstances;
• the fitness of the patient.

Criteria for suitable day-case procedures

• Minimal physiological trespass;
• not associated with excessive blood loss or fluid shifts;
• very low risk of serious postoperative complications (e.g. bleeding or airway obstruction);
• duration of up to 1 hour, 2 hours maximum;
• pain must be controllable with oral analgesics after discharge;
• the patient should be reasonably ambulant afterwards.

The use of surgical drains is controversial; if needed, these are removed before the patient goes home. Urinary catheters are surprisingly well tolerated and may allow urology patients to go home. Absorbable sutures and improved wound closure methods may reduce the need for patients to return for stitch removal.

Relatively uncontroversial day-case procedures (Table 69.5) make up the bulk of day surgery. However, other more major operations may now be included as minimally invasive surgical techniques using laparoscopy and lasers reduce post-operative problems and pain. Open abdominal, intrathoracic, intracranial and major vascular procedures are still universally considered to be unsuitable.

In general, longer and more invasive operations are associated with more pain, bleeding or other complications, although this is not absolutely true — some may simply be time-consuming without increasing morbidity. Laparoscopic surgery in particular is associated with increased morbidity and overnight admission, particularly for procedures such as cholecystectomy. Tonsillectomy is also controversial: while routinely performed on a day-case basis in many centres, anxiety about the risk of bleeding deters others. The pathology is important — small haemorrhoids or incisional hernias are suitable, very large ones may not be.

The push to ambulatory surgery in the USA has led to the inclusion of major surgery, such as mastectomy and vaginal hysterectomy, often with little regard for patient comfort and preference. This has resulted in a backlash, with legislation to prohibit the ‘drive-through’ mastectomy.

The social circumstances

• Day surgery needs ready access to a hospital or GP after discharge, although the demand on these should be minimal.
• A responsible adult to escort the patient home and care for them at least until the following morning is mandatory. For more major day-case operations, longer care may be needed. Elderly or disabled partners may be unsuitable.
• Patients must have reasonable home circumstances with good toilet facilities, few stairs to climb and access to a telephone.
• Patients should live within 60 minutes’ travelling distance, both to reduce discomfort on the way home and to have ready access to hospital care if needed. Patients should not travel home by public transport.
• Other options have been used where home circumstances are not ideal, such as hospital hotels supplying overnight supervision at low cost or, more rarely, transfer to a community hospital. An overnight stay in hospital (the ‘23-hour admit’) may permit more procedures and patients to be considered suitable ‘day cases’, but may not achieve the benefits of day surgery.
• Developing countries with long distances and difficult travelling conditions to reach medical care may find that these are obstacles to introducing day surgery.

The fitness of the patient for general anaesthesia

The patient should be medically stable and have been screened before admission to exclude major health problems. The American Society of Anesthesiologists (ASA) classification of patient fitness is often used, with the stipulation that ASA 1, 2 and stable 3 patients are suitable, although this may be difficult to define with accuracy. The aspects of patient fitness which have been shown to relate to complications during surgery and to unplanned overnight admission are severe symptomatic respiratory disease, symptomatic cardiac disease and hypertension.

Age. 70 is often taken as an upper age limit, but the physiological age of the patient is more important than actual age. Elderly patients may be suitable for day-case procedures under local or regional anaesthesia.

The lower age limit depends on the facilities available, the experience of the staff and the procedures undertaken. The healthy full-term neonate is suitable for minor day-case procedures, provided that there is immediate access to in-patient neonatal care if needed. More caution
is needed with pre-term or ex-preterm babies, who should not be considered before 60 weeks’ conceptual age because of the risk of perioperative apnoea.

**Obesity.** Weight limits expressed as body mass index (BMI) (weight in kg/height in m²) are often imposed, although there is little hard evidence as to what is unacceptable. Surgery and anaesthesia are undoubtedly more difficult and have more complications in overweight patients, who may also have more health problems. Although a BMI of 30 is often taken as an upper limit, in otherwise fit patients problems do not really become apparent until the BMI exceeds 35.

**Respiratory disease.** Asthmatics with no history of hospital admission for their asthma, and patients with chronic obstructive airways disease, are suitable for day surgery if they have reasonable exercise tolerance, usually expressed as the ability to climb a flight of stairs.

**Hypertension.** Untreated or previously unrecognised hypertension in apparently fit patients is the commonest predictable reason for cancellation on the day of surgery, and ‘white coat hypertension’ on the patient’s arrival in hospital is a recurring source of strife between surgeons, anaesthetists and GPs. However, this type of hypertension has been shown to be related to abnormal left ventricular function and to perioperative myocardial ischaemia. A preadmission blood pressure (BP) is mandatory, and BP _ 175/105 mmHg should be treated before surgery, together with electrocardiography (ECG) and full cardiac history to exclude more severe underlying cardiac disease.

**Cardiac disease.** Unsuitable conditions include cardiac failure, symptomatic valvular disease, severe or rest angina, fast ventricular arrhythmias, unpaced second or third degree heart block, or myocardial infarction within the previous 6 months. In patients with lesser degrees of heart disease, further cardiac assessment may be required.

**Diabetes.**

Well controlled noninsulin-dependent diabetes (NIDDM) usually poses no problems. Although otherwise fit insulin-dependent diabetics have been considered suitable, in practice, even with a well-controlled and well-motivated patient, the stress of surgery and fasting can upset the patient’s diabetic control, making their day surgery episode difficult and time-consuming for medical staff.

**Drug therapy.** Patients taking anticoagulants, systemic steroids, digoxin, drugs for dysrrhythmias and angina, and monamine oxidase inhibitors need individual anaesthetic evaluation before booking for day surgery. Oestrogen containing oral contraceptives need not be discontinued except for lower limb operations, particularly where a tourniquet will be used.

This is only a guide. There are no absolute exclusions — the severity must be evaluated — and local or regional anaesthesia may be suitable for patients who cannot safely be given a general anaesthetic. Simple guidelines (Table 69.7) should be circulated to surgical staff and displayed in out-patient departments.

**Assessment before admission for surgery**

This is an essential component of well-organised day surgery. The timing should allow any problems to be sorted out, but not be so far in advance that the patient develops new problems.

**Methods of assessing patients**

Surgeons are not good at assessing patients for anaesthetic fitness, particularly in the middle of a busy clinic. The ideal would be to have the patient seen by an anaesthetist, preferably the one who will anaesthetise the patient. This is usually impracticable in terms of time, cost and available anaesthetic time. The best alternative is a filtering process (Fig. 69.1) with specially trained nurses using patient questionnaires (Table 69.8) and locally agreed protocols of suitable criteria. Borderline cases are referred for anaesthetic opinions, and consultant anaesthetists involved in day surgery should be identified to advise.

**Assessment clinics**

A good assessment clinic prevents cancellation on the day of surgery for predictable reasons, particularly hypertension. It also speeds up the process of admitting the patient, and may reduce unplanned overnight admission for those who have not arranged for an escort home. It can reduce unnecessary investigations, perioperative complications and risk. Patient compliance may be improved — given information and the opportunity to discuss anxieties, they are more likely to turn up for their operations and to have obeyed their preoperative instructions (Fig. 69.2). It should also increase the number of suitable patients by addressing problems, and by arranging for borderline cases to be considered for local or regional anaesthesia. Assessment clinics are cost-effective (Table 69.9).

**Preadmission in formation**

This has been identified as a cause for patient dissatisfaction. Providing clear concise information means that patients arrive well prepared, having obeyed the fasting instructions, and knowing what to expect from the surgery and in the recovery period. The prolonged fluid fast of former times may be detrimental to recovery, and although a 4–6-hour fast from solid food is essential, clear fluids may be allowed up to 2–3 hours preoperatively. Information about expected levels of pain and restrictions on activity after specific procedures helps the patient to plan their care at home — for instance mothers of small children may need to arrange for help for longer than just overnight. All of the important information (Table 69.10) should be on one page, or patients may not read it. Separate leaflets on individual procedures are useful. Resist the temptation to overload the patient with information.

**Anaesthesia for day surgery**

Anaesthetic morbidity is a major reason for unplanned admission, in particular sleepiness, dizziness and nausea (Fig. 69.3). The choice is between local or regional anaesthesia with or without mild sedation, or general anaesthesia with local anaesthetic where appropriate to provide postoperative analgesia.

**Local or regional anaesthesia** is perhaps the ideal, although it is not suitable for all procedures or patients. It is excellent for elderly patients and is usually economical, although it may be more time consuming than general anaesthesia, and necessitates gentle surgery. Patients and surgeons may express a preference for general anaesthesia.

The type of local anaesthesia must be carefully chosen. Central anaesthetic blocks, epidural, spinal or caudal, may be less suitable because of the time taken to carry out the block and allow it to work, the time taken for the patient to mobilise and the high incidence of urinary retention.

Suitable blocks are listed in Table 69.11. The ideal choice of agent is a long-acting one, such as bupivacaine, and if speed of onset is
important lignocaine may be mixed with this. Prilocaine will be needed for Bier’s blocks (intravenous regional anaesthesia). Care should be taken not to exceed safe doses, and if the surgeon administers the local anaesthetic, an anaesthetist should be available for anything more than very minor procedures, in case of complications.

**General anaesthesia**

Propofol, a newer anaesthetic agent, has established itself as the agent of choice for the induction, and often also the maintenance, of day-case patients because of its good anaesthetic conditions, rapid problem-free recovery and lack of postoperative nausea and vomiting (PONV). Indeed, it is antiemetic, a major advantage in day surgery. Children are increasingly induced intravenously. For inhalation induction sevoflurane has now replaced halothane in many countries because of its ease of use and speed of recovery.

Maintenance of anaesthesia is commonly with a volatile agent, such as isoflurane or enflurane, and nitrous oxide in oxygen. The newer volatile agents, desflurane and sevo- flurane, with ultrafast immediate recovery times, have proved disappointing, as all similar volatile anaesthetic agents they have a high incidence of PONV which delays recovery, and little advantage has been shown to justify their increased cost. Many day surgery anaesthetists therefore use propofol by infusion to maintain anaesthesia, as well as for induction — total intravenous anaesthesia (TIVA). The increased cost may be justified in view of the excellent recovery, particularly after longer procedures and where the risk of PONV is high.

Short-acting opioids, such as alfentanil or fentanyl, are usually included in the general anaesthetic to reduce the dosage of other drugs and to provide some analgesia in the early postoperative period.

The laryngeal mask airway (LMA) has become popular in day surgery as it allows fast easy control of the airway, and endotracheal intubation and its hazards often can be avoided. It is now commonly used for straightforward laparoscopies, and for dental and head and neck procedures.

**Sedation**

This is given ideally by an anaesthetist, but sometimes by other medically qualified personnel. The sedationist must not be involved in the procedure: the single-handed operator—sedationist is neither safe nor medicolegally defensible. Monitoring is required and supplemental oxygen is usually given. Sedation means that the patient is relaxed and calm while maintaining rational verbal contact. It is all too easy to oversedate the patient beyond this level, so that the patient is anaesthetised and airway control may be lost. Sedation is best left to experienced anaesthetists.

The use of midazolam, a short-acting benzodiazepine, is popular but its long-lasting postoperative amnesia may mean that postoperative instructions are forgotten. Propofol in low dose is very suitable for sedation, with faster wake-up and less amnesia, although some patients may prefer not to recall events in theatre. Small doses of opioids may also be used with caution, but may result in respiratory depression or apnoea.

**Analgesia**

Good pain control is essential. It is a major reason for delay in discharge (Fig. 69.3), unplanned overnight admission, GP consultations after discharge, and, not least, patient distress and dissatisfaction. It limits early patient mobilisation and prolongs return to normal function. The use of morphine, while successful in controlling pain, is less successful in day surgery because of its sedation and high incidence of nausea, which may only become apparent after the patient leaves the DSU. In order to avoid its use, a mixture of analgesic methods is needed — so-called balanced or multimodal analgesia. Nonsteroidal anti-inflammatory drugs (NSAIDs) plus local anaesthesia, where possible, form the basis, with additional short-acting opioids and other mild analgesics if needed. Although none of these methods is sufficient alone, in combination they are very effective.

The best local anaesthesia will not last longer than the evening of surgery, so it is important to provide sufficient oral analgesia for 3—5 days postdischarge. These should be prepared in packs supplied to the DSU and prescribed according to the expected pain for that operation (Table 69.12). Combinations of regular NSAIDs with simpler analgesics for break-through pain are successful. Unless clear instruction on their use is given, patients’ compliance may be poor (Table 69.13).

**Discharge**

The patient must be seen before discharge by the surgeon and the anaesthetist, or their deputies. Formal discharge criteria are required, with documentation signed by the individual delegated to discharge the patient, usually a nurse. The patient and their escort must be given clear instructions on what to do after their general anaesthetic and surgery, including stitch removal and follow-up where needed (Tables 69.14 and 69.15).

**Follow-up, audit and quality control**

Good day surgery practice means that the incidence of non-attendance, cancellations, complications before and after discharge, overnight admission and readmission is audited, and improvements are made where needed. Where possible, a telephone call to the patient the next day reassures the patient and gives immediate feedback on the adequacy of analgesia and other problems. Specific audits should be conducted on patient satisfaction with their overall management, morbidity related to specific types of surgery and anaesthesia, and the adequacy of postoperative analgesia. The involvement of community services and GPs should be monitored.
Children in day surgery

Day surgery is the ideal for many paediatric surgical procedures, with well-documented psychological benefits for children. The principles for adults apply just as much to children, with a few crucial differences. Specially trained anaesthetic, surgical and nursing staff are required, and children should be kept separate from adults with designated children only days or areas. A visit to the DSU beforehand to prepare the child and the provision of child-friendly areas and toys set the scene for stress free surgery. Liaison with community services and the GP is essential, particularly for more major procedures. Children with single parents or in poor housing may need special assessment as to suitability.
The future of day surgery

Day surgery is no longer the fastest surgery on the fittest patients. The criteria for what is suitable are being stretched by the inclusion of older, less fit patients and more major procedures, enabled by developments in surgery and anaesthesia. Different modes of postdischarge care will be developed, although the cost-effectiveness of these must be established. Increasing attention will need to be paid to quality issues and to patients' attitudes as to what is actually acceptable. This underlines the importance of good day surgery practice.

Definition

Minimal access surgery is a marriage of modern technology and surgical innovation which aims to accomplish surgical therapeutic goals with minimal somatic and psychological trauma. Minimal access techniques are less invasive and less disabling and disfiguring than conventional techniques. With increasing experience they offer cost-effectiveness both to health services and to employers by shortening operating times, shortening hospital stays and allowing faster recuperation.
Extent of minimal access surgery

Minimal access surgery has crossed all traditional boundaries of specialties and disciplines. Shared, borrowed and overlapping technologies and information are encouraging a multi-disciplinary approach which serves the whole patient rather than a specific organ system. Broadly speaking, minimal access techniques can be categorised as follows.

Laparoscopy

A rigid endoscope is introduced through a metal sleeve into the peritoneal cavity which has been previously inflated with carbon dioxide to produce a pneumoperitoneum. There is little doubt that laparoscopic cholecystectomy has revolutionised the surgical management of cholelithiasis and has become the mainstay of management of uncomplicated gall-stone disease. With improved instruments and more experience, it is likely that other advanced procedures, currently regarded as controversial, will also become fully accepted.

Thoracoscopy

A rigid endoscope is introduced through an incision in the chest to gain access to the thoracic contents. Many feel that the benefits of thoracoscopy will prove to be even greater than those of laparoscopy.

Endoluminal endoscopy

Flexible or rigid endoscopes are introduced into hollow organs or systems, such as the urinary tract, upper or lower gastrointestinal tract, and respiratory and vascular systems.

Perivisceral endoscopy

Body planes can be accessed even in the absence of a natural cavity. Examples are mediastinoscopy, retroperitoneoscopy and retroperitoneal approaches to the kidney, aorta and lumbar sympathetic chain. Other more recent examples include subfascial ligation of incompetent perforating veins in varicose vein surgery.

Arthroscopy and intra-articular joint surgery

Orthopaedic surgeons have long used arthroscopic access to the knee, and have now moved their attention to other joints including the shoulder, wrist, elbow and hip.

Combined approach

The diseased organ is visualised and treated by an assortment of endoluminal and extraluminal endoscopes and other imaging devices.
Surgical trauma in open and laparoscopic surgery

Most of the trauma of an open procedure is inflicted because the surgeon must have a wound large enough to give adequate exposure for safe dissection at the target site. The wound is often the cause of morbidity including infection, dehiscence, bleeding, herniation and nerve entrapment. The pain of the wound prolongs recovery time, and by reducing mobility contributes to an increased incidence of pulmonary collapse, chest infection and deep venous thrombosis.

Mechanical and human retractors cause additional trauma. Body wall retractors tend to inflict localised damage which may be as painful as the wound itself. By contrast, during laparoscopy, the retraction is provided by the low-pressure pneumoperitoneum giving a diffuse force applied gently and evenly over the whole body wall, causing minimal trauma.

Exposure of any body cavity to the atmosphere also causes morbidity through cooling and fluid loss by evaporation. There is also evidence from the literature to suggest that the incidence of postsurgical adhesions has been reduced by the use of the laparoscope because there is less damage to delicate serosal coverings. In handling intestinal loops the surgeon and assistant disturb the peristaltic activity of the gut and provoke adynamic ileus.

In minimal access surgery the trauma of access and exposure is reduced while visualisation is magnified and improved.
Limitations of minimal access surgery

To perform minimal access surgery with safety, the surgeon must operate remote from the surgical field using an imaging system which provides a two-dimensional representation of the operative site. The endoscope offers a whole new anatomical landscape which the surgeon must learn to navigate without the usual cues which make it easy to judge depth. The instruments are longer and sometimes more complex to use than those common in open surgery. The result of all this is that the beginner in minimal access surgery is faced with significant problems of hand-eye co-ordination. Stereoscopic imaging for laparoscopy is still in its infancy. Future improvements in these systems will greatly enhance manipulative ability in critical procedures such as knot tying and dissection of closely underlying tissues. There are, however, some drawbacks, such as reduced display brightness and interference with normal vision due to the need to wear specially designed glasses. It is probable that brighter projection displays will be developed, at increased cost. However, the need to wear glasses will not be easily overcome. Looking further to the future, it is evident that the continuing reduction in costs of elaborate image processing techniques will make a wide range of transformed presentations available. It will ultimately be possible for a surgeon to call up any view of the operative region that is accessible to a camera and present it stereoscopically in any size or orientation, superimposed on past images taken in other modalities. It is for the medical community to decide which of these many imaginative possibilities will contribute most to effective surgical procedures.

Another problem occurs when there is intraoperative arterial bleeding. Haemostasis may be very difficult to achieve endoscopically because blood obscures the field of vision and there is a significant reduction of the image quality owing to light absorption.

Some of the procedures performed by this new approach are more technically demanding and are slower to perform. Indeed, on occasion a minimally invasive operation is so technically demanding that both patient and surgeon are better served by conversion to an open procedure. Unfortunately, there seems to be a sense of embarrassment or humiliation associated with conversion which is quite unjustified. It is vital for surgeons and patients to appreciate that the decision to close or convert to an open operation is not a complication but instead usually implies sound surgical judgement.

Another disadvantage of laparoscopic surgery is the loss of tactile feedback. Laparoscopic ultrasonography might be a substitute for the need 'to feel' in intraoperative decision making. Although ultrasonography has progressed significantly in the past several years, laparoscopic ultrasound remains in its infancy. The rapid progress in advanced laparoscopic techniques, including biliary tract exploration and surgery for malignancies, has provided a strong impetus for the development of laparoscopic ultrasound. Although in-completely developed, this technique already has advantages that far outweigh its disadvantages.

In more advanced techniques the large piece of resected tissue, such as the lung or colon, has to be extracted from the body cavity. Occasionally, the extirpated tissue may be removed through a nearby natural orifice, such as the rectum or the mouth. At other times a novel route may be employed. For instance, a benign colonic specimen may be extracted through an incision in the vault of the vagina. Although tissue ‘morcellers, mincers and liquidisers’ could be used in some circumstances, this has the disadvantage of reducing the amount of information available to the pathologist. Recent reports of tumour implantation in the sites of port holes have raised important questions about the future of the laparoscopic treatment of malignancy.

Hand-assisted laparoscopic surgery is a newly developed technique. It involves the intra-abdominal placement of a hand or forearm through a minilaparotomy incision whilst pneumoperitoneum is maintained. In this way the surgeon’s hand can be used as in an open procedure. It can be used topalpate organs or tumours, to reflect organsatraumatically, to retract structures, to identify vessels, to dissect bluntly along a tissue plane and to provide finger pressure to bleeding points while proximal control is achieved. In addition, several reports have suggested that this approach is more economical than a totally laparoscopic approach, reducing both the number of laparoscopic ports and the number of instruments required. Some advocates of the technique claim that it is also easier to learn and perform than totally laparoscopic approaches, and that there may be increased patient safety.

There is a growing need for improvement in dissection techniques in laparoscopic surgery and, specifically, for improving the safe use of electrosurgery and lasers. Ultrasonic dissection and tissue removal has been utilised by a growing number of specialties for several years. The adaptation of the technology to laparoscopic surgery grew out of the search for alternative, possibly safer, methods of dissection. The current units combine the functions of three or four separate instruments, reducing the need for instrument exchanges during a procedure. This flexibility, combined with the ability to provide a clean, smoke-free field, improves safety while shortening operating times.

Although dramatic cost savings are possible with laparoscopic cholecystectomy, the position is less clear cut with other procedures. There is another factor which may complicate the computation of cost benefit. A significant rise in the rate of cholecystectomy followed the introduction of the laparoscopic approach as the threshold for referring patients for surgery lowered. The increase in the number of procedures performed has led to an overall increase in the cost of treating symptomatic gallstones.
Preoperative evaluation

Preparation of the patient undergoing laparoscopic surgery

Although the patient may only be in hospital for a few hours, careful preoperative management is essential to minimise morbidity.

Preparation is very similar to that for open surgery, and aims to ensure that:

- the patient is fit for the procedure;
- the patient is fully informed and consented;
- operative difficulty is predicted where possible;
- appropriate theatre time and facilities are available.

History

Patients must be fit for general anaesthesia and open operation if necessary. Potential coagulation disorders (for example, associated with cirrhosis) are particularly dangerous in laparoscopic surgery. As adhesions may cause problems, previous abdominal operations or peritonitis should be documented.

Examination

Routine preoperative physical examination is required as for any major operation. Although laparoscopic surgery in general allows quicker recovery, it may involve longer operating time and the establishment of the pneumoperitoneum may provoke cardiac arrhythmias. Severe chronic obstructive airways disease and ischaemic heart disease may be contraindications to the laparoscopic approach.

Particular attention should be paid to the presence or absence of jaundice, abdominal scars, palpable masses or tenderness.

Moderate obesity does not increase operative difficulty significantly, but massive obesity may make pneumoperitoneum difficult, and standard instrumentation may be too short. Access may prove difficult in very thin patients, especially those with severe kyphosis.

Premedication

Premedication is the responsibility of the anaesthetist, with whom coexisting medical problems should be discussed, for example significant ischaemic heart disease.

Prophylaxis against thromboembolism

Venous stasis induced by the reversed Trendelenburg position during laparoscopic surgery may be a risk factor for deep vein thrombosis, as is a lengthy operation and the obesity of many patients. Subcutaneous heparin and TEDs should be used routinely in addition to pneumatic leggings during the operation. Patients already taking warfarin for other reasons should have this stopped temporarily or converted to intravenous heparin, depending on the underlying condition, as it is not safe to perform laparoscopic surgery in the presence of a significant coagulation deficit.

Urinary catheters and nasogastric tubes

In the early days of laparoscopic surgery routine bladder catheterisation and nasogastric intubation were advised. Most surgeons now omit these but it remains essential to check that the patient is fasted, and has recently emptied the bladder, before the blind insertion of a Verres needle.

Informed consent

The basis of many complaints and much litigation in surgery, especially laparoscopic surgery, relates to the issue of informed consent. It is mandatory that the patient understands the nature of the procedure, the risks involved and, where appropriate, what alternatives are available. A locally prepared explanatory booklet concerning the laparoscopic procedure to be undertaken is extremely useful.

In an elective case a full discussion of the proposed operation should take place in the out-patient department with a surgeon of appropriate seniority, preferably the operating surgeon, before the decision is made to operate. On admission it is the responsibility of the operating surgeon and anaesthetist to ensure that the patient has been fully counselled, although the actual witnessing of the consent form may have been delegated. The patient should understand what laparoscopic surgery involves and that there is a risk of conversion to open operation. If known, this risk should be quantified, for example the increased risk with acute cholecystitis or in the presence of extensive upper abdominal adhesions. The conversion rate will also vary with the experience and practice of the surgeon. Common complications should be mentioned, such as shoulder tip pain and minor surgical emphysema, as well as rare but serious complications including injury to the bile ducts and visceral injury from trochar insertion or diathermy.

A few patients may insist on having an open procedure (probably influenced by accounts of mishaps) and the surgeon should be prepared to offer this, although most will opt for laparoscopy if the surgeon offers an extensive experience and impressive safety record.
General intraoperative principles

Laparoscopic cholecystectomy is the treatment of choice for gallstone disease. The most accepted technique was outlined by Reddick and Olsen. The main drawback of the technique is the increased incidence of bile-duct injury compared with open cholecystectomy. However, with better understanding of the mechanisms of injury and with proper training, virtually almost all of these injuries can be avoided. This chapter highlights important technical steps that should be taken during any form of laparoscopic surgery to avoid complications.

Creating a pneumoperitoneum

The most common method of obtaining a pneumoperitoneum is by blind puncture using a Verres needle. Although this method is fast and relatively safe, there is a small but significant potential for intestinal or vascular injury on introduction of the needle or first trocar. The routine use of the open technique for creating a pneumoperitoneum avoids the morbidity related to a blind puncture. To do this, a 1-cm vertical or transverse incision is made at the level of the umbilicus. Two small retractors are used to dissect bluntly the subcutaneous fat and expose the midline fascia. Two sutures are inserted each side of the midline incision, followed by the creation of a 1 cm opening in the fascia. Free penetration into the abdominal cavity is confirmed by the gentle introduction of a finger. Finally, a Hasson (or other blunt-tip) trocar is inserted and anchored with the fascial sutures (Fig. 70.1). The open technique may initially appear time-consuming and even cumbersome. With practice, however, it is overall more efficient.

Preoperative problems

Previous abdominal surgery

Previous abdominal surgery is no longer a contraindication to laparoscopic surgery, but preoperative evaluation is necessary to assess the type and location of surgical scars. As men-tioned earlier, the open technique for insertion of the first trocar is safer. Prior to trocar insertion, the introduction of a fingertip helps to ascertain penetration into the peritoneal cavity and also allows adhesions to be gently removed from the entry site. After the tip of the cannula has been introduced, a 0°-laparoscope is used as a blunt dissector to tease adhesions gently away and to form a tunnel towards the quadrant where the operation is to take place. This step is accom-plished by a careful pushing and twisting motion under direct vision. With experience, the surgeon learns to differentiate visually between thick adhesions that may contain bowel and should be avoided, and thin adhesions that would lead to a window into a free area of the peritoneal cavity (Fig. 70.2).

Obesity

Laparoscopic surgery has proved to be a safe and effective procedure in the obese population. In fact, some procedures are less difficult than their open counterpart for the morbidly obese patient. Technical difficulties occur, however, in obtaining pneumoperitoneum. In reaching the operative region adequately and in achieving adequate exposure in the presence of an obese colon. Increased thickness of the subcutaneous fat makes insufflation of the abdominal cavity more difficult. With the closed technique, a larger Verres needle is often required for morbidly obese patients. Pulling the skin up for fixation of the soft tissues is better accomplished with towel clamps. Only moderate force should be used to avoid separating the skin farther away from the fascia. The needle should be passed at nearly a right angle to the skin and preferably above the umbilicus where the peritoneum is more firmly fixed to the midline. The open technique of inserting a Hasson trocar is easier and safer for obese patients. The main difficulty is reaching the fascia. A larger skin incision (1—3 cm) starting at the umbilicus and extending superiority may facilitate this. To reach the operative area adequately, the location of some of the ports has to be modified, and in some instances, larger instruments are necessary. When the length of the laparoscope appears to be insufficient to reach the operative area adequately, the initial midline port should be placed nearer to the operative field.

Operative problems

Perforation of the gall bladder

Perforation of the gall bladder is more common with the laparoscopic technique than with the open technique. Some authors have reported an incidence of up to 30 per cent, but this did not appear to be a factor in increasing the early postoperative morbidity. However, it is well known that bile is not a sterile fluid and bacteria can be present in the absence of cholecystitis. Unless the perforation is small, closure with endoloops should be attempted to avoid contamination.

Bleeding

In some of the larger series, bleeding has been the most com-mon cause for conversion to an open procedure. Bleeding plays a more important role in laparoscopic surgery because of factors inherent to the technique. These include a limited field that can easily be obscured by relatively small amounts of blood; magnification that makes small arterial bleeding look like a significant haemorrhage and light absorption that obscures the visual field.

How to avoid bleeding. As in any surgical procedure, the best way to handle intraoperative bleeding is to prevent it from happening. This can usually be accomplished by identifying patients at high risk of bleeding, by clear understanding of the laparoscopic anatomy and by careful surgical technique.

Risk factors which predispose to increased bleeding include:

• cirrhosis;

• inflammatory condition (acute cholecystitis, diverticulitis);

• coagulation defects: these are contraindications to a laparoscopic procedure.

Bleeding from a major vessel. Damage to a large vessel requires immediate assessment of the magnitude and type of bleeding. When the bleeding vessel is identified, a fine-tip grasper can be used to grasp it and apply either electrocautery or a clip, depending on the size of the vessel. When the vessel is not identified early and a pool of blood forms, compression should be applied immediately with a blunt instrument, a cotton swab or with the adjacent organ. Good suction and irrigation are of utmost importance. After the area has been cleaned, pressure should be released gradually to identify the site of bleeding. Insertion of an extra cannula may be required to achieve adequate exposure and at the same time to enable the concomitant use of a suction device and an insulated grasper. Although most of the bleeding vessels can be controlled laparoscopically, judgement should be used not to prolong bleeding but to convert to an open procedure at an early stage whenever control of bleeding is not achieved promptly.
Bleeding from the gall-bladder bed. Bleeding from the gall-bladder bed can usually be prevented by performing the dissection in the correct plane. When a bleeding site appears during detachment of the gall bladder, the dissection should be carried a little farther better to expose the bleeding point. After this step has been performed, direct application of the electrocautery usually controls the bleeding. If bleeding persists, indirect application of the electrocautery is useful because it avoids detachment of the formed crust. This procedure is accomplished by applying pressure to the bleeding point with a blunt insulated grasper and then applying electro coagulation by touching this grasper with a second insulated grasper that is connected to the electrocautery. One must be careful to keep all conducting surfaces of the graspers within the visual field while applying the electro-cautery current.

Bleeding from a trocar site. Bleeding from the trocar sites is usually controlled by applying upward and lateral pressure with the trocar itself. Considerable bleeding may occur if the falciform ligament is impaled with the substernal trocar or if one of the epigastric vessels is injured. If significant continuous bleeding from the falciform ligament occurs, haemostasis is achieved by percutaneously inserting a large straight needle at one side of the ligament. A monofilament suture attached to the needle is passed into the abdominal cavity, and the needle is exited at the other side of the ligament using a grasper (Fig. 70.3). The loop is suspended and compression is achieved. Maintaining compression throughout the procedure usually suffices. After the procedure has been completed, the loop is removed under direct laparoscopic visualisation to ensure complete haemostasis. When significant continuous bleeding from the abdominal wall occurs, haemostasis can be accomplished either by pressure or by suturing the bleeding site. Pressure can be applied using a Foley balloon catheter. The catheter is introduced into the abdominal cavity through the bleeding trocar site wound, the balloon is inflated, traction is placed on the catheter and it is bolstered in place to keep it under tension. The catheter is left in situ for 24 hours and then removed. Although this method is successful in achieving haemostasis, the author favours direct suturing of the bleeding vessel. This manoeuvre is accomplished by extending the skin incision by 3 mm at both ends of the bleeding trocar site wound. Two figure of eight sutures are placed in the path of the vessel at both ends of the wound.

Evacuation of blood clots. The best way of dealing with blood clots is to avoid them. As mentioned, careful dissection and identification of the cystic artery and its branches, as well as identifying and carrying out dissection of the gall bladder in the correct plane, avoid bleeding from the cystic vessels and the hepatic bed. Nevertheless, clot formation takes place when unsuspected bleeding occurs or when inflammation is severe and a clear plane is not present between the gall bladder and the hepatic bed. The routine use of 5000—7000 units of heparin per litre of irrigation fluid helps to avoid the formation of clots. When extra bleeding is foreseen, a small pool of irrigation fluid can be kept in the operative field to prevent clot formation. After clots have formed, a large-bore suction device should be used for their retrieval. Care should be taken to avoid suctioning in proximity to placed clips.

Principles of electrosurgery during laparoscopic surgery

Electrosurgical injuries during laparoscopy are potentially serious. The vast majority occurs following the use of mono-polar diathermy. The overall incidence is between one and two patients per 1000 operations. Electrical injuries are usually unrecognised at the time they occur, with patients commonly presenting 3—7 days after injury with complaints of fever and abdominal pain. As these injuries usually present late, the reasons for their occurrence are largely speculative.

The main theories are: (1) inadvertent touching or grasping of tissue during current application; (2) direct coupling between a portion of bowel and a metal instrument which is touching the activated probe (Fig. 70.4); (3) insulation breaks in the electrodes; (4) direct sparking to bowel from the diathermy probe; and (5) current passage to the bowel from recently coagulated, electrically isolated tissue. Bipolar diathermy is safer and should be used in preference to mono-polar diathermy, especially in anatomically crowded areas. If monopolar diathermy is to be used important safety measures include attainment of a perfect visual image, avoiding excessive current application and meticulous attention to insulation. Alternative methods of performing dissection such as ultrasonic devices may improve safety.
Postoperative care

The postoperative care of patients after laparoscopic surgery is generally very straightforward with a very low incidence of pain or other problems. The most common routine postoperative symptoms are a dull upper abdominal pain, nausea and pain around the shoulders (referred from the diaphragm). It is a good general rule that if the patient develops a fever or tachycardia or complains of severe pain at the operation site, something is wrong and they should be kept under close observation. In that case routine investigation should include full blood count, liver function tests, amylase and, probably, an ultrasound of the upper abdomen to detect fluid collections. If bile duct leakage is suspected an endoscopic retrograde cholangiopancreatography (ERCP) may be needed. In cases of doubt, relaparoscopy or laparotomy should be performed earlier rather than later. Death following technical errors in laparoscopic cholecystectomy has often been associated with a long delay in deciding to re-explore the abdomen.

In the absence of problems the patient should be fit for discharge within 24 hours. They should be given instructions to telephone the unit or their general practitioner and to return to the hospital if they are not making satisfactory progress.

Nausea

About half of the patients after laparoscopic surgery experience some degree of nausea and rarely this is severe. It usually responds to an antiemetic such as ondansetron and settles within 12—24 hours. It is made worse by opiate analgesics and these should be avoided.

Shoulder pain

The patient should be warned about this preoperatively and told that the pain is referred from the diaphragm and not due to a local problem in the shoulders. It can be at its worse 24 hours after the operation. It usually settles within 2—3 days and is relieved by simple analgesics such as paracetamol.

Abdominal pain

Pain in one or other of the port site wounds is not uncommon and is worse if there is haematoma formation. It usually settles very rapidly. Increasing pain after 2 or 3 days may be a sign of infection and occasionally antibiotics are indicated.

Analgesia

A 100-mg diclofenae suppository should be given at the time of the operation. This may be repeated two or three times postoperatively for more severe pain. Otherwise paracetamol 500—1000 mg 4-hourly usually suffices. Opiate analgesics cause nausea and should be avoided unless the pain is very severe. In that case suspect a postoperative complication (as above). The majority of patients requires between one and four doses of 1 g of paracetamol postoperatively.

Orogastric tube

An orogastric tube may be placed during the operation if the stomach is distended and obscuring the view. It is not necessary in all cases. It should be removed as soon as the operation is over and before the patient regains consciousness.

Oral fluids

There is no significant ileus after laparoscopic surgery, except in resectional procedures such as colectomy or small bowel resection. Patients can start taking oral fluids as soon as they are conscious. They usually do so 4—6 hours after the end of the operation.

Oral feeding

Providing the patient has an appetite a light meal can be taken 4—6 hours after the operation. Some patients remain slightly nauseated at this stage but almost all eat a normal breakfast on the morning after the operation.

Patients will require advice about what they can eat at home. They should be told they can eat a normal diet but should avoid excess. It seems sensible to keep off high-fat meals for the first week, although there is no clear evidence that this is necessary.

Urinary catheter

If a urinary catheter has been placed in the bladder during the operation it should be removed before the patient regains consciousness. The patient should be warned of the possibility and symptoms of postoperative cystitis and told to seek advice in the unlikely event of these occurring.

Drains

Some surgeons drain the abdomen at the end of laparoscopic cholecystectomy, although there is controversy about this. If a drain is placed to vent the remaining gas and peritoneal fluid it should be removed within 1 hour of the operation. If it has been placed because of excessive hepatic bleeding or bile leakage it should be removed when that problem has resolved, usually after 12—24 hours. Continued blood loss from a drain is an indication for re-exploring the abdomen.

Discharge from hospital

Some surgeons discharge a proportion of their patients on the day of surgery but most are kept in overnight and discharged next morning. The patient should not be discharged until they are seen to be comfortable and eating and drinking satisfactorily. They should be told that if they develop abdominal pain or other severe symptoms they should return to the hospital or to their general practitioner.

Skin sutures

If nonabsorbable sutures or skin staples have been used these can be removed from the port sites after 48 hours.

Mobility and convalescence

Patients can get out of bed to go to the toilet as soon as they have recovered from the anaesthetic and they should be encouraged to do so. Such movements are remarkably pain free when compared with the mobility achieved after an open operation. Similarly, patients can cough
actively and clear bronchial secretions and this helps to diminish the incidence of chest infections. Many patients are able to walk out of hospital on the evening of their operation, and almost all are fully mobile by the following morning. Thereafter the post-operative recovery is variable. Some patients prefer to take things quietly for the first 2 or 3 days interspersing increasing exercise with rest. After the third day patients have undertaken increasing amounts of activity. The average return to work is about 10 days.
Laparoscopic cholecystectomy is the treatment of choice for gallstone disease. The most accepted technique was outlined by Reddick and Olsen, and has been described extensively in the literature. The main drawback of the technique is the increased incidence of bile duct injury compared with open cholecystectomy. However, with better understanding of the mechanisms of injury and with proper training, virtually all of these injuries can be avoided. This chapter highlights important technical steps during routine laparoscopic cholecystectomy with particular emphasis on the safe performance of an open cholecystectomy.

Following introduction of the three working trocars, the operation is carried out using the surgical principles of open cholecystectomy. Most common bile duct injuries can be avoided by adhering to the following steps.

1. Ensure maximum cephalic traction on the gall bladder. This step minimizes redundancies in the gall bladder infundibulum for better visualisation of Calot’s triangle (Fig. 70.5).
2. The gall bladder should be pulled away from the liver by maintaining lateral and inferior traction on Hartmann’s pouch. This manoeuvre avoids alignment of the cystic and common bile duct, allowing more precise identification of both structures.
3. Dissection should begin high in the neck of the gall bladder and proceed in a lateral to medial direction. All dissection should be kept close to the gall bladder until the anatomy is well defined. The cystic duct node is a good landmark at which to start the dissection. The cystic duct should be the first spherical structure found in Calot’s triangle when dissecting in a lateral-to-medial direction.
4. Hartmann’s pouch should be turned medially for posterolateral dissection of the gall-bladder serosa. This manoeuvre aids identification of the junction between the neck of the gall bladder and the cystic duct. Dissection should proceed along the posterolateral aspect, dividing the serosal attachments of the neck of the gall bladder to the liver. The narrowing of the gall-bladder infundibulum into the cystic duct should be clearly defined in all of its circumference, particularly in the presence of acute inflammation or chronic scarring (Fig. 70.6).
5. Dissect the neck of the gall bladder from its hepatic bed. This approach, similar to that of the anterograde technique of open cholecystectomy, permits clear visualisation of the neck of the gall bladder as it narrows into the cystic duct. Identification of the cystic duct—common duct junction is no longer considered imperative if there is adequate visualisation of the gall-bladder—cystic duct junction. Extensive dissection in the region of the com-mon duct may be a source of avoidable morbidity.
6. A clear view of the cystic duct should be obtained before the application of clips, which should be placed as close to the gall bladder as possible under direct vision. When a short cystic duct is present, an endoloop or ligature around the gall-bladder neck can be used instead of a clip. Diathermy should never be used to divide the cystic duct or artery.
7. Operative cholangiography — intraoperative cholangiography is helpful for definition of the anatomy, detecting the presence of calculi and preventing, recognising or decreasing the severity of a bile-duct injury. However, a significant percentage of surgeons does not perform cho-langiography unless indicated. It is left to the surgeon’s discretion to decide upon the use of cholangiography.
8. Following division of the cystic duct and artery, dissection should continue close to the gall-bladder wall and away from the liver hilum. Excessive use of electro-cautery should be avoided in close proximity to the hilar structures. Bipolar diathermy is safer but less efficient than monopolar diathermy. Most surgeons use mono-polar diathermy with lower voltage during dissection. Progressive detachment of the gall bladder is much easier and occurs with less bleeding if dissection is carried in the correct plane close to the gall-bladder wall.
9. Convert to open cholecystectomy — the surgeon should consider his or her limitations and be able to determine when the degree of difficulty or uncertainty necessitates conversion to open cholecystectomy. Conversion should not be considered as ‘loss of face’ and should be under-taken when ‘progress no longer seems feasible’.
10. Removal of the dissected gall bladder from the abdominal cavity should be performed under direct vision from either the umbilical or the epigastric port. It is not uncommon for extraction to be complicated by a thickened gall-bladder wall or the presence of multiple large calculi. Enlarging the fascial incision by a few millimeters at each edge should not be left too late as this manoeuvre can prevent the spillage of calculi or bile into the abdominal cavity. Endoscopic retrieval bags can be used to prevent stone spillage if gall-bladder perforation has occurred (Fig. 70.7). Extending the incision by a small amount does not appear to increase postoperative pain and, overall, may save time. Reduction in postoperative shoulder tip pain may be achieved if care is taken to remove any residual fluid or blood and to obtain complete deflation before closure.

**Laparoscopic inguinal hernia repair**

Inguinal hernia is one of the most common surgical problems seen in general practice, and accounts for 15 per cent of operating time in a typical district general hospital. Despite the existence of many well-established traditional hernia repairs, results have been variable with recurrence rates ranging from 0.2 to 18 per cent. These unsatisfactory results have led to surgeons developing and seeking new methods of hernia repair. The main factor contributing to hernia recurrence is the tension produced after the repair by the suturing together of structures not normally in apposition. This theory led to the use of mesh to repair the hernia, making it a ‘tension free’ procedure. Today the tension free hernioplasty is one of the most successful variations of hernia repair.

Recently, with the introduction of minimal access techniques and the subsequent success of laparoscopic cholecystectomy, surgeons have investigated the possibility of repairing inguinal hernias using such an approach. The advantages to using a minimal access approach to hernia repair are mainly to do with patient comfort rather than hospital stay. Although laparoscopic hernia repair can be done as a day-case procedure, so can open hernia repair. Multiple hernias and recurrent hernias are more effectively dealt with using a laparoscopic approach.

**Types of laparoscopic hernia repair**

As with the open approach many variations on the laparoscopic approach have been developed, some of which have already fallen from favour.

**Transabdominal preperitoneal repair (TAPP).** The procedure is carried out under general anaesthesia, the patient’s abdomen is inflated with carbon dioxide gas, the peritoneum is incised above the hernia and a prosthetic mesh is stapled over the defect. The peritoneum is once again apposed over the mesh by the use of a stapling device.

**Extraperitoneal repair.** In this repair the abdominal cavity is not entered but instead surgical balloons are inflated in the extraperitoneal space,
and endoscopic trocars and instruments are placed in this operating tunnel (Fig. 70.8). Again a stapled prosthetic mesh is used for repair. By not incising the peritoneum this decreases the risk of mesh eroding into bowel and the occurrence of bowel obstruction due to herniation of the small bowel through the staple line in the peritoneum.

Results thus far have been encouraging: the repair has been shown to be effective and safe if it is carried out in a major laparoscopic centre with well-equipped and trained laparoscopic surgeons. Solid conclusions about recurrence rates cannot be made as the follow-up period is too short.

**Laparoscopic antireflux surgery**

Gastro-oesophageal reflux disease (GORD) is one of the most common disorders affecting the gastrointestinal system. Whilst the use of antacids, H2-receptor antagonists and proton pump inhibitors may allow healing of oesophagitis to take place, GORD is often a chronic or recurrent problem requiring long-term medical management. Open surgery for selected patients has been shown to be effective, but is a major undertaking associated with considerable morbidity. Hence the possibility of treating this condition effectively whilst exploiting the benefits of a minimal access approach is very attractive.

**Techniques of laparoscopic antireflux surgery**

The advantages of laparoscopic cholecystectomy over open surgery in terms of postoperative pain, hospital stay, return to normal activity and cosmesis have led to the application of this approach to several gastrointestinal procedures. Whereas open antireflux surgery provides poor exposure using either abdominal or thoracic approaches, a laparoscopic approach provides an unparalleled view of the diaphragmatic hiatus. Indeed, the anatomical detail provided by this technique combined with the potential benefits of minimal access surgery have led to the reincarnation of several antireflux opera-tions that were rarely performed in the past.

The laparoscopic Nissen fundoplication was introduced in 1991 and is the most widely performed laparoscopic antireflux-flux procedure. The operation is essentially the same as the open version with a few exceptions. Access is achieved via a five port arrangement with the surgeon standing to the left, right or between the legs of the patient, depending on prefer-ence. Whilst mobilisation of the oesophagus is underway it is important that the liver be adequately retracted, a process facilitated by the use of fan retractors. An enlarged left lobe of the liver is a relative contraindication to fundoplication as it may make retraction difficult and dissection hazardous.

The Rossetti modification of the Nissen repair involves using just the anterior fundus to perform the wrap (Rossetti). This reduces the amount of gastro-oesophageal dissection needed and also makes access easier to the short gastric vessels unnecessary. Division of all short gastric vessels may be required for a Nissen fundoplication to ensure a short, loose wrap to reduce the incidence of mechanical complications. The wrap is secured with four or five silk sutures which may be tied by an intracorporeal or extracorporeal technique. Nissen did not consider closure of the hiatus by bringing the crura together behind the oesophagus, an important step in the procedure. However, several authors advocate crural closure to promote physiological function of the lower oesophageal sphincter and prevent upward displacement of the wrap.

Given the recent introduction of the procedure and short follow-up times, results for the laparoscopic Nissen repair are promising. Operative times are, on average, less than 2.5 hours and conversion rates are low. The incidence of operative and postoperative complications is low and comparable to that reported from open series. Intraoperative complications include unrecognised pleural lacerations requiring chest drainage, hepatic laceration, gastric perforation and wrap necrosis with perforation. Most patients experience gastrointestinal side effects in the postoperative period, the commoner ones being early satiety, hyperflautence, diarrhoea, nausea and odynophagia, but these become less common with time. A low incidence of postoperative dysphagia has been attributed by one author to the enforcement of a liquid diet for 3 weeks after surgery.

As with all laparoscopic surgery it can never be assumed that just because a procedure can be performed laparoscopically, it should be adopted. As none of the laparoscopic versions of antireflux operations represents a major departure from their open counterparts, there is no reason to expect better symptomatic results. There should, however, be a reduction in hospital stay and wound complications, and earlier return to normal activities. In the past, gastroenterologists have perhaps been reluctant to refer patients for antireflux surgery, perceiving it to be a major undertaking in a field where the procedure of choice is by no means agreed upon. However, if laparoscopic antireflux surgery shows itself to be safe and effective, one might see a lowering of the threshold for referral. The important point is that the selection criteria should not change. As to the question of which procedure, the answer lies in long-term randomised prospective trials. Assessment of symptomatic success should be done objectively, for example using Visick grading. pH studies should be performed preoperatively and post-operatively to document healing, and where possible, assessment should be performed by independent parties.

**Laparoscopic splenectomy**

Laparoscopic splenectomy has been reported as a feasible and attractive procedure on selective patients with haematological disorders. The criteria for the effectiveness of laparo-scopic splenectomy include: technical feasibility, safety and, most importantly, long-term recurrence rates of thrombocytopenia. The ultimate aim is cure, through the removal of all splenic tissue including accessory spleen. Open spleenectomy has already achieved these goals with a technical feasibility of 100 per cent and an operative mortality of 0—4 per cent. The postoperative complication rate is 10—20 per cent and long-term cure rate is 65—90 per cent in patients with idiopathic thrombocytopenia purpura (ITP).

The majority of reported series on laparoscopic splenectomy has essentially focused on the technical problem of laparoscopic feasibility. The purpose of this review is to describe a technical modification of laparoscopic splenectomy using the hand port system to facilitate hand-assisted laparoscopic splenectomy.

**Selection of patients**

Not all patients or all haematological disorders can be treated by a laparoscopic-assisted approach. In the author’s experience, obesity, a previous history of upper abdominal surgery and the presence of an acute coagulation abnormality are relative contraindications to hand-assisted laparoscopic splenectomy. ITP represents the base indication, but patients with congenital spherocytosis, haemolytic anaemia, Hodgkin’s disease, lymphoma, splenic tumour and thrombocytopenia related to acquired immunodeficiency syndrome are all considered to be suitable. Although normal sized spleens are best suited for a laparoscopic approach, the hand-assisted method significantly facilitates the excision of large spleens where difficulties in laparoscopic access alone significantly complicate laparoscopic mobilisation, access to the splenic hilum and extraction. Abdominal computed tomography (CT) is the best preoperative investigation to measure the splenic volume in order to detect the pancreatic tail impacted within the splenic hilum, exclude lymph nodes at the splenic hilum and detect accessory spleens.

**Preoperative management**

All patients receive preoperative pneumococcal vaccination, especially children. Patients with ITP receive high doses of immunoglobulin G to increase their platelet count to an almost normal value; however, in the remaining patients, platelet transfusions might need to be used at the
time of surgery.

**Operative steps**

Exposure of the spleen and access to the splenic hilum are the most critical factors in achieving a safe dissection. The vertical approach to the splenic hilum is mandatory with:

- high insertion of the trocar along the left costal margin;
- rotation of the table to the right side;
- use of reverse Trendelenburg position for the operative table;
- use of a 300 laparoscope.

Dissection is then performed laterally and posteriorly by dividing the lateral peritoneal reflection of the spleen anteriorly upward in the inferior part of the gastrosplenic ligament. The splenic hilum is approached anteriorly and inferiorly. This approach is greatly facilitated if posterior, lateral mobilisation of the spleen up to the splenophrenic ligament is achieved, with the liberation of the upper part of the spleen. The hilar vessels are isolated with the fingers from the pancreatic tail and stapled using an endoscopic stapling device. Finally, the short gastric vessels are secured within the upper part of the gastrocolic ligament with complete mobilisation of the superior port of the spleen.

The second operative step is the extraction of the surgical specimen which is usually facilitated and greatly simplified in the presence of a hand inside, so the spleen can be placed in a heavy plastic bag and extracted through the hand port device. During all intraoperative manipulations, one must be careful to avoid parenchymal tear and spillage to prevent splenosis. Some authors have advocated the use of preoperative splenic embolisation before laparoscopic splenectomy.

Potential advantages are reported to be easier dissection, shrinkage of the enlarged spleen, and reduction of operative blood loss and a certain amount of autotransfusion before splenectomy.

Disadvantages include the invasiveness of the procedure, high cost, higher complication rates and lack of diagnosis of accessory spleen in its most unusual location.

Another disadvantage of the laparoscopic approach for splenectomy appears to be a significant increase in the operative time; however, with the use of the hand port device, in the author’s experience, the operative time is no longer than that of an open splenectomy.

Laparoscopic splenectomy is technically feasible in both normal sized and enlarged spleens. In the hands of the experienced laparoscopic surgeon the procedure is safe and has a low complication rate. The most common intraoperative complication is haemorrhage, which is responsible for most cases of conversion. Careful intraoperative search for and removal of accessory spleen is essential during the procedure, which is once again enhanced with the use of the hand-assisted device.
The future

Although there is no doubt that minimal access surgery has changed the practice of surgeons, it has not changed the nature of disease. The basic principles of good surgery still apply, including appropriate case selection, excellent exposure, adequate retraction and a high level of technical expertise. If a procedure makes no sense with conventional access, it will make no sense with a minimal access approach.

Improvements in instrumentation and the development of structured training programmes are the key to the future of minimal access surgery. It is certain that there is much that is new in minimal access surgery. Time will tell how much of what is new is truly better.

The cleaner and gentler the act of operation, the less the patient suffers, the smoother and quicker his convalescence, the more exquisite his healed wound. (Lord Moynihan of Leeds)

Learning objectives

• Audit is an obligatory activity in which all healthcare professionals must play a role.

• Audit can and will provide useful data about the outcome of clinical activity and will fulfill the requirements of ensuring that quality care is provided.

• Medical audit and resource management activities are inseparable.

• For audit to be undertaken properly and efficiently the acquisition of data must be part of normal everyday medical record keeping and must make full use of information technology as it becomes available.

The recent emphasis on quality of medical care (not just quantity) has made the importance of collecting good quality audit data more important than ever before.

Audit and the methods used to undertake audit allow us to gather simply information about our surgical activity. It allows us to look at what happens to our patients (outcomes) and it allows us to improve practice (completing the audit loop). A simple audit of the outcome of an operation can pick up variations from the expected at an early stage. This should reduce future damage to patients and any legal problems that might accompany disasters.

The features of a ‘simple’ audit

• Define the type of audit (e.g. case record review)

• Identify a representative sample (random selection or consecutive cases)

• Define the questions to be answered

• Define the criteria for assessment

• Establish the standards for comparison

• Perform the audit

• Record the results

• Re-audit at a defined time in the future
What is audit?

Audit can be defined as a systematic review of aspects of practice that results in a change in that practice. Johnson defined medical audit as ‘a means of quality control for medical practice by which the profession shall regulate its activities with the intention of improving overall patient care’. ‘A First Class Service’ (Department of Health, 1998) states ‘Clinical audit involves systematically looking at the procedures used for diagnosis, care and treatment, examining how associated resources are used and investigating the effect care has on the outcome and quality of life for the patient. Audit is a valuable tool to improve the quality of professional care and, ultimately, patient choice’.

Much of what is called audit is actually only fact gathering. The facts are essential to undertaking the audit, but unless the effects of the activity on patients are also included (i.e. outcome data) the facts alone cannot influence surgical practice.

Traditionally audit has been divided into medical and clinical audit. The term medical audit refers to an audit undertaken by doctors and consists of a review of clinical events; e.g. does one surgical procedure result in a better outcome compared with another? Clinical audit is usually taken as a review of all potential medical events surrounding the treatment of a patient. This will include nursing, physiotherapy, social aspects, etc. The boundaries between the two forms of audit are blurred and indeed ‘medical’ audit is merely a subset of clinical audit focusing only on the medical aspects. The majority of audits will consider aspects which are both medical and clinical.

The separation of the provision (and rationing) of resource from clinical audit is artificial. All medical activity costs money so an understanding of the management of the resources has to be included in the audit process. When healthcare resources are rationed, the limitation on funding is likely to have a direct effect on structure and process, and hence on outcome. ‘Total’ audit should include any activity which occurs in the delivery of healthcare to an individual patient or a group of patients.

It is, at least, a useful intellectual exercise to consider the financial implications of introducing a new technique. For example, arthroscopic stabilisation of the shoulder is a relatively new technique to appear in orthopaedic practice in the UK. If it is to be adopted by a hospital trust the following questions might need to be answered.

- Is there a surgeon who can perform the techniques?
- What training is required?
- What equipment is required? Is new equipment needed?
- What will the consumables cost and are they readily available?
- What are the operating theatre and ‘hotel’ requirements for the patients?
- What is the failure rate of the techniques, i.e. will there be a large number of patients who will need revision surgery or will be unsatisfied with the outcome?
- What is the rehabilitation time and when will the patients be able to return to work?
- And of course, how does this new technique compare with the usual accepted techniques when the same questions are asked?

Each and every surgical procedure could and probably should be examined in this way. In the example given above, data from prospective clinical trials comparing the new technique with the old are required to demonstrate a statistically significant improvement if the method is to be justified purely on the grounds of clinical benefit. For an individual surgeon, audit data showing that the results obtained by that surgeon are comparable to the results of the clinical trials are needed. The cost to the hospital, and the cost to the patient (in time off work, etc.) will also need to be calculated. Using data like

these there are several ways of justifying the introduction of a new technique as follows.

- The new technique is clinically better than the old — better outcomes (including patient satisfaction), decreased failure and decreased morbidity
- The technique is cheaper to patient, hospital or both.
- Patients can be treated more quickly using the new method, which produces the same results as the old method.
The components of audit

Audit is traditionally viewed as a loop, the components of which are structure—process—output. The term structure refers to the physical environment in which healthcare is provided; process refers to the activity of providing care; and output to the outcome of that care both for the individual and for the community as a whole. The loop is completed by the output feeding back on potentially both structure and process. Table 71.1 summarises what is needed to provide a quality service — structure, process, outcome data and feedback.

Both a quality service and an audit cycle need the feedback loop to be effective. The loop must be viewed as an unending sequence. Moreover, it is implicit in the definitions that a single clinician cannot perform audit alone; teamwork with finance managers and other clinical staff, etc., is obligatory.

All aspects of clinical audit must be compared with some form of standard and then retested against the standard on the next loop of the cycle. It is generally accepted that as far as specific surgical techniques are concerned the comparison must be against properly constructed prospective randomised clinical trials. Other independent and objective standards must be established for other comparisons.
Traditional methods of performing audit

Shaw in Frostick et al.'s Medical Audit: Rationale and Practicalities (1993) describes the traditional views of medical audit in terms of the ‘characteristics of effective audit’ and the ‘methods’.

The characteristics can be summarised as:

• explicit criteria for good clinical practice — guidelines for practice;
• objective measurement of patterns of current practice — looking at identified groups or activities;
• comparison of results amongst peers — acceptable published data;
• explicit identification of corrective action — agreed action and its implementation;
• documentation of procedure and results — a formal report of the proceedings and action required.

The methods that Shaw outlines are basically very simple and can be undertaken by a small group (i.e. a directorate) or on a larger scale. Examples of the usual types of audit that can and are performed include:

• workload and case mix;
• appropriateness of care;
• access to care;
• outcomes of care;
• quality of records;
• efficiency.

The advantages of a traditional approach to audit are as follows.

• It is simple and cheap.
• Data should be easy to acquire and their accuracy can be checked.
• The cycles and so the effectiveness of the audit can be repeated at short time intervals.
• There are simple educational outcomes which are derived from regular, small and well-run audit meetings.

The disadvantages of traditional audit are as follows.

• Meetings may occur but are not repeated so the audit cycle is not completed.
• The onus often falls on the most junior person on the firm to acquire and present the data.
• Morbidity and mortality meetings can be embarrassing and destructive.
• The education may be by guided ‘shaming’ not by guided learning.
Audit versus clinical research (Fig 71.1)

Clinical research requires that a prospective controlled trial is performed. Such a trial requires a hypothesis, a control and an experimental group and will be the subject of rigorous statistical analysis.

Audit data should be acquired prospectively but there will be no comparison between defined groups. Care will be needed in interpreting the data because there will be many factors that are not controlled. In order to make use of these data they will need to be compared with a standard, i.e. what is acceptable practice prior to the audit? The standard should be established by examining the published data and using prospective clinical trials as the primary source. It is important to examine the clinical trials on which the standard is based. This is to ensure that the patient groups are similar to those which will be the subject of the audit, and that the surgical procedure and other treatment roughly match what is being audited, etc.
Minimum dataset

Probably the most essential data item is the (new) National Health Service (NHS) number. This number is unique to each individual and should allow patients to be followed from birth to death. A number of audits in Scandinavia has been very successful at tracking patients over long periods and long distances because of the Swedish equivalent of the new NHS number. Outcome data on hip fractures and lower limb joint arthroplasty are examples of the type of long-term data collection that has occurred in Sweden (Thomgren, 1993).
Computers versus paper

How should audit be undertaken?

Traditionally we have been told that a simple paper based exercise is the best and most effective way of performing an audit. This is only true if the goals of the audit are limited or a pro forma is created prior to commencing the audit and completed for each patient.

A 'common' type of audit has been a review of clinical records. This is a simple method of ensuring that the standard record keeping is adequate from a medical and medicolegal standpoint. A random selection of case records from an identified group is gathered and criteria are defined to determine the adequacy of the notes; the next stage should be to recommend changes and to re-audit. This type of audit does not require any detailed methodology; it requires that a record of the defects and recommendations is kept. This type of audit method has value in educating new housemen about the need to keep adequate records and so should probably be used early on in their employment in the firm.

Another simple audit is to choose a particular disease or treatment (surgical operation, for example). Data about the patients in this group are then used either to review aspects of process (stay length, time to operation, etc.) or to review the actual patient outcome — alive or dead, cured or recurrence, etc. This methodology may offer reasonable insight into the pathological process under consideration. However, a number of possible sources of error of interpretation and difficulty must be highlighted. These include the following.

- Patients are identified from an unreliable source resulting in either patients who did not have the condition or, more often, missing varying numbers of patients who did have the condition. Patients may also be lost at follow-up.
- Inappropriate statistical tests may be used or the correct test used wrongly.
- Historical controls may be used for comparison which are not comparable.

If paper-based audits are to be undertaken a few simple rules should be followed.

1. Develop a simple and comprehensible pro forma which will record the information upon which the audit is based. Avoid proformas that require a lot of text entry. Wherever possible use a series of 'tick' boxes with either single or multiple choices. This type of pro forma can be completed speedily and accurately as the person placing the ticks is presented with all of the answers. The disadvantage of this type of form is that it can look complex and large, especially if there is a lot of choices for each field.

2. Undertake the audit prospectively. Retrospective data are helpful as a basis of a pilot study in the sense that the potential numbers under study might be predicted from a review of the admissions, etc., over the last months or years. There is usually very little sense in auditing a rare event as it will require many years of data acquisition in order to get a study of sufficient size to make any worthwhile comment. The retrospective data may also give a clue to the types of outcome measures that should be employed.

3. Choose outcome measures that can be readily assessed.

4. Choose a method of assessment that will be independent of bias that might be introduced by the initiator of the audit. Patients will often tell doctors what they wish to hear and therefore either an independent person needs to assess the outcome or a method that is neutral in its presentation needs to be used (e.g. a patient questionnaire).

Computer-based audits

Using modern information technology is very attractive and can be efficient and effective. Alternatively, there may be a tendency to develop such complexity that data will not be entered.

The main advantages of using a computer-based system for audits are as follows.

- Large numbers of entries can be analysed easily.
- In the future electronic patient records will automatically record information concerning a clinical event that will allow us to perform effective audits.

The main disadvantages are as follows.

- Knowledge of the construction and operation of a database is required.
- Commercial databases are often very expensive but increasingly online national databases are being created that make use of a central server.
- Appropriate fields for the database need to be created before data entry. If fields are added after data are captured it can be extremely difficult to complete the new fields.
- The level of complexity of the database needs to be determined at the outset and will be dependent upon the uses to which the database will be put.
- Entry of data will need to be checked (validated) against an independent source to ensure accuracy. It is usual to select randomly 10 per cent of cases and compare the computer records with the original case records held by the hospital.
- Methods of highlighting inappropriate entries into particular fields and the completion of obligatory fields will need to be considered.

Coding

Traditionally all patient diagnoses and treatments have been coded, i.e. given an alphanumeric code for the purposes of storing the diagnosis on computer. The International Classification of Diseases (ICD) coding system has been accepted as the international method of coding diagnoses and treatments. The codes (ICD version 10) are available on CD-ROM and are a fairly comprehensive system. Using this coding system allows easy international comparison of some aspects of data.
collection, especially disease incidence, geographic distribution of disease, etc. The Department of Health in the UK has invested in an alternative coding system, originated by Dr James Read. In the latest form of this coding system there is automatic mapping to ICD-b. The development of the Read Codes is attempting to unify an alphanumeric coding system with the use of familiar clinical terms in real language. With modern computers there is a real question as to whether coding is needed at all. Its main role seems to be in defining terms so that what one surgeon defines as an infection is the same as another surgeon. Without this audit data cannot be compared or combined and much of their power is lost.
Defining and using appropriate outcome measures are the hardest parts of undertaking an audit that is going to achieve a worthwhile end. In general, there has to be a decision as to whether the outcome is doctor or patient orientated. Doctor-based outcomes look at such outcomes as mortality, complications and the cost of consumables. A patient orientated outcome may measure patient satisfaction. In some situations the operation may be a technical failure but the patient is happy with the result, producing a poor result for doctor orientated audit, but a good result for patient based audit.

Whatever method of assessing outcome is to be used the surgeon must be certain that the instrument is measuring something relevant to the audit being undertaken. Moreover, the outcome measure must be recordable within a time frame that will be relevant but also achievable. For example, following laparoscopic herniorraphy it would be reasonable to assess patient satisfaction with the process of the operation within a short, perhaps 3-month, time frame. The success of the operation in terms of recurrence of the hernia cannot be fully assessed for many months or perhaps several years after the procedure.

In order for outcome scores to be useful, they must be rigorously validated. The specific ‘tests’ that need to be used are as follows.

- **Internal consistency** (Cronbach’s alpha) determines whether the questionnaire or score is measuring a single essential concept.
- **Reproducibility** (test—retest reliability) determines that the score will give a roughly similar result if repeated.
- **Validity**: does the score actually measure what the developers are interested in? This is divided into content validity (the questions deal with all aspects that they are intended to cover) and construct validity (whether the questionnaire supports the hypothesis).
- **Sensitivity to change**: will the score reveal small changes which are of clinical importance during the period of study?

To develop a score/questionnaire there are several ways of establishing the types of question and the specific questions to be asked. It is possible to ask a panel of experts what they think are the important issues to be assessed in a disease or operation or anatomical region (face validity). The list that is created is then collated to come up with groups of questions and specific questions within each group. Once the draft questionnaire has been created the validation tests will be applied. An alternative method in order to create a patient orientated questionnaire is to ask the patients what they think is important, especially functional aspects. Again the responses are collated and can be refined by posing the questions to another group of patients. The questions should also be exposed to a panel of experts at an appropriate stage. Once again the validation tests will have to be applied before the questionnaire can be used in a study.
Audit and statistics

Details of statistical tests will not be covered here but general comments are required so that statistics are not abused when performing an audit. Descriptive statistics are useful and acceptable — distribution of ages, operation type, etc. Many surgeons will quote a ‘mean’ and ‘standard deviation’ for items such as age; this assumes that the data are normally distributed which is not necessarily the case. It is often better to use median and range for ages, time after surgery, etc. It is unlikely that incidence or prevalence can be calculated from an audit as the size of the overall population (the denominator) will not be known. The use of tests of significance is not acceptable in audit data. Performing tests of significance requires a comparison between two groups, one of which represents a control group. A control group is one which is identical to the test group except in the one aspect that is being examined. Therefore, tests of probability can only be used where patients are entered into a prospective randomised clinical trial.

The presentation of data in a publication is a source of concern in many audit papers. Often the scenario arises that a surgeon will find that a certain number of patients underwent a specific procedure some years before. The surgeon will then try and find the details from records of those patients but for various reasons it is only possible to find, for example, 75 per cent of the original records. The surgeon will next try and contact this 75 per cent of patients to find out the ‘outcome’ of the operation (usually using an invalidated questionnaire or score). Only, for example, 50 per cent of those contacted will reply to an enquiry (i.e. 50 per cent of 75 per cent of the original number). Some of the remainder may have died but many simply will not be traceable. In this process if the original number was 100, the assessment will be undertaken for only about 37 patients. Many authors will then make comments about the data that can only be applied to the 37 who were assessed but the report is written as if it refers to the total number.
National audits (Fig 71.2)

Over the years a number of national enquiries has been undertaken. The National Confidential Enquiry into Maternal Mortality and the National Confidential Enquiry into Perinatal Death are the ‘oldest’ of these audits. The National Confidential Enquiry into Perioperative Deaths (NCEPOD), which first reported in 1988, has examined surgical and anaesthetic deaths and made various recommendations. The return of information to NCEPOD has, to some extent, been voluntary. Under the most recent NHS reforms NCEPOD and the other National Confidential Enquiries will be controlled by the National Institute for Clinical Excellence (NICE). Moreover, participation will be obligatory.

The Royal College of Surgeons of England established a comparative audit service in the early 1990s. Surgeons contributed data confidentially and voluntarily to the service based at the College. Surgeons were ranked in order of number of a particular operation or number of complications, etc. Only the surgeons themselves were able to identify their own position in the ranking. During the period for which the service was offered the audits were changed from retrospective to prospective. The main disadvantage of the audits was that few (about 20 per cent) surgeons responded to the audits—the enthusiasts took part but the others saw no benefit.

Clinical governance

In simple terms clinical governance tries to answer the following questions.

- Are we doing the right thing?
- Are we doing it right?
- Are we measuring what is going wrong?
- Are we responding to this to make things better?

The National Institute for Clinical Excellence

A new National Institute for Clinical Excellence will be established to give new coherence and prominence to information about clinical and cost effectiveness.

The main roles of NICE will be to produce guidelines for clinical practice based on clinical evidence and associated with cost effectiveness. A number of stages of the work of NICE has been identified:

- stage 1 — identification — which is subdivided into the introduction of new technologies into the NHS and their impact on healthcare, and examining current practice and to look for variations in quality;
- stage 2 — evidence collection — ‘undertaking research to assess the clinical and cost-effectiveness of health interventions’;
- stage 3 — appraisal and guidance — examining the evidence and producing guidelines;
- stage 4 — dissemination — distribution of guidelines and the methods required to audit their effect;
- stage 5 — implementation — at a local level, through clinical governance and other approaches;
- stage 6 — monitoring — the impact and keeping under review, taking into account the views of patients and their representatives and any new research findings.

It can be seen from these stages that the work of NICE is massive and far reaching and will have one of the greatest effects on healthcare delivery since the inception of the NHS.

Commission for Health Improvement (CHIP)

The Government identifies CHIP as an independent statutory body that will monitor quality issues. The commission will have extensive powers to act ‘where there is evidence of systematic failure’. For clinicians to be able to justify their actions good quality audit data will have to be available.
The future of audit in surgery

Over the years a number of attempts has been made to develop an audit system which will acquire data as a part of everyday activity. The advantage of this type of data acquisition is that we can derive outcome data, etc., as a part of normal working practice rather than having specifically to undertake audit projects. In order to achieve this it will be necessary to ensure that a few basic rules are followed.

• Standard proformas will need to be developed to allow consistent data entry.
• There will be obligatory fields that have to be completed on all patients.
• Specific data fields will need to be created that are disease or speciality specific.
• Data validation will need to be undertaken to check correct data entry.
• Education of both healthcare workers to understand the electronic records and the general public to demonstrate confidentiality and accuracy of records will be necessary.
• The systems must be able to produce reports automatically for clinical purposes and for audit.

Using an electronic record does not eliminate the need to ‘think’ what audits to undertake but facilitates the acquisition and storage of useful data. An individual will still need to develop specific audit projects and apply the accepted rules to undertake the study. If the systems are successful the completeness of data should be high; patients will be traceable and surgeons will have direct and rapid access to understanding their own practice and how it affects their patients.
Further reading

Introduction

Vast numbers of clinical publications are printed in the surgical literature every year. Many are flawed and it is important that a surgeon trainee has the skills to examine critically research done by others. In addition, a surgeon should be able both to design and to complete an original study. Performing research can be arduous and time-consuming. However, surgical research is good for society as it advances medicine, it is good for patients as the clinical outcome is often improved for patients in clinical trials, and it is good for surgeons as it is a way of keeping track of personal clinical results. In addition, much clinical work is tedious and repetitive. Rigorous evaluation of even the simplest techniques and conditions can help to keep the surgical brain active throughout a long career and ensure a good outcome for the patient.

The earlier a surgeon develops skills in surgical research the better. The hardest trial to do, or article to write, is the first. The best way to develop a critical understanding of the research of others is to perform studies of your own. It is unlikely that the first piece written by any surgeon will be an earth shattering randomised trial. Starting small is often the best way.

This chapter contains all the information required to complete a randomised trial. Using it, a surgeon will be armed to write a surgical paper and to evaluate research carried out by others.
Identifying a topic

The hardest part of research is to come up with a good idea. It appears that all the best trials have already been completed, but a careful consideration of scientific support for surgical action reveals deficiencies in surgical knowledge. Facts commonly taken for granted often have no basis. The best research often answers the simplest question. Once an idea has been formed, or a question asked, it needs transforming into a hypothesis. It is helpful to approach surgeons who regularly publish research articles and who have a special interest in the surgical area being considered. As ideas are suggested, keep thinking whether the question posed by the proposed research really matters. Spend some time refining the question because this is probably the most important part of research. Choosing the wrong topic at this stage can lead to many wasted hours.

Once a topic has been identified do not rush into the study. It is worth spending a considerable time investigating the subject in question. The worst possible thing is to find at the end of a long arduous study that the research has already been done.

First port of call for information is the medical library. Avoid textbooks, as most are out of date as soon as they are published. Look for current articles about the proposed research; review articles and meta-analyses can be particularly helpful. At this stage most clinicians go to an electronic library and perform a database search. It is very important to learn how to do an accurate and efficient search as early as possible. Details are beyond the scope of this chapter, but most librarians will help out if a little interest and enthusiasm is shown. Current techniques involve searching on Medline or other collected databases but as electronic information advances and the worldwide web becomes more user-friendly new search strategies may emerge. Collections of reviews are becoming available — the Cochrane Collaboration brings together evidence-based medical information and is available in most libraries (Table 72.1).

Once a stack of articles on the subject has been obtained it is important that these are carefully perused. If the proposed research project is still looking good after some thorough reading it is worth further discussion with experts. Do not be afraid to contact authors who have written a paper on a similar subject. All scientists are flattered by interest in their work and most will not pilfer your ideas.

Now it should be possible to start to plan the research project. During the first phase it is very important to keep in the mind the following questions.

• Why do the study?
• Will it answer a useful question?
• Is it practical?
• Can it be accomplished in the available time and with available resources?
• What findings are expected?
• What impact will it have?
Project design

Next to choosing the subject for study, time spent carefully designing a project is never wasted. There are many different types of scientific study. The design used depends totally on the study. Beloved of present scientists, the randomised controlled trial is regarded as the best method of scientific research. It must not be forgotten that much surgical practice has been advanced by other different types of study such as those listed in Table 72.2. For example, testing a new type of operation often requires a pilot study to assess feasibility followed by a formal randomised controlled trial.

Research can be qualitative or quantitative. Quantitative research uses hard data to speak for themselves. A medical condition is analysed systematically using hard objective end-points such as death or amputation. In qualitative research data often come from patient narratives, and the psychosocial impact of the disease and its treatment are analysed, for example narratives of breast cancer. This sort of data is often collected using quality of life measurements. A variety of different quality of life questionnaires exists to suit several different clinical situations. Much of the best research is both quantitative and qualitative.

As finances for healthcare are always stretched, it is also important to include a cost—benefit analysis in any major area of research so that the value of the proposed intervention or change in treatment can be assessed.

Sample size

Calculating the number of patients required to perform a satisfactory investigation is a very important prerequisite to the study. An incorrect sample size is probably the most frequent reason for research to be invalid. So often surgical trials are marred by the possibility of error caused by the inadequate number of patients investigated.

• Type I error — benefit is perceived when really there is none (false positive).
• Type II error — benefit is missed because study has small numbers (false negative).

Calculating the number of patients required in the study can overcome this bias. Unfortunately, it very often reveals that a larger number of patients is needed for the study than can possibly be obtained from available resources. This often means expanding enrolment by using a multicentric study. There is no point in embarking on a trial when it will never be possible to recruit an adequate sample size. Never forget that more patients will need to be randomised than the final sample size to take into account patients who die, drop out or are lost to follow-up.

The following is an example calculation for a study to recruit patients into two groups. In order to calculate a sample size it is common practice to set the level of power for the study at 80 per cent with a 5 per cent significance level. This means that if there is a difference between study groups, there is an 80 per cent chance of detecting it. Based on previous studies, realistic expectations of differences between groups should be used to calculate sample size. The formula below uses the figures of a reduction in event rate from 30 to 10 per cent (e.g. new treatment expected to reduce complication rate such as wound infection from 30 to 10 per cent):

\[
8 \times \frac{(100-r)+s(100-s)}{(r-s)^2} \times \frac{5}{100-10} = 60 \text{ needed in each group}
\]

Eliminating bias

It is important to imagine how a study could be invalidated by thinking of things that could go wrong. One way to eliminate any bias inherent in the data collection is to have observers or recorders who do not know which treatment has been used (single blind). In the best randomised studies neither patient nor researcher is aware of which therapy has been used until after the study has finished (double blind). Randomised trials are essential for testing new drugs. In practice, however, in some surgical trials randomisation may not be possible or ethical.

Study protocol

Now that the question to pose has been decided and it has been checked that sufficient patients will be available to enroll into the study, it is time to prepare the detail of the trial. At this stage a study protocol should be constructed to define the research strategy. It should contain a paragraph on the background of the proposed study, the aim and objectives, a clear methodology, definitions of population and sample sizes, and methods of proposed analysis. It should include the patient numbers, inclusion and exclusion criteria, and the time scale for the work. At this stage it is helpful to construct a flow diagram giving a clear summary of the research protocol and its requirements (Fig. 72.1). It is helpful to imagine the paper that will be written about the study, before it is performed. This may prevent errors of data collection.

When a study is planned, sufficient time should be reserved at the beginning for fund-raising and obtaining ethical approval if required, and afterwards for collecting the data and writing it up. A data collection form should be designed or a computer collection package developed. Do not forget that if data are collected on computer, appropriate safeguards for privacy and confidentiality will be necessary. It is important to ensure the co-operation of any other specialities or clinicians who will be involved in the study and to agree on the sharing of responsibility for the trial. This will also help to prevent disagreement about who takes the credit once a study is ready for presentation and publication.

Ethics

Common sense is the best guide to whether a study is ethical or not. If there is any doubt consult a local ethics committee, available in all hospitals. Whenever a patient has treatment chosen by chance, ethical approval is required. All multicentric trials need approval. Even for nonrandomised trials it is important to try and obtain written consent for any new or extraordinary procedure or therapy. All studies involving animals require approval from statutory licensing authorities.

Leave plenty of time for this to be obtained and do not embark on the study until approval has been granted. Ethics committees prefer to see fully developed trial protocols but it is often possible to get some preliminary advice from the committee chairman. Ethics committee forms are often long and detailed, and it is important that these are filled in correctly. All dealings with ethics committees should be intelligent and courteous.

Most ethics committees are briefed to ensure that a project does not incur hidden expenses to a hospital. The cost of nonroutine
investigations and extra treatments should be covered by a grant application, or at least underwritten by a hospital finance department.
Statistical analysis

Many find the statistical analysis the most difficult part of research. It is also the most commonly criticised part of papers written by other clinicians.

There are many useful books about statistics which can be consulted; if in any doubt a statistician will be pleased to give assistance in analysing research. Statisticians like to be consulted before research has been conducted rather than being presented with the results at the end of the trial; they often give helpful advice over study design.

The following terms are frequently used when summarising statistical data:

*Mean*: the result of dividing the total by the number of observations (the average).

*Median*: the middle value with equal number of observations above and below — used for numerical or ranked data.

*Mode*: the value with the highest frequency observed — used for nominal data collection.

*Range*: the largest to the smallest value.

The most important decision for analysis is whether the distribution of results is normal (parametric). Normally distributed results have a symmetrical, bell-shaped curve, and the mean, median and mode all lie at the same value. Some types of data, such as blood group, are not normally distributed and require other methods of analysis (nonparametric).

**Parametric tests**

When the results are normally distributed a t-test can be used to compare the outcome between intervention and control groups. Confidence intervals are the best guide to the possible range in which the true differences are likely to lie. A confidence interval that includes zero usually implies a lack of statistical significance.

**Nonparametric tests**

Statistical tests such as the chi-squared test, Wilcoxon Signed Rank test (single sample) and the Mann—Whitney U-test (compares two samples) can be used because they make no assumptions about the underlying population distribution.

Scientists usually employ *P* values to describe statistical chance. A *P* value <0.05 is taken to imply a true difference. It is important not to forget that *P* = 0.05 simply means there is only a one in 20 chance that the differences between the variables happened by chance. If enough variables are examined in any study significant differences will occur simply due to chance.

Statistics simply deal with the chance that observations between populations are different. Clinical results should show clear differences. If statistics are required to demonstrate differences between results, they are unlikely to have major clinical significance.

**Computer software packages available**

Statistical computer packages offer a quick way to analyse descriptive statistics such as mean, median and the range, as well as the most commonly used statistical tests such as the chi-squared test. Various packages are available commercially and are useful tools in data analysis.
Analysing a scientific article

The simplest way to analyse an article from a scientific journal is to look at the checklist of requirements for good scientific research. The CONSORT document has been produced as a guideline of how to conduct clinical trials. A good paper will look at a specific clinical problem for which improving the outcome would realise significant clinical benefits. Looking in detail at the study design will often be the best way of deciding whether or not a trial is a good one. The CONSORT document includes a checklist for the conduct of good randomised trials (Table 72.3). Often clinicians over-look biases which others find obvious to detect that can have a profound influence on the outcome of any study.
Presenting and publishing an article

There is no point in conducting a research project and then leaving the results unpresented. Even when results of a trial are negative they are worth distributing; few research projects are worthless. However, most studies do not provide dramatic results and few surgeons publish seminal articles.

The key to both presentation and publication is to decide on the message and then aim for an appropriate forum. Big important randomised studies merit presentation at national meetings and publication in international journals. Small observational studies are more often accepted for presentation at regional or hospital meetings and publication in smaller specialist journals. Help and advice from clinicians familiar with presentation and publication is invaluable at this stage. The most important piece of advice is to follow accurately instructions for journal submission. Most inter-national meetings will accept presentations eagerly (especially by poster) as this increases the attendance at a conference.

Most surgeons publish research in peer-reviewed journals. The work that is submitted is checked anonymously by other surgeons before publication. If in doubt about whether to submit to a journal, many editors will give advice about the suitability of an article by letter or telephone.

Convention dictates that articles are submitted in IMRAD form — Introduction, Methods, Results and Discussion. Increasingly, electronic publication and the world-wide web may change the face of scientific publication and in the next decade these restrictions on style may disappear. For now the IMRAD format remains inviolable. The length of an article is important: a paper should be as long as the size of the message. Readers of big randomised multicentre trials wish to know as much detail about the study as possible; reports on small negative trials should be brief.

Introduction
This should always be short. A brief background of the study should be presented and then the aims of the trial outlined.

Methods
The methodology and trial design should be given in detail. It is important to own up to any biases. Any new techniques or investigations should be detailed in full; if they are com-mon practice or have been described elsewhere this should be referenced instead of described.

Results
Results are always best shown diagrammatically using tables and figures if possible. Results shown in the form of a diagram need not then be duplicated in the text.

Discussion
It is important not to repeat the Introduction or reiterate the Results in this section. The study should be interpreted intelligently and any suggestions for future studies or changes in management should be made. It is important not to indulge in flights of fantasy or wild imagination about future pos-sibilities; most journal editors will delete these.

References
This section should include all relevant papers recording previous studies on the subject in question. The number should reflect the size of the message and the importance of the work. The Reference section does not usually have to be exhaustive but should include up-to-date articles.
Evidence-based surgery

Surgical practice has been considered an art: ask 50 surgeons how to manage a patient and you will probably get 50 different answers. There is so much clinical information available that no surgeon can know it all. Evidence-based surgery is a move to find the best ways of managing patients using clinical evidence from collected studies. It was estimated that sufficient evidence to justify routine myocardial thrombolysis for heart attacks was available years before the ISIS studies which finally made it clinically acceptable. No one had gathered all the available information together. Centres such as the Cochrane Collaboration have been collecting randomised trials and reviews to provide up-to-date information for clinicians. The Cochrane Library presently includes a data-base of systematic reviews, reviews of surgical effectiveness and a register of controlled trials. It is expected that this will gradually smooth out the differences between clinicians as the best way of managing patients becomes more evident.

Collecting published evidence together and analysing it often requires reviews of multiple randomised trials. These meta-analyses involve complex statistical analyses designed to interpret multiple findings and synthesise the results of multiple studies.

Introduction

In addition to the overall design of the theatre, including good quality, well-maintained equipment, the single most important aspect of theatre safety is the high performance of all theatre staff in their various roles. This requires careful protocols and guidelines which need to be adhered to, good initial training and on-going education, with good managerial aspects that include motivating staff.

The risks for the patient start when he or she leaves the ward and continues until the safe return from theatre. All too often discussion of theatre safety is confined to procedures in the operating theatre, whereas in reality this is only part of the overall delivery of high-quality care.
Theatre design

Operating theatres should be sited near surgical wards and the main lifts, and they should be within easy access of the accident and emergency department and X-ray department; ideally the intensive therapy unit (ITU) and anaesthetic office should be close by.

Principles in design

The operating suite should include the following areas.

1. An outer reception area including:
   - the reception office;
   - the reception bay for patients to wait after checking in, for which there should be soft lighting and gentle music;
   - an area for storage of trolleys;
   - an area for hanging of clean gowns and overshoes for parents to wear when accompanying children to the anaesthetic room.

2. A ‘clean zone’ including a wide, clean corridor which allows access to and from the following:
   - the anaesthetic rooms;
   - the recovery bay;
   - the clean storage area;
   - the emergency autoclave;
   - staff relaxation rooms/changing rooms;
   - a storage area for large equipment including X-ray image intensifiers, etc.

3. The operating theatres.
   - There should be a dirty or ‘back’ corridor where there are adequate disposal areas for soiled linen, soiled disposable drapes, disposable instruments and cleaning of used instruments prior to their delivery by direct lift shaft to the Central Sterile Supplies Department (CSSD).
   - Laminar airflow is important in maintaining theatre asepsis; most theatres have between 20 and 40 air changes per hour, with the air being pumped in through filters in the ceiling and exiting through ventilation flaps adjacent to the floor. Humidity and air control are important both for patient safety and for staff comfort (a hot humid atmosphere leads to a reduction in concentration and performance by the operating surgeons).
   - The operating theatres, recovery rooms and anaesthetic rooms must always be designed to have adequate power points, emergency electricity; piped gases, anaesthetic scavenging systems, ancillary lighting and wall suction. Cardiac resuscitation equipment must be readily available.
   - Of considerable importance are the proper location of telephones and the use of internal vacuum tubes for the transportation of samples and specimens.
Preoperative preparations

Staff

Health and safety policies

The following health and safety policies should be implemented for all theatre staff:

• all staff should have a chest X-ray before commencing work;
  • appropriate vaccination schedules, e.g. hepatitis B, and tetanus immunisation policies should be in place;
  • policies for staff protection when handling patients with a high-risk transmittable disease, e.g. hepatitis B or C, human immunodeficiency virus (HIV);
  • protocols for accident procedure;
  • protocols for incident procedure;
  • ionising irradiation guidelines with instructions for use for the X-ray image intensifier. All staff who use such instruments must be in possession of the Irradiation Protection Certificate;
  • policy with regard to the adequacy of exhaustible anaesthetic gases;
  • guidelines for the use of a laser;
  • infection control policy with regular monitoring.

Staff facilities

• Changing area — this should be adequate inside with secure lockers, and with clean and adequate supplies of clean clothing, which should be of a close-woven coloured material with trousers for both sexes which should have elasticated ankles. Appropriate disposal bags for dirty linen, adequate toilets and washing facilities including hand basins and showers. Caps, masks and aprons should be available. Staff should have their own comfortable, regularly cleaned, antistatic footwear.
  • Masks — these are important for staff protection and for operations involving splashing, such as drilling, there should be visor protection of the eyes. They are of questionable value in reducing infection rate. They should be:
    — fabric not cotton;
    — not touched by hands;
    — not put in pockets;
    — destroyed after single use.

Equipment

• Trolleys should be clean, have safety rails and have oxygen cylinders with well fitting tubes and masks, all of which are regularly checked so that empty cylinders are replaced. Trolleys must be able to be tipped into the Trendelenburg position in case of regurgitation of gastric contents.
  • The operating table should be cleaned with regular checks to see that it can be raised and lowered smoothly with the appropriate gears for Trendelenburg tilt, lateral tilt and an adequate braking system. Accessories should be clean and available and fit well, and it is particularly important to ensure that stirrups fit well.
    — Settlement of negligence claims in this area is very costly.
  • The lights should be modern and easily movable by members of the scrubbed team and by other theatre personnel.
  • The suction apparatus should be clean and thoroughly checked, with spare suction tubes and catheters available.
    • Anaesthetic machines should be in good working order — many of them are now supplied on a loan basis with a strict policy as to the correct connections and nontransferable piping. They must be regularly serviced and a record of this must be maintained.
      — All electrical equipment should be regularly checked and marked accordingly.
        — A fire policy, regular fire drills and weekly testing of fire doors are essential safety precautions.
Patient movement

Safety procedures

A fully filled in request slip should be given to the theatre porters giving a clear indication of the name of the patient and the ward. The patient should be transferred from the bed to the trolley and safety rails raised; the patient is to be made comfortable and warm, during this procedure (it is important to ensure that the patient’s dignity is preserved and that the patient’s body is not unduly exposed) curtains should be drawn and doors closed where appropriate.

Before leaving the ward it is important to ensure that:

- the correct patient has been sent for, in accordance with the written operating list;
- the consent form is completed by the appropriate doctor (it is desirable that the surgeon performing the operation or senior member of the team has obtained the consent and this is preferably done in the out-patients’ department before elective surgery);
- the site and side, e.g. right or left breast or right or left foot, has been marked where appropriate, preferably by the operating surgeon;
- the patient has been seen by the operating surgeon;
- any intraoperative investigations, such as X-rays or frozen section histology, have been booked;
- the full notes and X-rays are available and are transported with the patient;
- the wrist identification tag has been checked;
- the patient leaves the ward accompanied by an escort and the porter.

Transfer of the patient from reception to the anaesthetic room

Safe transfer from the bed to the trolley will have involved the patient either moving themselves or being transferred using a slide; the following points should be checked:

- worn canvasses, which may split, should be discarded;
- the patient should not be lifted but slid on a special sliding board which is correctly placed using handles on the canvas. Correct posture should be adopted by staff to avoid back strain;
- the position of the patient’s head in relation to the canvas should be checked;
- the use of transferable trolley tops overcomes many of these problems.

With regard to the trolley the patient should be placed correctly so that the head end can be rapidly tipped into the Trendelenburg position in an emergency. The patient should be positioned so that there is no pressure against the rails; intravenous lines and infusions should be correctly attached to the trolley and the patient’s covers should be in place. The notes and X-ray should be stacked under the trolley.

An appropriate lifting and handling policy can virtually eliminate back strain amongst staff if properly designed protocols are followed. Back injury is expensive and debilitating. It is avoidable.

The reception area

This is an important area which must be designed to receive the incoming and existing patients on trolleys together with an office where there are telephones and where the receptionist can check in and record the patient’s details, often with computer-recording facilities which permit reliable data collection for audit purposes.

Important safety aspects include:

- an appropriately trained reception clerk;
- the insistence of written lists at all times which cannot be changed by crossing out but must be rewritten;
- correct operative description;
- identification of the side to be operated on, i.e. right or left;
- the appropriate forms for sending for patients must contain specific details (never send for the ‘next patient’).

At reception. The patient should be greeted, the trolleys locked together and, wherever possible, lifting by canvas is avoided by the use of the sliding modules which are both smooth and comfortable. Preliminary identification of the patient and the checklist should include:

- name, including the name on the wrist band;
- the operation to be undertaken;
- the consultant in charge;
- the time at which the last meal and/or drink was taken;
- the presence of a valid consent form, the notes and X-rays.

A more extensive checklist is then carried out by the anaesthetic nurse in the anaesthetic room.
The anaesthetic room

On arrival at the anaesthetic room the patient is greeted, and once again a further full checklist and protocol must be undertaken, including:

• the presence of false teeth;
• the presence of a prosthesis, especially with metal components;
• the wearing of any jewellery;
• allergies to drugs, plasters, dressings or disinfectants. These should all be checked. Allergies must be marked on the front of the notes, on the drug chart and on the anaesthetic form;
• the care plan is checked, the patient is watched, observed and engaged in appropriate conversation. Prior to the induction of the anaesthetic, the gowns are loosened in privacy, the patient is otherwise kept well covered;
• electrocardiogram (ECG) electrodes are applied;
• the diathermy indifferent electrode is applied correctly;
• the induction of the anaesthetic is carried out by the anaesthetist, assisted by the designated anaesthetic nurse or assistant. The operation site is appropriately exposed. The covers and drapes are removed and installed in a warmer;
• all drugs given are recorded;
• all drugs are kept locked;
• the patient is transferred into the operating room with all lines well secured and with the appropriate documents. Ensure protection of the patient against trauma.

Special points. Special points to note are:

• the full check must have been carried out;
• the patient is observed at all times, particularly during induction and transfer of the patient from the anaesthetic room to the operating theatre. Cross matched blood, if required, is available and the correct units are in the storage fridge;
• the limbs are safeguarded, especially if paralysed;
• nerves are protected from pressure;
• eyes are protected, the lids must be closed on induction to avoid inversion of the eyelashes and to protect the cornea against abrasions, drying and foreign bodies.

Tourniquets. Pneumatic cuffs and tourniquets are usually applied in the anaesthetic room; they should be regularly checked by an engineer:

• the pressure and time should be recorded by the nurse or operating theatre assistant;
• the tourniquet width and position must be checked by the operating surgeon;
• Esmarch rubber bandages used must be applied with care to avoid burns;
• ‘disinfectant’ must not be allowed to run under the Esmarch bandage or tourniquet;
• the use of more sophisticated equipment must be carefully supervised, and its design understood by the surgeon.
Operating theatre

Regular maintenance will ensure correct air ventilation with 20—40 changes per hour in a general surgical theatre. Ultra-clean air will be used in orthopaedic theatres. The temperature should range between 19 and 22°C with a humidity of 45—55 per cent. The lights should be of appropriate design and will therefore differ in orthopaedic and general surgical theatres.

Anaesthetic gases and suction should be piped with different colour coding. Cables on the floor should be kept to a minimum. Trolleys should be steel with no sharp corners.

The operating table should have a smooth action for raising and lowering the table, the appropriate handle and gears to alter the tilt giving Trendelenberg or reverse Trendelenberg positions, lateral roll and a bridging system for use in procedures such as nephrectomy. The function of electrically operated tables must be understood before starting the operation.

The mattresses must be well maintained, cleaned and sealed. The table should be checked to see that it is correctly orientated, particularly when an intraoperative X-ray is anticipated.

Diathermy

In surgical diathermy a high frequency alternating current is passed through body tissue and the concentration of current producing an area of high current density liberates heat —temperatures may rise to 1000°C or above. Current frequencies in the range of 400 kHz—10 mHz are used, and in this range there is minimal muscular response.

Mono polar diathermy

A high-frequency current is generated from the diathermy machine and is delivered to the active electrode held by the surgeon. There is high current density where the electrode touches body tissue, producing local heating, and the current then spreads through the body and returns to the diathermy machine or generator via the patient electrode.

Bipolar diathermy

The surgeon holds a pair of forceps connected to the diathermy generator, the current passes down one limb of the forceps, through a small piece of tissue and then back through the other limb of the forceps to the generator. There is no requirement for a plate and the system uses considerably less power, but it cannot be used for cutting and tissue must not be squeezed between the diathermy forceps. As the bipolar current will only pass directly from one diathermy arm to the other it is very safe.

Safety measures. Certain safety measures are essential.

• The diathermy generator and accessories require a regular service with a full record being kept.

• Plugs, leads and sockets need to be checked to ensure that all are sound.

• The foot pedals should be checked to ensure that they are completely sealed and sensitive to light pressure.

• The alarm systems should all be in order.

• The appropriate mode of diathermy, whether it be monopolar or bipolar, should be selected prior to use and the correct setting to be used is checked. When monopolar diathermy is used care must be taken to ensure that the coagulation and cutting levels are correctly set (cutting and fulguration involve higher power current than coagulation; these are not applicable to bipolar).

• Make sure that the indifferent electrode in the mono polar system uses a flat surface which is dry and there is no thick hair present, as this may interfere with conduction.

• Ensure that the patient is protected from metal, and that the skin is checked after removal of the plate.

• Ensure that the live electrode is always placed in the quiver and never on the drapes or on the tray. Insulation of the instruments should be checked regularly.

If diathermy is ineffective, before increasing the current, look for:

• faulty connection;

• faulty active electrode;

• poor contact of plate;

• a disconnected or faulty cable.

Precautions. The following precautions should be taken:

• staff should understand the clear rules of operation of diathermy;

• the alarm system, generator and equipment should be checked regularly;

• the power should not be turned up if the diathermy appears to be ineffective without first carrying out a number of checks;

• diathermy should never be used in the presence of ether and should be kept at least 50 cm from the anaesthetic machine;

• alcoholic disinfectants must be dried before diathermy is used. The commonest causes of diathermy injury are:

• incorrect application of the patient plate;
• the patient touching earth, metal objects such as parts of the table;

• careless technique, e.g. the electrode not being put back into the cover.

Positioning the patient

When the patient is transferred from the anaesthetic room to the operating theatre, the trolley should be positioned close to the operating table and the height of the latter should be adjusted. The optimal way of transfer is using the 'patient slide' as this avoids lifting at awkward angles which may cause back problems to the staff. It also avoids the use of a canvas which may be worn or defective or where the lifting poles have been inserted incorrectly. The patient should be positioned correctly in respect of the cushions, particularly if either the lithotomy or Lloyd-Davies position is used. The patient’s legs should be supported so that undue pressure on the calf does not occur. Both surgeon and anaesthetist should be fully aware of the optimal position required during movement: the airway and intravenous drip lines should be protected and particular care taken to ensure that the patient’s head is on the canvas, so that in the paralysed patient the head does not become unsupported with hyperextension of the neck. Lithotomy poles and Lloyd-Davies stirrups must be securely anchored to the table.

Protection of nerves

This is particularly important in thin patients.

• In the Lloyd-Davies stirrups, care must be taken to protect the lateral peroneal nerve. It is important to ensure that the stirrups are well padded so that there is no direct contact with metal.

• If the arms are by the patient’s side or placed on an arm board, care must be taken to protect the ulnar nerve at the elbow.

• If the arm is placed above the head, as it may be in some breast biopsy procedures, then care should be taken to ensure that the shoulder is supported posteriorly, as failure to do this will result in a brachial plexus traction injury.

• In patients with rheumatoid arthritis the team should always be aware of the possibility of a fracture dislocation of the odontoid peg with subluxation. Endotracheal intubation in such patients is a risky procedure and patients should wear a protective cervical collar.

• Patients who have lumbar disc problems should be positioned particularly carefully if lithotomy is to be considered.

• In patients in whom hyperextension of the cervical spine is required, such as thyroidectomy, the surgeon should ensure that the weight of the head is not being taken on the unsupported hyperextended cervical spine.

Deep venous thrombosis prophylaxis must be considered. The calves should be protected against pressure by whatever means is chosen: graduated support stockings or intermittent flow compression. Subcutaneous low-dose heparin is widely used additionally (see Chapter 15 on ‘Arterial disorders’).

The patient

On entry to theatre the patient should be clean, the gown should be appropriately applied and, before anaesthesia is started, the ties at the back should have been loosened (the patient’s modesty should be protected), fingernails should be clean and free from coloured varnish.

In theatre the appropriate area of skin should be disinfected with care taken to avoid splash (particularly adjacent to the diathermy plate) or pooling of alcoholic disinfectant, which must not be allowed to run under a tourniquet. The appropriate drapes should be used with attention to the possibility of allergy.

Tourniquets must be applied correctly with the appropriate time of starting noted.

Theatre staff

Although the number of persons in the theatre should be kept to a minimum from the point of view of infection, it is obvi-ously important to have a clear policy whereby nurses of ade-quate seniority act as the scrub nurses. The circulating nurses must be aware of the importance of meticulous counting of swabs, needles and instruments, and also the handling of samples and specimens. Appropriate training with the possibility of advancement and promotion is considered important in the maintenance of morale and standards.

• Of particular importance are the counts at the beginning and the end of the procedure. It is essential to have an instrument, swab and needle count prior to closure after laparotomy, and a final count prior to removal of any equipment from the theatre. In this respect, swabs, packs, disposable equipment, instruments, needles and such items as tapes are to be recorded. The creation of swabs in bundles of five with a radio marker and red string bundles is helpful. Dirty swabs should be placed singly in the swab holders. It is important to stress that all swabs should be removed from the previous surgery before any current count is taken.

• It is important to have a count before body cavities, incised organs or joint spaces are closed.

• Rubber tubes and tapes should never be cut.

• Nothing should be removed from the operating theatre until the incision is closed and the scrub nurse indicates that all is correct.

• Particular care should be taken when there is a change over of staff, which may occur during prolonged surgery, such as a oesophagectomy, pancreatectomy, spinal or neurosurgical procedures. At such a time:
  — the surgeons should stop;
  — the first scrub nurse only descubs when the second scrub nurse and the surgeon have indicated. The time and the names of those who change should be noted in the theatre record.

• Nonradio-opaque swabs should not be used during surgery and radiopaque swabs should not be cut.

• Needles should be checked, both for number and the fact that they are complete.
With regard to power tools, the nurse should check that all detachable parts are neither faulty nor loose.

The surgeon

The surgeon should be thoroughly familiar with the procedure and should have received appropriate training. If he or she is a doctor in training then appropriate senior cover must be present.

- He or she should be in good health with no upper respiratory chest infection and no septic lesions, and should not have a positive carrier state for *Staphylococcus aureus*.
- The scrub up procedure should be carried out thoroughly, with brushes restricted to cleaning nails. Gowning, mask-ing and gloving should proceed with aseptic precautions, and the amount of talking and movement should be cut to the minimum.
- Assistants should not lean on patients, as this may cause damage, bruising or neuropraxia.

Specimens

Great care should be taken with the handling of specimens.

- The specimens must be identified and, if multiple, should be placed into separate labelled specimen pots which should be appropriate for the study required, namely histology, cytology, microbiology or biochemistry.
- For histology and cytology the appropriate method of fixation should be selected and checked (all too often samples for microbiology are placed in formalin and vice versa).
- All specimens and all request forms should be labelled fully and clearly, and clinical details must be given.
- The circulating nurse should check with either the scrub nurse or the surgeon that the correct fixative or microbiological storage agent has been selected.

The samples should be checked for a good seal prior to transport.

- Specimens at high risk of infectivity should be identified and treated securely according to the policy.
- Formalin splashing when placing a large specimen in a container must be avoided.
- The record book must be signed with the full description of the specimen and the time that it left theatre.

Disposables

Those disposables such as drains should be secured to the patient and checked for patency. Those disposables to be discarded such as soiled linen, drapes and other waste should be disposed of appropriately, and material of high infectivity needs to be sealed and marked accordingly.

The record book

This should be kept in each theatre; if a surgical procedure is different from the one that was planned it is the responsibility of the surgeon to inform both the patient subsequently and the relatives.

Radiation and image intensification

All surgeons using X-ray equipment should be in possession of a certificate, to the effect that they have attended a course on Protection Against Ionizing Radiation. Staff should reduce exposure to the minimum and good-quality aprons must be available.

- Random dose recording should be a part of quality control.
- Pregnant staff must not be in the vicinity of radiation.
- Sterility must not be compromised.

Lasers

Lasers should be used in a designated operating theatre by fully trained medical staff. In addition to this, further precautions are appropriate:

- warning signs must be present on the operation doors;
- no reflective or inflammable fixtures or furnishings must be present in that operating theatre;
- care with the direction of the laser beam is critical in safe usage;
- protective eye wear must be worn at all times;
- the surgeon should warn the staff before firing the laser.
The recovery room

All too often the recovery room has received too little attention and is often inadequate in terms of size and equipment. With increasing medicolegal considerations it is now imperative that each theatre suite has a fully equipped adequate recovery room in which patients recuperate to a stable level with regard to their cardiorespiratory system before transfer back to the ward. The recovery room should meet the following criteria:

• the temperature should be between 19° and 22° C, and the bed linen should be warmed;

• lighting should be adequate;

• fire doors should be free;

• piped oxygen should be available with a range of masks in appropriate sizes;

• suction apparatus should be attached to the wall, regularly checked and appropriate tubing and sucker attachments available;

• there should be no trailing tubes or wires;

• adequate monitoring equipment is essential.

Monitoring equipment should be available for every patient in the recovery room, screens and curtains are appropriate for those spending a longer time in the recovery room, and defibrillation equipment should be immediately accessible.

Management of the patient in recovery includes attention to the following:

• the airway, with monitoring of the oxygen saturation;

• pulse rate, blood pressure and respiratory rate which should be regularly recorded on charts. The patient should be easily accessible on a trolley which has brakes, safety rails and head-lowering facilities;

• pain relief is mandatory and if the patient is having a patient-controlled analgesic set up then adequate intravenous analgesics to overcome initial pain is important;

• pressure areas should not be overlooked;

• hand hygiene of the staff between patients is important;

• an emergency bell available to each bay should be clearly marked and in good working order;

• stands attachable to trolleys for intravenous infusions should be at hand and fit well;

• with regard to drug administration, this should be recorded on the patient’s chart with both time and dosage and, of course, the controlled drugs register should be kept up to date and double signed;

• where a central venous pressure line is present, and particularly if there are multiple channels, these should be handled in a strict aseptic way and clearly labelled.

Before the patient leaves the recovery room a clear record of the readings should have been made and the line should be well secured. Additional observations should include:

• drains;

• the presence of a stoma;

• urine output;

• nasogastric aspiration in terms of both quality and quantity. The position of a drainage bag is checked (a leakage is all too common, stains the pillow and leads to the patient developing a sore rash on his or her cheek);

• chest (under water seal) drains should be monitored and be placed below the level of the chest.
Transfer of the patient to the ward

Prior to transfer, the ward nurse will come down and there should be a clear verbal handover between the nurse incharge of that patient in the recovery room and the ward nurse. The following documents should accompany the patient:

- nursing record;
- postoperative recovery chart;
- anaesthetic record;
- operation record;
- prescription chart;
- fluid balance and temperature charts.

- The patient should be clearly identified by both the recovery room nurse and the ward nurse to ensure the correct transfer of the patient to the correct ward. The linen should be clean, and the patient comfortable and well positioned on the trolley away from pressure points.
Management of the operating suite

There is good evidence that theatre safety is based on good management. This implies a good staff relationship with the appropriate training facilities and schedules to maintain morale. A good career structure will enhance standards and provide a good reputation, enhancing future recruitment. High standards and patient safety are at a premium. Additional points that must be considered in the safer running of theatres include:

• a ready supply of clean linen;
• safe disposal of dirty linen and waste products;
• rapid transfer of instruments to and from CSSD to avoid delay;
• adequate pharmaceutical supplies with close liaison with the pharmacy;
• monitoring of the medical and surgical supplies and requisitions so that excess stocks of items do not accumulate; conversely the amount of expensive emergency ordering must be cut to a minimum. It should be remembered that larger stores utilise much revenue, equipment may also go out of date and this is wasteful. Stock level checking is an important part of the theatre sister's role but does require time;
• transfer of specimens to the laboratory — this should take place on a regular basis. The use of sealed containers in a vacuum tube system for small specimens is highly efficient;
• instrument maintenance is essential and saves money;
• there should be close liaison with the electronics, central sterile supply and theatre infection control officer;
• health and safety rules and procedures should be understood by all staff;
• an accident record should be kept, and regular audit should take place.
Summary

In the delivery of a health service the proper provision of an operating suite with appropriate training of personnel is an essential but costly investment. Breakdown in safety and aseptic techniques will lead to increased patient mortality and morbidity, and increase costs. Septic complications and accidents in theatre are very expensive and potentially avoidable.

Introduction

Ethics and surgical intervention must go hand in hand. In any other arena of public or private life, if someone deliberately cuts another person, draws blood, causes pain, leaves scars and disrupts everyday activity then the likely result will be a criminal charge. If the person dies as a result, the charge could be manslaughter or even murder. Of course, it will be correctly argued that the difference between the criminal and the surgeon is that the latter causes harm only incidentally. The surgeon’s intent is to cure or manage illness and any bodily invasion that occurs only does so with the permission of the patient.

Patients consent to surgery because they trust their surgeons. Yet what should such consent entail in practice and what should surgeons do when patients need help but are unable or unwilling to agree to it? When patients do consent to treatment, surgeons wield enormous power over them—the power not just to cure but to maim, disable and kill. How should such power be regulated to reinforce the trust of patients and to ensure that surgeons practise to an acceptable professional standard? Are there circumstances where it is acceptable to sacrifice the trust of individual patients in the public interest through revealing information that was communicated in what patients believed to be conditions of strict privacy?

These questions about what constitutes good professional practice concern ethics rather than surgical technique. Surgeons may be expert in the management of specific diseases and yet have little understanding of how much and what sort of information is required for patients to give valid consent to treatment. Surgeons can understand the delicate techniques associated with specific types of procedures without knowing when these should be administered to patients who are unable to consent at all. Surgeons can recognise their own mistakes and those of colleagues without knowing how much should be said about them to others. And so it goes on.

Traditional surgical training offers little help in the resolution of such ethical dilemmas. This chapter provides guidance which is morally coherent, widely endorsed and legally justifiable. Our focus will be the practice of surgery within the United Kingdom, although much of the analysis will also apply to surgical work elsewhere.
Respect for autonomy

What is the difference between veterinary surgeons and surgeons who treat humans? Both are trained in anatomy, physiology, biochemistry, and the other clinical and surgical skills required to care for the bodies of their patients. As a by-product of employing these skills, both invade these bodies in ways which can cause harm in order to meet need. Finally, both work within the same duty of care — to protect their patient’s life and health to an acceptable standard. To distinguish between the two types of surgeon, we must ask another question. What is the major difference between animals and humans, and how does this difference create special duties for human surgeons which are of no concern for those who work only with animals?

We can only wonder at the attributes and abilities of many animals, characteristics which humans can only aspire to. For example, we can respect the big cats of the sub-Saharan plains because of their strength and speed — for behaving in the unique ways that characterise their species. The same can be said of humans. What makes us unique as animals is our autonomy — our ability to formulate both goals and beliefs about how they should be achieved. Humans can attempt to plan their lives on the basis of reason and choice in ways which other animals cannot. Therefore, when we talk of the particular type of respect which it is appropriate to show to humans, the focus should primarily be on our autonomy rather than our particular physical characteristics. Respect for human dignity is respect for human autonomy.

It is for this reason that surgeons have a duty of care towards their human patients which goes beyond just protecting their life and health. Their additional duty of care is to respect the autonomy of their patients — their ability to make choices about their treatments and to evaluate potential outcomes in light of other life plans. Such respect is particularly important for surgeons because without it the trust between them and their patients may be compromised, along with the success of the surgical care provided. We are careful enough at the best of times about who we allow to touch us and to see us unclothed. It is hardly surprising that many people feel strongly about exercising the same discretion in circumstances where someone is not only going to do these things but to inflict what may be very serious wounds on them as well.

For all of these reasons, there is a wide moral and legal consensus that patients have the right to exercise choice over their surgical care. In this context a right should be interpreted as a claim which can be made on others and which they believe that they have a strict duty to respect, regardless of their own preferences. Thus, to the degree that patients have a right to make choices about proposed surgical treatment, it then follows that they should be allowed to refuse treatments that they do not want, even when surgeons think that they are wrong. For example, patients can even refuse surgical treatment which will save their lives — either at present or in the future through the formulation of advance directives specifying the types of life saving treatments which they do not wish to have if they become incompetent to refuse them.
In surgical practice, respect for autonomy translates into the clinical duty to obtain informed consent before the commencement of treatment. The word ‘informed’ is important here. Because of the extremity of their clinical need, patients might agree to surgery on the basis of no information at all. Agreement of this kind, however, does not constitute a form of consent which is morally or legally acceptable. Unless such patients have some understanding of what they are agreeing to, their choices may have nothing to do with planning their lives and thus do not count as expressions of their autonomy. Worse still, if patients are given no information, their subsequent choices may be based on misunderstanding and lead to plans and further decisions which they would not otherwise have made.

For agreement to count as consent to treatment, patients need to be given appropriate and accurate information about:

- their condition and the reasons why it warrants surgery;
- what type of surgery is proposed and how it might correct their condition;
- what the proposed surgery entails in practice;
- the anticipated prognosis of the proposed surgery;
- the expected side effects of the proposed surgery;
- the unexpected hazards of the proposed surgery;
- any alternative and potentially successful treatments for their condition other than the proposed surgery, along with similar information about these;
- the consequences of no treatment at all.

With such information, patients can link their clinical prospects with the management of other aspects of their life and lives of others for whom they may be morally and/or professionally responsible.

Good professional practice dictates that obtaining informed consent should occur in circumstances which are designed to maximise the chances of patients understanding what is said about their condition and proposed treatment, as well as giving them an opportunity to ask questions and express anxieties. Where possible:

- a quiet venue for discussion should be found;
- written material in the patient’s preferred language should be provided to supplement verbal communication;
- patients should be given time and help to evaluate their own understanding and to come to their own decision;
- the person obtaining the consent should ideally be the surgeon who will carry out the treatment. It should not be
  — as is sometimes the case — a junior member of staff who has never conducted such a procedure and thus may not have enough understanding to counsel the patient properly.

Surgeons should always attempt to approximate these conditions, even when they might not be completely achievable.

Good communication skills go hand in hand with properly obtaining informed consent for surgery. It is not good enough just to go through the motions of providing patients with information required for considered choice. Attention must be paid to:

- whether or not the patient has understood what has been stated;
- not using overly technical language in descriptions and explanations;
- the provision of translators for patients for whom English is not their first language;
- asking patients if they have further questions.

When there is any doubt about their understanding, surgeons should ask patients questions about what has supposedly been communicated to see if they can explain the information in question for themselves.

Surgeons have a legal, as well as moral, obligation to obtain consent for treatment based on appropriate levels of information. Failure to do so could result in one of two civil proceedings, assuming the absence of criminal intent. First, in law, intentionally to touch another person without their consent is a battery, remembering that we are usually touched by strangers as a consequence of accidental contact. Surgeons have a legal obligation to give the conscious and competent patient sufficient information ‘in broad terms’ about the surgical treatment being proposed and why. If the patient agrees to proceed, no other treatment should ordinarily be administered without further explicit consent.

Negligence is the second legal action which might be brought against a surgeon for not obtaining appropriate consent to treatment. Patients may have been given enough information about what is surgically proposed to agree to be touched in the ways suggested. However, surgeons may still be in breach of their professional duty if they do not provide sufficient information about the risks which patients will encounter through such treatment. While standards of how much information should be provided about risks vary between nations, as a matter of good practice, surgeons should inform patients of the hazards that in their view any reasonable person in the position of the patient would wish to know. In practice, this is probably best decided through surgeons asking themselves what they or a close relative or friend should be entitled to know in similar circumstances. Only through supporting this standard of disclosure of information linked to the requirements of a reasonable person can surgeons help to ensure that they, their relatives and friends will be treated with respect and dignity.

Finally, surgeons now understand that when they obtain consent to proceed with treatment then patients are expected to sign a consent form of some kind. The detail of such forms can differ but they often contain very little of the information supposedly communicated to patients, who signed it. Partly for this reason, the process of formally obtaining consent can become overly focused on obtaining the signature of patients rather than ensuring that appropriate types and amounts of information have been provided, and that they have been understood.
Both professionally and legally, it is important for surgeons to understand that a signed consent form is not proof that valid consent has been properly obtained. It is simply a piece of evidence that consent may have been attempted. Even when they have provided their signature, patients can and do deny that appropriate information has been communicated or that the communication was effective. Surgeons are therefore well advised to make brief notes of what they have said to patients about their proposed treatments, especially information about significant risks. These notes should be placed in the patient’s clinical record.
Practical difficulties

Thus far, we have examined the moral and legal reasons why the duty of surgeons to respect the autonomy of patients translates into the specific responsibility to obtained informed consent to treatment. For consent to be valid, patients must:

• be competent to give it — to be able to understand, remember, deliberate about and believe whatever information is provided to them about treatment choices;
• not be coerced into decisions which reflect the preferences of others rather than themselves;
• be given sufficient information for these choices to be based on an accurate understanding of reasons for and against proceeding with specific treatments.

Surgeons will face four key practical difficulties in aspiring to these goals.

First, surgical care will grind to a halt if it is always necessary to obtain explicit informed consent every time a patient is touched in the context of their care. Fortunately, such consent is unnecessary because patients will have already given their implied consent to whatever bodily contact is required in order to fulfill the therapeutic goals when they gave their explicit consent to treatment. Yet, the fact that this is so underlines the importance of obtaining proper and explicit consent in the first place, along with taking care to note any sign of the patient withdrawing that consent or placing restrictions on it — say, through verbally refusing or physically resisting specific aspects of care.

Second, some patients will not be able to give consent because of temporary unconsciousness. This might be a by-product of their illness or injury, or it could simply be the result of the administration of general anaesthetic. The moral and legal rules which govern such situations are clear. If patients are at risk of death or of serious and permanent disability if surgery is not immediately performed then the situation is one of medical necessity and intervention can occur without consent. However, surgery not entailing such risks should be postponed until patients regain consciousness and are able to give informed consent for themselves. Surgeons must take care to respect this distinction between procedures which are therapeutically necessary and those which are done merely out of convenience, even when in the course of one operation they discover problems unknown to the patient which they believe to require further surgical work. For example, a surgeon was successfully sued for battery by a female patient for performing a hysterectomy thought to be in her best interests when all that she had explicitly consented to was a dilatation and curettage.

Third, informed consent may be made impossible by incompetence of other kinds. In the case of children, parents or someone with parental responsibility are ordinarily required to give explicit written consent on their behalf. This said, surgeons should:

• take care to explain to children what is being surgically proposed and why;
• always consult with children about their response;
• where possible, take their views into account and note that even young children can be competent to consent to treatment provided that they too can understand, remember, deliberate about and believe information relevant to their clinical condition.

When such competence is present, children under English law can provide their own consent to surgical care, although they cannot unconditionally refuse it until they are 18 years old. With the exception of the latter, these provisions illustrate the importance of respecting as much autonomy as is present among child patients and remembering that, for the purposes of consent to medical treatment, they may be just as autonomous as adults.

Where competence is severely compromised by psychiatric illness or mental handicap, other moral and legal provisions hold. If patients lack the autonomy to choose how to protect themselves then others charged with protecting them must assume the responsibility. Yet, care must be taken not to abuse this duty. For example, adult voluntary psychiatric patients have the same rights to consent to and refuse treatment as any other competent adult. Even when they have been legally detained for compulsory psychiatric care, it does not follow that such patients are unable to provide consent for surgical care. Their competence should be assumed and consent should be sought. If it is established with the help of their caters that such patients are also incompetent to provide consent for surgery and that they are at risk of death or serious and permanent disability then therapy can proceed. However, if treatment can be postponed then this should be done until, as result of their psychiatric care, patients become able either to consent to or refuse it. As with children, respect should always be shown for as much autonomy as is present.

If, for whatever clinical reason, adult patients are permanently incompetent to consent to surgery, therapy can again proceed if it is necessary to save life or to prevent serious and permanent injury. In the UK, the final decision to proceed with surgery which is elective and can be postponed rests ultimately with the surgeon and other doctors responsible for the patient’s care. It does not depend on the views of the relatives of the patient. The moral justification for this is that the patient’s professional caters are more likely to act consistently in their best interests than their relatives.

Thus, it is always a futile exercise in the UK to ask the relatives of incompetent patients to sign consent forms for surgery on adults who cannot do so for themselves. Indeed, to do so can be a great disservice to relatives who may feel an unjustified sense of responsibility if the surgery fails. This said, relatives should be treated with politeness and consulted about issues which pertain to determining the best interest of patients. In other legal jurisdictions, relatives can be given powers of guardianship to provide consent for surgical treatment, although even here surgeons should ensure that such powers are vested in the specific person asked to provide it.
Matters of life and death

It has been noted that the right of a competent adult to consent to and refuse treatment is unlimited, including the refusal of life-sustaining treatment. Probably the example most familiar to surgeons of this is Jehovah’s Witnesses who refuse blood transfusions at the risk of their own lives. There can be no more dramatic example of the potential tension between the duties of care to protect life and health and to respect autonomy, with autonomy always constituting the trump card.

The tension does not stop here, however. For there will be some circumstances where the protection of the life and health of patients is judged to be inappropriate, where they are no longer able to be consulted and where they have not expressed a view about what their wishes would be under such circumstances. Here a decision may be made to with-hold or to withdraw life-sustaining treatment on behalf of the incompetent patient. The fact that such decisions can be seen as omissions to act does not excuse surgeons from morally and legally having to reconcile them with their ordinary duty of care. Ultimately, this can only be done through arguing that such omissions to sustain life are in the patient’s best interests.

The determination of best interests in these circumstances will rely on one of three objective criteria, over and above the subjective perception by the surgeon that the quality of life of the patient is poor. There is no obligation to provide or to continue life-sustaining treatment:

- if doing so is futile — when clinical consensus dictates that it will not achieve the goal of extending life. Thought of in this way, judgements about futility should not be linked to evaluations of a patient’s quality of life;
- if patients are imminently and irreversibly close to death — in such circumstances it would not be in their best interest slightly to prolong life (e.g. through the application of intensive care) when, again, there is no hope of any sustained success. Not needlessly interfering with the process of a dignified death can be just as caring as the provision of curative therapy;
- if patients are so permanently and seriously brain damaged that, lacking awareness of themselves or others, they will never be able to engage in any form of self-directed activity. The argument here is backed up by morally and legally reasoning that further treatment other than effective palliation cannot be in the best interests of patients as it will provide them with no benefit.

When any of these principles are employed to justify an omission to provide or to continue life-sustaining treatment, the circumstances should be carefully recorded in the patient’s medical record, along with a note of another senior clinician’s agreement.

Finally, surgeons will sometimes find themselves in charge of the palliative care of patients whose pain is increasingly difficult to control. There will come a point in the management of such pain when effective palliation might only be possible at the risk of life because of the respiratory effects of the palliative drugs. In such circumstances, surgeons can with legal justification administer a dose which might be lethal. The argument employed to justify such action refers to its ‘double effect’ — that both the relief of pain and death might follow from such an action. As intentional killing — active euthanasia — is rejected as professional and legal medical practice throughout most of the world, a potentially lethal dose is only regarded as appropriate when it is motivated by palliative intent.

Debates rage about whether or not it is realistic in such circumstances to believe that surgeons can or should keep all ideas out of their minds about helping such unfortunate patients to die, especially as we have seen that clinical decisions are already made that foreshorten the lives of incompetent patients in specific circumstances. Deciding whether or not potentially lethal palliation is justified will require an evaluation — by either the patient, the clinician or both — of whether or not the life in question is too valuable on other grounds to risk. Once a negative conclusion is reached and the risks are incurred, it seems impossible in the face of continued and dramatic palliative failure then to purport to banish thoughts of the desirability of death from the scene. What is clear is that surgeons should document that their intent is purely palliative through only gradually and incrementally increasing doses of the drugs that they administer for this purpose.
Confidentiality

Respect for autonomy does not only entail the right of competent patients to consent to treatment. Their entitlement to exercise control over their life and future corresponds to the duty of surgeons to respect their privacy — not to communicate information revealed in the course of treatment to anyone else without consent. Generally speaking, such respect means that surgeons must not discuss clinical matters with relatives, friends, employers and others unless the patient explicitly agrees. To do otherwise is regarded by all of the regulatory bodies of medicine and surgery as a grave offence incurring harsh penalties. For breaches of confidentiality are not only abuses of human dignity; they again undermine the trust between surgeon and patient on which successful surgery and the professional reputations of surgeons depend.

Important as respect for confidentiality is, however, it is not absolute. Surgeons are allowed to communicate private information to other professionals who are part of the healthcare team — provided that the information has a direct bearing on treatment. Here the argument is that patients have given their implied consent to such communication when they explicitly consent to a treatment plan. Certainly, patients cannot expect strict adherence to the principle of confidentiality if it poses a serious threat to the health and safety of others. There will be some circumstances when confidentiality either must or might be breached in the public interest. For example, it must be breached as a result of court orders or in relation to the requirements of public health legislation. It may be ignored in attempts to prevent serious crime or to protect the safety of other known individuals who are risk of serious harm.
As part of their duty to protect life and health to an acceptable professional standard, surgeons have a subsidiary responsibility to strive to improve operative techniques through research — to assure themselves and their patients that the care proposed is the best that is currently possible. Yet, there is moral tension between the duty to act in the best interests of individual patients and the duty to improve surgical standards through exposing patients to the unknown. risks which any form of research inevitably entails.

The willingness to expose patients to such risks may be further increased by the professional and academic pressures on many surgeons to maintain a high research profile in their work. For this reason, surgeons, and physicians who face the same dilemmas, now accept that their research must be externally regulated to ensure that patients give their informed consent, that any known risks to patients are far outweighed by the potential benefits and that other forms of protection for the patient are in place (e.g. proper indemnity) in case they are unexpectedly harmed. The administration of such regulation is through research ethics committees, and sur-geons should not participate in research which has not been approved by such bodies.

In practice, it is not always clear what is to count as surgical research which should be subjected to regulation and what constitutes a minor innovation dictated by the contingencies of a particular clinical situation. Surgeons must always ask themselves in such circumstances whether or not the innovation in question falls within the boundaries of standard procedures in which they are trained. If so, what may be a new technique for them will count not as research but as an incremental improvement on personal practice.

Yet, if the improvement is to be thought of in this way, no conclusions can be drawn from it to alterations in standard practice or to an evaluation of their efficacy. Equally, there will be no consequences for surgical training, as the innovation in question should only have been attempted against the background of the already existing training and experience of the surgeon in question. Where a proposed innovation exceeds these conditions then it does count as research and should be approved by a research ethics committee. Such surgical research should also be subject to a clinical trial designed to ensure that findings about outcomes are systematically compared with the best available treatment and that favourable results are not because of arbitrary factors (e.g. unusual surgical skill among researchers) which cannot be replicated.
Maintaining standards of excellence

To optimise success in protecting life and health to an acceptable standard, surgeons must only offer specialised treatment in which they have been properly trained. To do so will entail sustained further education throughout a surgeon’s career in the wake of new surgical procedures. While training, surgery should only be practised under appropriate supervision by someone who has appropriate levels of skill. Such skill can only be demonstrated through appropriate clinical audit to which all surgeons should regularly submit their results. When these reveal unacceptable levels of success, no further surgical work of that kind should continue unless further training is undergone under the supervision of someone whose success rates are satisfactory. To do otherwise would be to place the interest of the surgeon above that of their patient, an imbalance which is never morally or professionally appropriate.

Surgeons also have a duty to monitor the performance of their colleagues. To know that a fellow surgeon is exposing patients to unacceptable, levels of potential harm and to do nothing about it is to incur partial responsibility for such harm when it occurs. Surgical teams and the institutions in which they function should have clear protocols for exposing unacceptable professional performance and helping colleagues to understand the danger to which they may exposing patients. If necessary, offending surgeons must be stopped from practising until, again, they can undergo further appropriate training and counselling. Too often such danger has had to be reported by individuals whose anxieties have not been properly heeded and who have been professionally pilloried rather than congratulated for their pains. Surgeons and anyone else discovered to participate in such coverup and ostracism should share the blame and punishment for any resulting harm to patients.
Conclusion

The two general duties of surgical care are to protect life and health and to respect autonomy, both to an acceptable professional standard. The specific duties of surgeons were shown to follow from these: acceptable practice concerning informed consent, confidentiality, decisions not to provide or to omit life-sustaining care, surgical research and the maintenance of good professional standards. The final duty of surgical care is to exercise all of these general and specific responsibilities with fairness and justice, and without arbitrary prejudice. The conduct of ethical surgery illustrates good citizenship: protecting the vulnerable and respecting human dignity and equality. To the extent that the practice of individual surgeons is a reflection of such sustained conduct, they deserve the civil respect which they often receive. To the extent that it is not, they should not practise the honourable profession of surgery.
